{% **Z&Z & paternalism/Humean-view-of-preference**: End of paper, §VI, will discuss the privatization of Medicare in the US starting Jan 01 2006, and an empirical investigation into consumer choices. The first five sections discuss that people often don’t take optimal decisions because of the many biases, and to what extent they need assistance, referring to libertarian paternalism of Thaler & Sunstein (2003).

P. 12 has nice citation of owner of restaurant who, when told to reposition his wine list so as to increase profits based on behavioral biases, replied:
“tell me something I didn’t learn in hotel school.”
Slovic, Lichtenstein, & Fischhoff (1988 p. 628) have a similar text referring to car salespeople.

§VI is about Medicare Part D, the privatization starting Jan 06. It discusses adverse selection and, what it considers to be more serious, moral hazard, referring to the joint work with Winter et al. (2006), who had 4739 people of 50 years and older fill out forms on self-administered internet questionnaire from November 7–15, 2005. There were N = 1996 Medicare-eligible persons (aged 65

and higher). The paper makes some plausible average-estimates of costs for groups of people, speculates on what optimal decisions are for them, and sees if these groups do what is estimated to be optimal. In particular, they asked subjects to choose between some hypothetical plans, all with same actuarial value. Here subjects often chose suboptimal, such as choose a clearly riskier plan rather than a safer.

P. 23: "The new Medicare Part D prescription drug insurance market illustrates that leaving a large block of uninformed consumers to "sink or swim," and relying on their self-interest to achieve satisfactory outcomes, can be unrealistic. To make the Part D market work, in the sense that it provides choices that consumers want, and achieves the efficiencies it seeks, CMS will have to make a diligent effort to manage the market, and to reach all consumers and provide them with information and assistance in making wise choices." Then it pleas for libertarian paternalism, though not taking all the nuances of libertarian paternalism. %}

{% **paternalism/Humean-view-of-preference**: Opening sentences say, as did Arrow long ago, that long time both normative and descriptive studies assumed rationality, and that it changed early 1980s, when they departed. Now there is what the authors call the reconciliation problem.

P. 556: Freedom interpretation appeals to free choice and consumer sovereignty. (Evolutionary justification could be: If let all choose what they want, the best will survive. This evolutionary argument ignores evolution at the group level.) Section 2 nicely relates Kahneman et al.'s (1997) Back to Bentham to the happiness literature. I favor the approach described in Abdellaoui, Barrios, & Wakker (2007), where introspective data is to be used when it can be related to revealed-preference data. We should keep the virtues of the ordinal revolution.

Section 3 uses term soft paternalism to combine libertarian and asymmetric paternalism.

P. 560 top says that nudging takes advantage of preference incoherence. I would rather take it as preference incompleteness, although one can lead that into incoherence by letting variations in framing decide.

P. 560 $\ell\ell$. –9 ff. takes loss aversion as a "fundamental asymmetry in human desire, rather than a mistake …" This is opposite to definitions/intrpretations that I prefer, where loss aversion is a pure framing effect distinct from the rational basic utility.

P. 561 discusses Bleichrodt, Pinto, & Wakker (2001) but, incorrectly, claims that BPW would consider reference dependence as true preference rather than a bias. This is not so.

Section 4 is on consumer sovereignty as discussed by some people. %}

{% **foundations of probability** %}
Meijs, Wouter (2005) "Probabilistic Measures of Coherence," Ph.D. dissertation.\

{% This paper measures risk aversion, loss aversion, discounting, and present bias, for subjects from eight countries in Europe. N > 12,000 subjects. They correlate those with demographic variables. For parametric families, they use quasi-

hyperbolic discounting for time. For risk, they assume EU but with sign dependence and a kink in utility at 0. They call is prospect theory but their footnote 13 writes that they do not consider probability weighting. They thus use sign-dependent CRRA utility with a kink at 0. Section 2, pp. 80-84, usefully surveys many other studies that did the same, e.g. in Table 2.

P. 78 is typical of experimental economists when writing: "Preferences are elicited using Multiple Price List (MPL) designs, as *introduced* by Holt and Laury (2002) for risk preferences, and by Coller and Williams (1999) for time preferences." [italics added] (**Prospect theory not cited**)

Findings:

risk aversion is negatively correlated with income

negative relationship between risk aversion and cognitive ability (**cognitive ability related to risk/ambiguity aversion**)

time discounting is negatively associated with age

men are also more present biased than women.

older respondents and males are less loss averse. (**relation age-risk attitude**) %}

Mellers, Barbara A. & Ilana Ritov (2010) "How Beliefs Influence the Relative Magnitude of Pleasure and Pain," *Journal of Behavioral Decision Making* 23, 369–382.

{% Ask subjects, after lottery is played, how elated versus disappointed they felt. Of course, elation/disappointment depends on the other options and outcomes. Thus, a negative outcome in some situation can give higher elation than a positive

outcome in another situation. Note that elation/disappointment is not hedonic utility as in Kahneman, Wakker, & Sarin (1997) but is only a special regret-like emotion. The term "emotional" in the title refers to this measure of elation/disappointment **real incentives/hypothetical choice**: They told the subjects there would be real payment according to the sum total of the payments in all the gambles they participated in, but in reality gave each subject a predetermined payment which the subjects seem not to have noticed. %}

Mellers, Barbara A., Alan Schwartz, Katty Ho, & Ilana Ritov (1997) "Decision Affect Theory: Emotional Reactions to the Outcomes of Risky Options," *Psychological Science* 8, 423–429.

{% They discuss the IARPA forecast tournament. In 2011 the Intelligence Advanced Research Project Agency (IARPA; https://www.iarpa.gov/index.php/about-iarpa), the research wing of the intelligence community, sponsored a multiyear forecasting tournament. Five university-based programs competed to develop the most innovative and accurate methods possible to predict a wide range of geopolitical events. But they analyze one small subquestion: If a group that participated in it, gives more nuanced answers to subjective-attitude questions about politics or so but unrelated to the questions of the competition, than a control group who did not participated. They find it weakly. One confound can be that the experimental group just got conditioned to answer in refined ways for this experiment, losing this attitude the moment they are outside this experiment.

The authors have an enthusiastic style when writing about their forecasting tournaments, as for instance on their 2nd page: "Tournaments are inherently multifaceted manipulations that have arisen in response to the practical demands of real-world organizations to provide policy-makers with timely probability estimates of the consequences of options (Tetlock & Gardner, 2015; Wolfers & Zitzewitz, 2004)." Or the last page: "Notwithstanding this litany of limitations, we caution against underestimating the societal value of forecasting tournaments."

A nice text that logically distinct concepts can still be empirically related: "From a formal philosophical perspective, these two classes of variables are clearly logically distinct. Forecasts are beliefs about matters of (future) fact, whereas policy attitudes are ultimately value judgments about what society ought to do. But of course that does not imply that fact-grounded forecasts and value-grounded attitudes must also be psychologically distinct."

Section 3.5, on incentives: It is important for properness that there are no other incentives interfering. The description of the incentives here is vague though. For example, is “dependent upon one’s skills” linear?? %}

Mellers, Barbara A., Philip Tetlock, & Hal R. Arkes (2019) “Forecasting Tournaments, Epistemic Humility and Attitude Depolarization,” *Cognition*, 188, 19–26.

{% Nice title.

P. 229 Figure 4 depicts the basic model, with H transforming physical stimulus (probability, outcome, or whatever) into subjective perception (decision weight, utility, or whatever), then C turning subjective perception into subjective value evaluation (such as EU), and then J turning this subjective value into response to experimental question (e.g. monetary equivalent, binary choice, and so on). The authors discuss the related separation for some models, where it is usually debatable, of course. Then they discuss it for their preferred theory: Change-of-process theory. The latter assumes subjective perception H (or at least utility u) constant, and only what comes after changes per context.

Pp. 231 ff. describes the theory that is the authors’, and also my, favority: Change-of-process theory. It assumes that the utility function is invariant, and it is the other components that are changing and causing preference reversals (something the title also refers to). But what I found missing is any argument for it. It is presented out of the blue. My argument comes from something that psychologists do not think about: The normative approach. I think that EU is normative, so, each person has a utility function representing him if-he-were-rational. Hence, I try to find their utility functions, resolving all biases at best no matter how many they are. And thus I have a prior belief in the existence of invariant utility prior to having seen any data. The authors do not think this way, at the end of §VII doubting the very existence of true preferences.

P. 232: Strangely enough, the authors assume a model for one-nonzero-outcome prospects that combines probabilities and outcomes additively rather than multiplicatively. This cannot work well for probability 0 (and, similarly, outcome 0). They investigate this mathematical problem the Ψ way: By running an experiment. (So, they had subject choose between a 0 chance of gaining $200 and a 0 chance of gaining $100, for instance). P. 234 3rd para describes the results: The experiment confirms the mathematical failure of their model. To defend, they resort to Ψ's ultimate weapon: context dependence!

Section VII last para similarly investigates the philosophical question of the existence of true preference by doing an experiment.

Pp. 242-243, **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**: they indicate the support of their change-of-process theory, and their supportive experimental findings, for this view. %}

{% **updating: discussing conditional probability and/or updating**; **three-doors problem**: Discussed in the beginning at p. 145 (and again p. 151) with references given. The paper has a nice collection of similar paradoxes. Deeper paradoxes, such as the waiting rule paradox or sleeping beauty, are not discussed in this paper.

The writing of the paper is sometimes unfortunate.

(1) On p. 145, the authors give an incomplete description of the Monty Hall problem (not specifying the strategy of the host), only write "under natural assumptions that we discuss later", and then discuss much the mistakes made there. However, those mistakes are only mistakes under the common assumptions of the Monty Hall problem, and those are not at all natural, it being a very peculiar game. Those common assumptions will only be specified on p. 151, but without them the text on p. 145 is incomprehensible.

(2) Similarly, in the alternating paradox on p. 155, the description suggests the right procedure to be assumed (two-stage, that first a relevant (having heads on first or second toss) triple of coin flips is selected at random, and only then a relevant pair of tosses (two consecutive tosses of which the first is heads) is selected from the triple), with probability at heads < 1/2. But the vague "at random" at the end of the first sentence does not make it fully clear. It is linguistically possible that not the relevant triple is chosen at random, but the relevant pair is chosen at random (if you know what I mean), in which case

probability heads is 1/2. This is the more so as the opening sentence cannot always be (if tails on the first two tosses) and has to be partly retracted later anyhow. To get the selection of a relevant pair, are we conditioning on the event of a triple chosen at random and containing a relevant pair, or on a relevant pair chosen and then the corresponding triple taken?

(3) The last example of Zenet's student pretending clairvoyant abilities, will never work. The experimenter will just verify all predictions made and see that they were right 50% of the times, as with rndomness. She may get the idea of choosing a statistical analysis à la Gilovich et al. streaks only if she knows about the students strategy of always predicting after three heads observed (serving as a "streak"), but then she is not fooled by the student anymore and in fact knows that this "clairvoyance" is just a very simple strategy, related to the gambler's fallacy. The authors seem to deliberately avoid making this point clear.

It is true that many people, when analyzing data, are not aware of biases in their sampling, and the hot-hand example of Gilovich et al. (1985) is a sad example. Similarly, in extensive game theory, many game theorists just use Bayesian updating for every event specified in their own way without verifying the underlying random process and that there may be more info than just the event they chose to condition on. %}

{% **probability communication**;

ratio bias: denominator neglect. They investigate it for CE tasks, where it seems not to have been done before. Relate it to numeracy (Berlin numeracy task); higher numeracy gives more EV maximization, which can be taken as rational. More precisely, it gives less concave utility and more linear probability weighting. Unfortunately, the authors use the T&K'92 one-parameter family of probability weighting, so, we cannot distinguish between level (optimism) and

inverse S (likelihood insensitivity).

P. 2 cites many papers that argue that this is because lower numeracy gives more nonlinear perception.

cognitive ability related to likelihood insensitivity (= inverse S) %}

Millroth, Philip & Peter Juslin (2015) "Prospect Evaluation as a Function of Numeracy and Probability Denominator," *Cognition* 138, 1–9. https://doi.org/10.1016/j.cognition.2015.01.014

{% **cognitive ability related to risk/ambiguity aversion**: A thorough study, with many references, replicating the choice paradoxes of Kahneman & Tversky (1979), and relating them to numeracy (measured using Berlin Numeracy Test; p. 518). As with KT, choices are hypothetical.

P. 525, Conclusion: (i) the replication does not come out very well and the authors find quite less of the paradoxes than KT did. (ii) the paradoxes involving probability weighting come out stronger than those involving reference or sign dependence. (iii) they also find, surprisingly, that high-numerate subjects commit more paradoxes than low-numerate.

The low-numerate use super-pessimistic strategies of just minimizing the probability of the minimal outcome, which does not give the paradoxes. This may be (part of) the explanation (p. 524, §4.3).

p. 517: single-subject design means every subject makes only one choice—many experimental economists take this as gold standard.

P. 518: use Bayes factor in Bayesian hypothesis testing, briefly explained, with references to justify it.

P. 521: when finding differences between two groups, one should always verify that not noise was different for one group, and caused the difference. The authors discuss this in detail, although defensively, on pp. 521-522. %}

Miyamoto, John M. (1983) “Measurement Foundations for Multiattribute Psychophysical Theories Based on First Order Polynomials,” *Journal of Mathematical Psychology* 27, 152–182.

{% Lemma 1, p. 443, is useful because it gives a powerful tool for characterizing linear-exponential (CARA) and log-power (CRRA) functions. Let U be a continuous strictly increasing function from a subinterval of the positive (positive means 0 is not included) reals to the reals. Let 0.5U(x) + 0.5U(z) = U(y) imply 0.5U(tx) + 0.5U(tz) = U(ty) whenever all arguments are in the domain. Then U is log-power (CRRA). This result is powerful because, first, unlike virtually all statements in the literature it allows for an arbitary interval as domain and, second, it requires only fifty-fifty mixtures. An immediate corollary, through the transformation
x --> ln(x), is: let 0.5U(x) + 0.5U(z) = U(y) imply 0.5U(t+x) + 0.5U(t+z) = U(t+y) whenever all arguments are in the domain. Then U is linear-exponential (CARA). So, this also holds on arbitrary intervals.

This paper corrects a result by Krantz et al. (1971) who in the log-power family overlooked the log function (power 0) and the negative powers. %}

{% **criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity** This paper, which I like much, criticizes, as did many papers before, the Anscombe-Aumann framework (AA) when applied to ambiguity. It criticizes AA for its monotonicity assumption that, as the authors explain on p. 1022, imposes a weak separability condition on the ambiguous events that does not fit with ambiguity. Wakker (2010 §10.7.3) called it Jaffray's framework and argued that it is more plausible than the AA framework. Unlike the many preceding criticisms, this paper does more: it not only complains about the problem, but also fixes it. That is, it develops an alternative model, with the order of horse and

roulette events reversed (roulette comes first), making it much better suited to analyze ambiguity. Such a basic approach had been done before by the impressive Jaffray (1989), but he used a peculiar framework and an overly extreme complete-ignorance model because of which it was not applicable. This paper instead uses a natural framework with the realistic rank-dependent utility, also known as Choquet expected utility, whose variation is nicely called Expected Choquet Utility, reminiscent of Machina's nice expression of Aumann-Anscombe framework.

The paper provides an axiomatization, essentially by combining Savage's (1954) axioms with Sarin & Wakker's (1992) cumulative dominance.

In the framework of this paper, the relation between ambiguity aversion and preference for probabilistic preference reverses, where the latter now is related to ambiguity *seeking* rather than aversion, which is psychologically more plausible. Wakker (2010 §11.6, p. 328) qualified the AA implication of equating ambiguity aversion with preference for probabilistic mixing as an historical accident.

This paper also links putting up probabilistic (roulette) events first with better incentive compatibility of the random incentive system (RIS). %}

{% An impressive paper giving many valuable preference foundations.

They assume a two-variate product space $\Pi^{i=1,\ldots,n}{}_{j=1,\ldots,m}X^i{}_j$. So, we deal with matrices with m rows and n columns, giving $m \times n$ dimensions. Say there is both time and uncertainty, with n states of nature and m timepoints. One of the components can also refer to persons or commodities or other things. The first basic result, which in itself has been known before as the authors cite, is:

Assume that we only have separability of each row and each column. This, by Gorman's (1968) theorem, is already enough to give full separability and an overall additive representation. This particular form of Gorman's theorem has a long history as the problem of aggregation in economics. (Can we just take aggregate demand of every commodity in the market and only then aggregate over individuals, or should we first aggregate over individuals.) My Rotterdam predecessors Van Daal & Merkies worked on this. The result is so nice because the separability of columns and rows just feels like weak monotonicity. The result is stated in Proposition 1.(b), where a more general result is stated that holds if their domain X is a full product set. The result underscores **restrictiveness of monotonicity/weak separability**.

Then, as the authors show in their Theorem 1 (p. 156), because for every row, for instance, we already have a cardinal representation, requiring ordinal identity of conditional preferences give that these rows have the same representation up to one positive factor. Doing this for columns too, we get a weighted-average representation as with EU and discounted utility while avoiding extra conditions such as bisymmetry, tradeoff consistency, or Savage's (1954) P4. This result is not very new or very deep, but nice and useful, and gives a host of applications and improvements on existing results. It gives a generalized version of Harsanyi (1955) and Anscombe-Aumann (1963), allowing subjective probabilities in the second stage. The authors also handle quite general subsets of product sets, as in Segal (1992) and Chateauneuf & Wakker (1993). %}

{% Proves that a quasi-concave separable function on an atomless space is concave. For usual additive separable representations with finite dimensions, $V = V_1 + \cdots + V_n$, we have a state space $S = \{s_1, \ldots, s_n\}$ and a function, act, $x = (x_1,\ldots,x_n)$ and V represents preferences over acts. One can say that S is endowed with the discrete counting measure $\mu(s_j) = 1$ for all j and that V_j is state-dependent utility, and V state-dependent expected utility. When Wakker & Zank (1999) extended this to infinite state spaces S, one unanticipated difficulty was writing the very definition of V, in the absence of a measure μ on S such that V would be absolutely continuous with respect to that measure, so that V could not be written as a kind of integral.

This paper studies state-dependent EU functionals on infinite, even atomless, state spaces that are endowed with a measure μ so that they can be written as an integral. The set of acts is taken as L^p_+. The state-dependent functional is called separable. The state-dependent utility is called kernel. It cites mathematical literature on this, e.g. on continuity results. It shows that for a separable function quasi-concavity implies concavity. %}

{% **three-doors problem**: This paper does an experiment on the three door problem. The author investigates to what extent non-Bayesian updating, illusion of control, and status quo bias play a role. (**updating: testing Bayes’ formula**)
The start of the paper is not good. As happens usually, the three door problem is not properly described. Here is the, incomplete, description that the author gives:

> Suppose you’re on a game show, and you’re given the choice of three doors:

behind one door is a car; behind the others, goats. You pick a door, say No. 1, and the host, who knows what's behind the doors, opens another door, say No. 3, which has a goat. He then says to you, 'Do you want to pick door No. 2?' Is it to your advantage to switch your choice?

What is missing in this description is that the host will deliberately always open another door that does not have the car. (For specialists: and, further, that if the host has two doors to choose from, i.e., if "you" initially chose the door with the prize, that then the host randomly chooses the door to be opened. %}

{% **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**: It has been widely understood that cardinality of utility has two different meanings. First, just the mathematical property of uniqueness up to unit and location. Second, that it can be given psychological interpretations. This paper discusses the issue anew, adding new literature. In the beginning of §2, the author writes "In his Manual, Pareto ([1909] 1971: 112 and 396) maintained that utility cannot be measured; i.e., that it is impossible to identify a unit of utility and express the utility of commodities as a multiple of that unit." I regret that the author, as did so many, leaves out the crucial premise that Pareto added. Pareto made his claim only for the case where we only want to explain market demand and equilibrium. %}

Moscati, Ivan (2013) "How Cardinal Utility Entered Economic Analysis, 1909-1944," *European Journal of the History of Economic Thought* 20, 906–939.

{% The most central idea in decision under uncertainty, and the dividing line between Bayesian EU and nonEU, is the sure-thing principle. It was Savage's (1954) main invention. How did the idea come about? I have wondered since my youth. It was mainly in exchanges between Samuelson and Savage, two of the greatest minds ever. This paper carefully documents the history and origin of the idea. It is very valuable to me, answering questions I had since my youth.

independence/sure-thing principle due to mutually exclusive events: The crucial point why the sure-thing principle is normative, is that it concerns separability about mutually exclusive events, between which no physical interaction is possible. (The interaction is only in the, confused, minds of nonEU maximizers.) P. 225 cites a May 11 1950 letter by Marschak who points it out to Samuelson, but Samuelson's reaction is confused. He brings in utility and is confused that utility of tea and pretzles will interact, which is besides the point. P. 227 middle cites Samuelson (1950a) on properly criticizing the Friedman-Savage EU explanation of gambling and insurance with EU. Samuelson (1952 Econometrica) writes that much brooding on "mutually exclusive" in 1950 made him understand the importance of "mutually exclusive." He does not credit Marschak there.

P. 229 cites Sept. 13, 1950 letter by Friedman where Friedman writes that under EU all preferences are completey determined by binary gambles: "Dear Paul: … It has never seemed to me obviously true or necessary that individual's reactions to complicated gambles should be completely predictable from their reactions to two-side ones—which has always seemed to me the fundamental empirical content of the B[ernoulli]–M[arshall] hypothesis"

P. 230 brings up Savage's letter of August 12, 1950, where he first formulates the sure-thing principle as a form of event-wise monotonicity (in the same way that every separability can be written as monotonicity).

On p. 231 this paper suggests that Savage (1954) used the term sure-thing principle only for his P2. But this is not so. It also included P3 (monotonicity w.r.t. outcomes) and P7. Only later it became a tradition in the field to use the term sure-thing principle only for P2, a tradition that I follow.

P. 231 shows that Samuelson had changed his mind on EU, and now considered it normative, in his letter to Friedman of August 25, 1950. It is nowhere stated that the mutual exclusiveness of events played a role in Samuelson's considerations, whereas my memory (I read the relevant letters in the early 1990s) tells it did; but I must have been confused then. Looks like Marschak was the one to bring the argument in in this communication on the sure-thing principle. Note that von Neumann & Morgenstern (1944) repeatedly justify the addition-operation in their EU formula by emphasizing that it is about mutually exclusive events. %}

Moscati, Ivan (2016) "How Economists Came to Accept Expected Utility Theory: The Case of Samuelson and Savage," *Journal of Economic Perspectives* 30, 219–236.

{% The intro argues that Friedman was the first to argue that the vNM cardinal EU utility U can be different than the cardinal economic utility u. The book discusses the historical role of Hölder (1901). It also discusses the mentalist vs. the instrumental view of utility.

A central theme is the distinction between cardinal utility and utility as a ratio scale, but I did not understand it and to me the difference is minor. Well, it becomes substantive if the 0 level of utility has a special meaning as a reference point, separating gains and losses, but this is not the distinction that the book makes.

P. 190, §11.8, writes: "After an initial period characterized by various changes of mind about the validity of EUT, the parties in favor and against stabilized, and the supporters turned out to be significantly both more numerous and more academically prominent than the opponents."

{% Version of 1 June 2022: Discusses as-if (also called paramorphic) versus process (also called homeomorphic) modeling in behavioral economics. Puts relevant arguments on the table. Comnects decision theory with philosophy (e.g. realism vs. antirealism). Lists many problems for process models: Transitivity is violated; researchers disagreeing. Therefore, goes against processs modeling and pleas for strict as-if. My subjective opinion is opposite: The many problems for process models are not very different from problems for most models. Hold as much for as-if models. Some problems is not enough reasons to entirely discard process insights. Those did, and will, bring many good things. %}

{% Gotten from Ido Erev on 5 sept. 1990.

Tests effects of framing and talking with subjects on their violations of the sure-thing principle. Done before by MacCrimmon (1967) who did it with hypothetical choice. This paper uses real incentives. Those were grades for a statistics course … (I expect that ethical committees would not approve this nowadays, 2020.) All subjects received a simple verbal description. Some received, in addition, a matrix representation that made the common outcome salient, and some in addition received a decision tree figure where the common outcome was not clear. In total, the matrix representation gave most verifications of the sure-thing principle (76%), the just-verbal almost the same (73%), and decision trees the least (65%). So, no spectacular results. The discussion never mentions the possibility that the matrix structure, which makes the role of the s.th.pr. more salient, may lead to more consistent choices not because such is genuine preference, but because this becomes an easy heuristic. %}

{% Remarkably, Mosteller started as a mathematician, but later turned to psychology. Arrow (1982): first empirical test of EU.

P. 373 seems to argue that PE is difficult because probability is a more difficult concept than money (**PE doesn't do well**)

P. 374 seems to argue against deterministic tests, and to favor probabilistic choice models; they let subjects repeat choices everal times

P. 377: they deceived subjects by giving them more money than said. (**deception when implementing real incentives**)

P. 383 mentions the **utility of gambling**. P. 402 discusses it more. "Indeed, the writers would prefer to defer discussion of this point until a way of testing arguments about it is provided."

P. 385, end of 2nd column: a subject who violates probabilistic reduction (Wakker's (2010) decision under risk assumption 2.1.2) by gambling rather on one hand than the other

Real incentives: repeated gambles for money, all with real incentives. Losses were also implemented. A **losses from prior endowment mechanism** was used although it might in extreme cases not cover all losses. P. 399 mentions that this gives an income effect. P. 400 mentions house money effect, that subjects befome more risk seeking after prior gains.

inverse S: Suggest that their data for probability transf. agree with Preston & Baratta's but this is not much so. Sprowls (1953) says they are more variable. P. 397: For Preston & Baratta probability transformation (assuming linear utility) intersects the diagonal at about 0.2, in this experiment at 0.5 for guardsmen, and not for the students (they are always risk averse). Domain: [–0.05, 5.50]

P. 398 has nice discussion of problem with transforming fixed probabilities, that they must violate transitivity and do not sum to 1. (**biseparable utility**) Then also, nicely, for two-outcome gambles, that subjects focus on a particular outcome, and let the other outcome have rest of unitary decision weight. This would be biseparable utility (RDU for two outcomes) if the particular outcome were always the best, or always the worst. Point out that for more than two

outcomes the formula then is not clear.

SEU = SEU: p. 398 has good discussion, with footnote 16 pointing out that additive subjective probabilities if unequal to objective probabilities cannot be transforms of the latter.

P. 402, §VI.E: **utility of gambling**. %}

{% Impressive data sets (total N = 17,720!) is used to investigate loss aversion. Throughout, loss aversion is confirmed. Many psychologal factors underlying it are discussed. They cite much literature. Their data set contained over 3,000 millionaires, who also were loss averse for moderate stakes.

Loss aversion due to framing (what I call loss aversion is always due to framing, being reference dependent; genuine utility (reference independent) I call basic utility) is probably what the authors call "loss aversion rooted in preference construction," referring to the constructive view of preference. The authors distinguish it from "rooted in status quo bias" and other factors (p. 408 1st column), but for me those need not be different and they can be one component in combination. In general, it is difficult to see how and to what extent different psychological factors are really distinct or overlapping/joining. The authors distinguish endowment effect from loss aversion, but I take endowment effect to be part of loss aversion.

One problem is that the authors do not consider utility curvature or probability weighting (or other concepts from risk theories) but ascribe all risk aversion to loss aversion. For instance, an indifference (0,.5:–300, 0.5:100) ~ 0 is taken to give loss aversion $\lambda = 3$. They sometimes discuss "rational risk aversion" and suggest to measure it in one study (p. 416), but that only uses an introspective question: "[W]here would your household prefer to put most of its savings and investments?" (1 = very low return/very low risk; 5 = very high return/very high risk)" and it is used as a covariate in regressions (taking away quite some of loss aversion). So, they do not really correct for utility curvature or probability weighting. They also defend by saying that they also find loss aversion for millionaires. It can be argued that, because of the richness of millionaires, utility of small stakes should be linear, but it need not neutralize probability weighting, or other factors from other theories.

For cars taken as multiattribute objects, they measure attributewise loss aversion, finding that it is smaller for attributes better known to subjects (p. 414 1st column). Loss aversion is moderated by being young (p. 414 2nd column discussion has a typo on this; **relation age-risk attitude**), education, knowledge, and experience (**cognitive ability related to risk/ambiguity aversion**).

P. 408 2nd column writes that loss aversion is robust, but I think it is strong but very volatile.

P. 422 1st & 2nd column has the usual enthusiasm: “These results have important implications. … The finding that older people are more loss averse has substantial implications, … extremely important.”

A replication by Zeif & Yechiam (2022) does not find loss aversion for moderate amounts ($40), but of about 1.5 for $100. %}

{% Do a multivariate generalization of decreasing differences to characterize more concave than. The authors' term loss is not related to reference points or prospect theory or the like. In their terminology, under EU, fear of loss is equivalent to concave utility. %}

Müller, Alfred & Marco Scarsini (2012) "Fear of Loss, Inframodularity, and Transfers," *Journal of Economic Theory* 147, 1490–1500.

{% The authors assume EU with utility u. They introduce an index $0 \le \gamma \le 1$ for a utility function u, an anti-index for the nonconcavity of u. $\gamma = 1$ means complete concavity, and $\gamma = 0$ means strictly increasing and not any restriction otherwise. $0 < \gamma < 1$ means that the function can have convexities, but not too pronounced, and bounded by γ. For u, we take the maximal γ such that

$0 \le \gamma u'(y) \le u'(x)$ for all $y \ge x$.

So, u´ may be increasing, but not by a factor more than 1/γ, so to say. The authors give an extension to nondifferentiable functions through discrete approximations. Besides the definition using derivates, there are also an euivalent integral and an equivalent γ-transfer formulation, and 1+γ stochastic dominance. The conditions are related to greediness and thriftiness conditions of Chateauneuf, Cohen, & Meilijson (2005). The dual definitions for nonconvexity are also given.

§3 explains that the authors' concepts can well capture local convexities, e.g. because of aspiration or other reasons for local jumps in u´. Zank once told me an example: just above the level where you can buy a new house, marginal utility is steep.

§4.2 considers reference dependence and loss aversion. On a bounded interval [–d, d], under concavity for gains and convexity for losses, γ can be determined (both for nonconvexity and nonconcavity), involving loss aversion λ. They show that loss aversion can be reinterpreted as part of utility curvature. %}

{% Reanalyze the data of a working paper Schulte-Mecklenbeck, Pachur, Murphy, & Hertwig (2018), with N = 142 and 91 choices between risky prospects with at most two nonzero outcomes, with both gains and losses. (§2). Use standard parametrizations of PT to fit data with Prelec's two-parameter family.
P. 309, end of §1.1.2: "Prospect theory is arguably the most important and influential descriptive model of risky choice to date." (**Prospect theory/Rank-Dependent Utility most popular for risk**)
P. 310, beginning of §1.2: "Multiparameter models' estimation methods may be prone to overfitting and in doing so adjust to noise instead of real risk preferences (Roberts and Pashler 2000). This can sometimes be observed when parameter values emerge that are highly atypical and extreme. A common solution to this problem is to set boundaries and limit the range of parameter values that are potentially estimated."
They propose a new hierarchical maximum likelihood estimation method (HML), which the estimates of an individual's parameters are influenced by the

estimates of other individuals. This is also done in hierarchical Bayesian methods. I know too little about it to know where this paper is innovative in this regard. Pp. 310-311: "We therefore address to what degree an estimation method combining group-level information with individual-level information can more reliably represent individual risk preferences compared with using either individual or aggregate information exclusively."

P. 312: Very unfortunately, payments are not what they are said to be, but when incentivized the authors divided all payoffs by 10. I never understood why researchers not just call payoffs what they are.

P. 317: for population fitting, for time 1 choices they find $\alpha = 0.73$ (power of utility; taken the same for gains and losses); $\lambda = 1.11$ (loss aversion); $\delta = 0.88$ (power of weighting function, being index of pessimism), $\gamma = 0.65$ (likelihood-insensitivity index of weighting function), and for time 2 choices they find $\alpha =$ 0.73 (power of utility; taken the same for gains and losses); $\lambda = 1.18$ (loss aversion); $\delta = 0.84$ (power of weighting function, being index of pessimism), $\gamma =$ 0.68 (likelihood-insensitivity index of weighting function).

Pp. 317-318: "On the aggregate, cumulative prospect theory's predictions appear to perform well."

Compared to a classical maximum likelihood estimation (only per individual without using population info), their HML method has, unsurprisingly, somewhat worse within-sample fit, but better out-of-sample prediction and more stability of parameter estimates.

P. 320 bottom: "The benefits of hierarchical modeling may, for example, diminish hen more choice data are available." %}

{% **PT, applications**, loss aversion: Supports prospect theory; i.e., implications of reference dependence and diminishing sensitivity. They let subjects exchange money/lotteries in a market setup, when outcomes are losses.

risk averse for gains, risk seeking for losses: Beautiful data supporting this. The resulting equilibria suggest risk seeking for losses, in agreement with prospect theory. When reframed as gains (pp. 818-819), the resulting equilibria suggest risk aversion! The latter was done for only one equilibrium with only 9 subjects.

real incentives/hypothetical choice: Hypothetical questions (called questionnaires) revealed results that nicely agree with real-incentive market behavior. Some more risk aversion for real incentives.

losses from prior endowment mechanism. Done. They must hope that subjects do not integrate the total amounts.

Some results suggest that loss aversion (Conjecture 1, p. 820) and risk-seeking-for-losses (Conjecture 2, p. 820) decrease with experience. The latter nicely suggests that convex utility for losses reflects diminishing sensitivity rather than intrinsic value. I agree much with the interpretations in this paper.

The paper is strange in claiming that learning effects (reducing risk seeking for losses) would violate prospect theory, contrary to writings by Kahneman & Tversky (1986) and others that learning and incentives can make choices more rational.

random incentive system: P. 806 top of 2nd column uses it. Footnote 3 there states that the Holt (1986) compound-prospect argument can be ignored. %}

{% Big Japanese data set is analyzed for relation between discounting, decreasing impatience, and smoking. Novelty is that sign effect (less discounting for losses than for gains) is incorporated. P. 1444 end of 4th para they report that: "hyperbolic discounting estimated from monetary choice questions exhibits neither a predicted nor a stable correlation with smoking." They criticize this measure for being noisy. The measure is derived from intertemporal indifferences (derived from choice list) about receiving in 2 days vs. 9 days, 90 vs. 97 days, and three of 1 month vs. 3 month. So, none considers immediate payoff and present bias.

P. 1448 explains that the authors use hypothetical choice citing three references (footnote 10) that find no differencve. Given hypothetical anyhow, I would have preferred way longer periods because in short term there is little discounting.

They take another question, about whether people did homework fast in their youth (§3.2.2) instead as proxy for discounting. This relates positively with smoking. It can, however, be for reasons different than time attitude. For instance, both smoking and postponing homework are protest attitudes against parents. Sign effect in sense of making discounting less for losses can decrease smoking, which is what the authors claim, but also in sense of making discounting for gains stronger can increase smoking I would say. Opening sentence in §2 strangely connects Becker & Murphy (1988) with forward-looking.

In Table 4, the probability of rain at which one takes an umbrella is index of risk seeking

P. 1453 §3.3 nicely tests time invariance: If time preference changes if both consumption and decision time change, but their difference remains the same. So, whether one can use stopwatch time. They have the longitudinal data for it, and find it violated. %}

Nagel, Rosemarie (1995) "Unraveling in Guessing Games: An Experimental Study," *American Economic Review* 85, 1313–1326.

{% This paper follows up on Heinemann, Nagel, & Ockenfels (2009 RESTUD), HNO henceforth, adding a competitive entry game and doing neuro measurements. The first of the two games, the stag hunt game, is described in my annotations at HNO.

The second of the two games, the entry game, is as follows.

Imagine the 2-player game where each can choose safe (A) or risky (B), with payoffs, for some parameter $0 < x < 15$.

	A	B
A	x^x	x^{15}
B	15^x	0^0

It is a competitive game. If both go risky, they lose. It is favorable to do what your opponent does not do. If playing against a random member from a big population, and most players do one thing, then it is best to do the other thing.

There are two pure NE (Nash equilibria), (A,B) and (B,A), but none is symmetric so, they cannot arise in a symmetric game. The randomized NE is (x/15: A, (15–x)/15: B) for both players. It has the intuitive property of increasing probability of choosing the safe x as x increases. It is symmetric and stable.

In both games, the authors measure whether players prefer A or B for several values of x, and call the switching value the CE. As with HNO, this is an unconventional CE, and they also measure conventional CEs of lotteries, and by transitivity one can derive matching probabilities of the favorable event, being the opponent's choice B in the stag hunt game and A in the entry game.

In the entry game, a level 2 player always does the opposite of a level-1 player, which in some situations leads to the paradox of less taking the safe option x as x increases. Yet the switching value can still serve as a sort of CE. It does show that the effect of x on behavior is complex and sometimes antimonotonic. Therefore, it is not surprising that in the entry game the authors find more switches of preferences as x increases, what they call more entropy. They put this forward as an argument that the entry game is of a different nature. They use the term threshold strategy if there are no switches. Entry games also require more response time.

game theory can/cannot be viewed as decision under uncertainty (pp. 52-53 discuss it): They compare nature (my term; meaning: generated by nature) uncertainty with strategic uncertainty. The latter is mostly related to higher-level, say level k, thinking. The stag hunt game is simple, requiring little strategic thinking, and the entry game requires much. They find that stag hunt is similar to risk, but entry is different, by neuro measurements (p. 53 4th para; p. 58 last column middle of 2nd para) and also behaviorally based on CEs and correlation. P. 57 2nd column 1st para: CEs of entry games were even uncorrelated with those of risk and stag hunt games.

As do HNO, working with SEU, the authors suggest, following some other economists, that, the moment subjective probabilities have been assigned, the case is (like) decision under risk (abstract ℓ. 3; top of p. 53; p. 58 2nd para ℓ. 3; p. 59 2nd column 1st para last line; p. 59 2nd column lines –4/–6), and any deviation is taken as impossible to involve subjective probabilities. As I write at HNO, in the source method this is not so. Further, in the entry game, subjects can be perfectly Bayesian with subjective probabilities but still have less preference for the safe option x as it increases because they think it increases the probability of the opponent going for safe, so, it improves the risky probability of winning. They would do the same if such probabilities were generated by some natural process rather than a rational opponent, so that it need not necessarily be a difference between natural and strategic uncertainty.

P. 59: "The anterior insula thus reflects risk preferences and guides choice selection both in individual and [in] social settings."

P. 60 penultimate para precludes that the findings are entirely driven by social preferences. It can still be that social preferences do play a role, alongside with other effects. %}

{% Considers n-tuples $(x_1,\ldots,x_n)$ in Re^n with n variable. I (not the author) interpret it as 1/n probability prospects. Under EU, certainty equivalents, denoted CE, with utility denoted as φ, is $\varphi^{-1}([\varphi(x_1) + \ldots + \varphi(x_n)]/n)$, with φ endogenous. This paper axiomatizes functions CE for which there exists a continuous strictly monotonic φ. The axioms are (reordered but kept author's numbering):

(i) The function CE is symmetric;

(v) $CE(a,\ldots,a) = a$;

(ii) Write $CE(x_1,\ldots,x_r,x_{r+1},\ldots,x_n) = a$; then $CE(x_1,\ldots,x_r,x_{r+1},\ldots,x_n) = CE(a,\ldots, a, x_{r+1}, \ldots, x_n)$;

(iii) CE is continuous and $a \le CE(x_1,\ldots,x_n) \le b$ if each $a \le x_i \le b$ for all i;

(iv) $x_1 < x_2$ implies $x_1 \le CE(x_1,x_2) \le x_2$.

Condition (ii) is called associativity of the mean. It has a remarkable relation with vNM independence. It is a version of vNM independence: Jf $(x_1,\ldots,x_r) \sim a$ then $[r/n: (x_1,\ldots,x_r), (n-r)/n: (x_{r+1},\ldots,x_n)] \sim [r/n: a, (n-r)/n: (x_{r+1},\ldots,x_n)]$.

So: this can be taken as giving the vNM EU axiomatization for equal-probability prospects, which amounts to all rational-probability prospects, under the restriction of continuous utility!

To excite us even more, the theorem on p. 78 shows that constant absolute risk

aversion is equivalent to linear-exponential utility!! (The theorem only states sufficiency but the text directly preceding states necessity.) %}

{% Marvelous theorems, but written in a difficult, mathematical, manner, and several typos. He does not only consider sigma-additive probability measures but, more generally, finitely additive measures. Because of that, he has to deal with ultrafilters, and has to write complex definitions in §2 regarding step probability distributions. On p. 108 last two para's he introduces n-tuples of outcomes and their cumulative probabilities, as Abdellaoui (2002, Econometrica) will do later. Then he, first, considers only three fixed outcomes (so, two-dimensional subspace!) and proves everything there, as he also did in his 1990-JET paper etc. He can, obviously, put his general representations of 1992 for general rank-ordered sets to good use. Axiom 5 is, however, not just multisymmetry but rather it is very similar to act-independence of Gul (1992, Assumption 2), as explained by Köbberling & Wakker (2003 MOR). Here is an explanation. He uses Wakker's (1993, MOR) truncation continuity to obtain an extension to nonsimple

prospects.

P. 104 penultimate para is correct. Nakamura has a rich probability space, and a general consequence space. Wakker (1993) did the extension to nonsimple probability distributions for general consequences, but had no underlying preference foundation of RDU for simple probability distributions for general consequences, but only for continua of outcomes or, at least, solvability for outcomes (Wakker 1991, in Doignon & Falmagne, eds.). %}

Nascimento, Arnaldo, Che Tat Ng, & Rich Gonzalez (2022) "Measuring Attractiveness and Discriminability," working paper.

{% The authors provide numerical analyses of (source) preference and insensitivity for various parametric families of weighting functions w. As local index of source reference they take $w(p) - p$. For a subset S of [0,1], the index is the integral of $w(p) - p$. Over the whole [0,1] it, thus, is $\int w(p) - ½$. For an interval [q,r], the discriminability (opposite of insensitivity) is w(r)–w(q) – (r–q). This is equivalent to the integral of $w' - 1$ over the interval. The authors consider w's of bounded variation, then, I guess, am not sure, write $w' - 1$ as the sum of an increasing and decreasing function, and whichever gives the bigger discriminability, that they take. They then numerically analyze the effects of parameters of parametric families on their measures. %}

Nascimento, Arnaldo, Che Tat Ng, & Richard Gonzalez (2025) "Measuring Probabilistic Risk Attitude," *Management Science*, forthcoming.

{% This paper is the first to axiomatize the Goldstein-Einhorn probability weighting family. It corrects Gonzalez & Wu (1999), who claimed to have it but made a mistake. In the rest of this annotation, I present the maths in my own words.

Assume PT throughout. Consider the following preferences, which I, coincidentally, used in the tradeoff method, with X_pY denoting the lottery (p:X, 1−p:Y):

$X_pY \sim X'_pY'$ &

$X_pY' \sim X'_pY''$

It implies that Y´ is the utility-midpoint between Y and Y´´, as I often used. Here another implication is important: the first indifference means that the oddsratio of w at p is a utility-difference ratio. That is,

$$\frac{w(p)}{1-w(p)} = \frac{U(Y)-U(Y')}{U(X)-U(X')}$$

The second indifference gives, similarly, identical ratios

$$\frac{w(p)}{1-w(p)} = \frac{U(Y')-U(Y'')}{U(X)-U(X')}$$

Similarly,

$X_qY \sim X'_qY''$ gives a double ratio:

$$\frac{w(q)}{1-w(q)} = \frac{U(Y')-U(Y'')}{U(X)-U(X')} = 2\frac{U(Y)-U(Y')}{U(X)-U(X')} = 2\frac{w(p)}{1-w(p)}$$

Thus, the oddsratio of w at q is twice that at p.

Gonzalez & Wu (1999) formulated a preference condition that this remain the same if we replace p and q by p´ and q´ where w has oddsratios t times those at p and q for any t´>0. If f denotes how the oddsratio of w depends on that at p, we get

$$f(y) = 2f(x) \Rightarrow f(ty) = 2f(tx). \qquad (*)$$

Gonzalez & Wu erroneously thought that this implies linearity of f. But it does not. To wit, assuming f strictly increasing and continuous. Its domain and range are $\mathbb{R}^{++}$. Take any y and then x<y with f(y) = 2f(x). Write y = dx for d>1, where d abbreviates doubling. On [x,dx] one defines f arbitrarily given the preceding constraints.

LEMMA. For every integer n, f is uniquely determined on $[d^nx, d^{n+1}x]$ and, further, f is uniquely determined on its whole domain.

PROOF. We have $f(d^nx)=2^nf(x)$ (Eq. * with y = dx and t = d^n and induction, similarly for negative integers n).

Further, take any z in [x, dx] and write it as tx. Then dz in [dx, d^2x]. f(dz)/f(z) = f(dx)/f(x) = 2. Inductively, $f(t^nz) = 2^nf(z)$, similarly for negative integers n. f is uniquely determined on its whole domain. □

One sees that the construction in the lemma is not only necessary, but also sufficient, for Eq. (*), and f need not be linear. It is a sort of periodicity. A special case is if f(2x) = 2f(x).

My first hunch to get a sufficient condition would be to add an indifference $X_pY'' \sim X'_pY'''$ to the above ones, set

$X_rY \sim X'_rY'''$ to get

$$\frac{w(r)}{1-w(r)} = 3\frac{w(p)}{1-w(p)}$$

and then treat it as above to get f(z) = 3f(x) ⇒ f(tz) = 3f(tx). I conjecture that this 3-fold periodicity of f, together with the 2-fold periodicity, implies linearity, as desired.

This paper takes a somewhat different, and more appealing, approach. It uses three indifferences

$X_pY \sim X'_pY'$ &

$X_sY' \sim X'_sY''$

$X_qY \sim X'_qY''$

Note that the only change is that the second indifference has s instead of p. Similar algebra as above shows that the w odds ratio at q is the sum of those at p and s. The authors then require that indifferences are maintained if we replace p,s,q by p´, s´, q´ that have odds ratios t times those of p, s, r. This gives a functional equation strong enough to imply linearity of f.

This paper pp. 3-6 before §5 gives didactical account of the underlying functional equations. %}

{% The author considers bargaining situations where all probability distributions over outcomes are available. Each individual maximizes expected utility over probability distributions with utility function U. It is an interval scale, i.e., is unique up to scale and location.

I disagree with p. 158, last sentence of penultimate para: "Of course, the graph is only determined up to changes of scale since the utility functions are not completely determined." U is an interval scale when representing risky preferences through the expected utility formula, but nothing in the world requires it to be that when an input to the bargaining solution. An example: assume that player 1 maximizes expected value for risk. Then changing the unit of payment from cent to dollar, i.e., multiplying all outcomes by 100, does not matter for his risk attitude. But it may still matter much for his bargaining attitude. He may be willing to do many concessions if all outcomes are below $1000, but change much if the outcomes exceed $1000. Nothing in the world precludes this. One may counter that the bargaining solution depending only on U means that the info on what the underlying outcomes are should be forgotten but this is entirely unrealistic. In any application, one knows the outcomes better than their utility values. I have a similar problem with Ghirardato, Maccheroni, & Marinacci (2005); see my annotations there. %}

{% No author is specified. It is the main editor Andrea Taroni. This editorial supports Peters (2019). It starts criticizing economics for assuming infinite growth whereas this cannot be because our resources are finite. ??? It may not be clear at first where this strange claim comes from, or what it would serve for. It gets clearer if one has read Peters & Gell-Mann (2016). That paper has weird and incorrect claims about all of economics making wrong assumptions about (un)bounded utility. Probably this was lingering in the editor's mind one way or the other. Strange is then still that Peters & Gell-Mann, erroneously, claim that all of economics assumes that utility must be bounded, whereas this editorial criticizes economics for assuming no upper bound. Oh well. Strange is also that this beginning has nothing clear to do with the rest of the text, or it should be "just throw out anything negative about economists coming to mind." The editors sentence

"Still, as the issue of climate change becomes ever more urgent, it is notable that natural scientists' argument that economists ignore the limits of growth is, essentially, the basis upon which the case for action put forward by environmental activists such as Greta Thunberg rests."

illustrates that he is going for the grand picture, not hindered by knowledge.

The sentence

"For example, we now instinctively calculate expectation values with the implicit belief that they reflect what happens over time."

further ilustrates that he/she is just buying all the erroneous marketing of Peters. It also appears from the final text of the editoral:

"It may sound obvious to say that what matters to one's wealth is how it evolves over time, not how it averages over many parallel states of the same individual. Yet that is the conceptual mistake we continue to make in our economic models. By correcting for this error when studying aggregate systems, it also becomes possible to make a statement that is pertinent to the issue Murphy was concerned with in 2012: a measure such as gross domestic product, an ensemble average, does not reflect individual wellbeing, a time average. There is therefore no need to optimize it blindly.

Another mindset is possible: it requires moving beyond average thinking."

Sounds like, in my words: "Economics should stop taking averages." %}

event/outcome driven ambiguity model: outcome driven

This paper does not provide proofs but uses the formula "proof available from the author upon request." It was done, as the author explained to me in an email of March 22, 2006, because the proofs were deemed simple, and not merely to save space. He uploaded proofs and explanations on internet in Sept. 06 on his homepage.

source-dependent utility: uses the Kreps-Porteus (1978) two-stage-expectation representation,

$\mathrm{EXP_T}\big[\varphi\big(\mathrm{EXP_S}[U(f(s))d\pi]\big)d\mu\big]$,

where $\mathrm{EXP_S}[\ldots]$ denotes expectation over S, etc. The model is EU iff φ is linear. It reinterprets the model for ambiguity, where T does not reflect uncertainty at a different time as it does for Kreps & Porteus, but uncertainty from a different source of uncertainty for which there can be more ambiguity. Ambiguity aversion then results if φ is concave, so that here we find smaller certainty equivalents. This paper generalizes the model to **state-dependent utility**, and considers local measures of risk/ambiguity aversion being matrix-generalizations of the Pratt-Arrow measure.

{% **preference for flexibility** ; P. 106 ℓ. 5 has typo: the last ≥ should be ≠.

The model axiomatized: Every act f assigns to every state θ a nonempty set f(θ) of outcomes, an opportunity set (or menu). The agent has to choose between acts today. Then from f(θ) she has to choose one element (an outcome) tomorrow, and that is the outcome she ends up with. If her utility function tomorrow is v_ω, then she will choose the v_ω maximum from any opportunity set f(θ) tomorrow. Today she is uncertain about her preference and utility function tomorrow, an uncertainty expressed by a subjecive probability distribution λ. So, for each state θ she takes the λ weighted average of those maxima. Next, of those she takes the μ weighted average, where μ is the subjective probability measure over the states of nature. %}

Nehring, Klaus D.O. (1999) "Preference for Flexibility in a Savage Framework," *Econometrica* 67, 101–119.

Elementary explanation of preference for flexibility

{% Assumes CEU (Choquet expected utility) with linear utility function. Under CEU, unambiguous events are meant to be those for which the capacity is additive. If on a collection of events the capacity satisfies additivity, then it need not be possible to extend it to the algebra generated by the collection while preserving additivity. This point is reminiscent of the definition of additive probability measures in probability theory, where these are first defined on subcollections and then extended to sigma-algebras, and the subcollections must be appropriate. Def. 4 defines unambiguous event as rank-independence of the total decision weight of such an event, so, the capacity being additively separable as regards that event. It does so in an Anscombe-Aumann type setting with linear utility. I think that this definition implicitly assumes that we have expected utility for risk,

also if it were formulated without committing to the Anscombe-Aumann framework. %}

{% **ordering of subsets**: The author considers a qualitative probability relation that need not be complete and represents it by a set of priors through unanimous representation (known way to get incompleteness). Gives preference axioms for it. The main axiom is the adaptation of the usual additivity. It here claims that for two equally likely events, each can be partitioned into two equally likely smaller

events, and then that the four resulting smaller events are equally likely again (it is formulated somewhat differently and less transparently, as splitting in Axiom 8 p. 1062, but the text following states that it is only used as I just described). Richness is through equidivisibility: Each set can be split up into two equally likely subsets. Further continuity. A 1/k event is such that, in the terminology of Wakker (1981) the vacuous event and the universal event differ by at least k times that event. It is used to define convergence, and then continuity. By equidivisibility, we can divide the universal event into 2^n equally likely events for each n. A very restrictive implication follows: All probability measures in the set of priors must agree on these events and assign the same probability 2^{-n} to them. Thus, they all agree on a rich set of events, and we in fact have a rich set of events with known probabilities, something like Anscombe & Aumann (1963) but, fortunately, without multistage setup, so, more like the hybrid models of Wakker (2010).

The proof is to split the universal event up into always more refined 2^n equally likely partitions, where the probabilities are 2^{-n} and then all dyadic numbers. All other events can then be calibrated. Abdellaoui used this method in several empirical papers.

In several places the author claims, and I disagree, that the aforementioned restrictive assumption (all priors agreeing on rich set of dyadic events) can hardly be avoided if one wants uniqueness (of convex closure). He only puts forward Example 1 on p. 1065, but this is only one example showing that without equidivisibility and with nonatomicity instead it does not work. There is much between equidivisibility and nonatomicity, and much besides nonatomicity too. (He also puts forward that any structure can be embedded in a larger structure that has equidivisibility, by adding objective-probability events, on p. 1057 penultimate para and p. 1066 last para) but, again, the same kind of argument can be used to defend virtually any richness assumption in any model whatsoever.)

In several places (e.g. p. 1055 next-to-last para, p. 1058 ℓ. 5) the author writes that his model is to be taken as rational.

questionnaire versus choice utility: The author interprets the likelihood relation as a cognitive primitive, not based on observable preference and not uniquely related to betting-on but only through a one-sided implication (called likelihood compatibility on p. 1056). He has been sympathetic to such interpretations since his youth, often referring to it in personal communications. He argues that taking the ordering as primitive is more convincing than taking the set of priors as primitive. He does not impose many restrictions on the likelihood relation and preferences over event-contingent prospects (acts), only a kind of stochastic dominance relation. He argues for the desirability of not having many such relations.

There is some rhetorics: P. 1056 penultimate para incorrectly suggests that the model advanced here is "the" formalization of verbal statements by Ellsberg (1961) and Schmeidler (1989), suggesting words from their mouths about incomplete cognitive likelihood ordering that they did not write themselves. A second example is p. 1057 top on models that relax the onesided implication of likelihood compatibility where the author writes that this "severs radically the connection between belief and preference" but has no argument to offer other than restating definitions.

P. 1070 has a mysterious suggestion that belief not just be cognitive likelihood relation but also corresponding behavior. It may reflect other suggestions elsewhere in the paper, also hard to understand for me, that the cognitive relation be only part of the belief and that there be more to belief.

End of paper considers utility-sophistication (preferences depend only on utilities of outcomes through some functional) and in terms of this derives results that multiple-prior preferences have the exact same set of priors as resulting from the likelihood ordering, with a central role for the dyadic events where all priors agree. %}

Neilson, William S. (1994) “Second Price Auctions without Expected Utility,” *Journal of Economic Theory* 62, 136–151.

{% If a person does RDU, and turns down a gamble (p, 125; 1–p, –100) at every level of wealth, where w(p) = 1/2, then we get the same phenomena as Rabin (2000, Econometrica) got for the special case of w(1/2) = 1/2 (this is EU). Of course, under common assumptions on w, such gambles have to be more extreme and the

examples are not empirically realistic anymore, so I think that this is no paradox for RDU. %}

{% %}

Neilson, William S. (2002) "Comparative Risk Sensitivity with Reference-Dependent Preferences," *Journal of Risk and Uncertainty* 24, 131–142.

{% This paper considers a structure that is isomorphic to an additively decomposable structure, where the isomorphism (from the additively representable space to our structure) is $(x_0,x_1,\ldots,x_n)$ --> $(x_0,x_1-x_0,\ldots,x_n-x_0)$. It translates axioms that characterize additively decomposable representations through this isomorphism. That is, with $x_{-i}c_i$ denoting x with x_i replaced by c_i, for all i not equal to 0, $x_{-i}c_i > y_{-i}c_i$ if and only if $x_{-i}(c_i+\varepsilon) > y_{-i}(c_i+\varepsilon)$, for all variables in question, which is as usual. For the 0th coordinate, however, we now have $(c_0,x_1,\ldots,x_n) >(c_0,y_1,\ldots,y_n)$ if and only if $(c_0+\varepsilon,x_1+\varepsilon,\ldots,x_n+\varepsilon) >(c_0+\varepsilon,y_1+\varepsilon,\ldots,y_n+\varepsilon)$. The condition just stated is equivalent to the author's self-referent separability. The additive representation maps, through the isomorphism, into $u_0(x_0) + u_1(x_1-x_0) + \ldots + u_n(x_n - x_0)$. It means that the x_js designate final wealth.

The Fehr & Schmidt (1999) model is a special case of this model. I do not agree with the author's suggestion, on top of p. 687 and in the abstract, that he has now axiomatized the Fehr-Schmidt model. One reason is that an axiomatization of a special case of a general model can be way different than the general model (e.g. all quantitative models are special cases of the general quantitative representation that is characterized by transitivity, completeness, and countable-denseness, which does not mean that the latter result can claim all existing axiomatizations).

The model gives a nice point of departure for reference dependence through differences, which can be useful in welfare evaluations and risky choice (prospect theory), etc. A difficulty with prospect theory is that under prospect theory it is natural to compare different options only if they have the same reference level.

The author defines constant absolute risk aversion by relating it to a common increase of reference level x_0 and the other final wealth levels x_j, so that changes w.r.t. x_0 ($x_i - x_0$) are unaffected. This implies separability w.r.t. the 0^{th} coordinate and implies that the model depends only on the deviations w.r.t. x_0, $x_1-x_0,\ldots,x_n-x_0$, and not on x_0 itself. It does not imply exponential utility. %}

Neilson, William S. (2006) "Axiomatic Reference-Dependence in Behavior toward Others and toward Risk," *Economic Theory* 28, 681–692.

{% **biseparable utility violated; source-dependent utility**; **event/outcome driven ambiguity model: outcome driven**:

This is the published version of Neilson (1993). Nothing essential was changed. The paper considers a two-stage setup as in Anscombe-Aumann with known probabilities and vNM EU in the second stage, but unknown (so, then subjective) probabilities and Savage-EU in the first stage. So, uses richness of state space. The utility functions in the two stages can be different, so that RCLA is violated. So, it is the smooth model of KMM, but with the two stages exogenously given, meaning that it is in fact the Kreps & Porteus (1978) model only with the first-stage probabilities subjective instead of objective.

The first-stage (first here refers to left stage, the one resolved first temporarily) utility is more concave than the second-stage (interpreted as ambiguity aversion) if and only if weak risk aversion in the first stage holds in terms of second-stage utility units. This condition has a drawback. Using second-stage utility as inputs is not a big problem because these can readily be expressed as second-stage probabilities. However, using the first-stage subjective probabilities needed to define first-stage expectations in weak risk aversion is problematic because these are not given as empirical primitives, unlike in Kreps & Porteus where the first-stage probabilities were objective and not subjective. %}

{% **PT falsified**: a useful paper putting PT to new tests and demonstrating that we need better parametric families.

The defenses of PT demonstrating that it accommodates the Allais paradox,

gambling, insurance, etc., have usually focused on only one of these phenomena. Parametric fittings of PT have not been checked yet for what they say about these known phenomena. This paper is the first, to my knowledge, to see if the parameters found for PT can do more and explain known patterns of choices jointly, and if the parameters found give plausible behavior outside the immediate paradoxes. The current parametric families don't perform well. For example, the T&K families, if explaining the Allais paradox, must be very risk averse, too much to give much gambling for low probabilities. Similar observations apply to coexistence of gambling and insurance. Risk premia are calculated and often are not very plausible. %}

{% This paper axiomatizes discounted expected utility (DEU) in the Keeney & Raiffa (1976) multiattribute utility framework with probability distributions over n-tuples, where n-tuples are streams over time. Thus, all uncertainty is resolved at time 0. The authors use, besides standard axioms giving expected utility (Axiom 3 is von-Neumann-Morgenstern independence), two special axioms. Axiom 6 allows to replace any sure outcome α at time t by an equivalent standard gamble (p:I_+, 1−p: I_-) where I_+ is the best outcome and I_- the worst. It is a weakened version of Keeney-Raiffa utility independence. Axiom 7 is a weakened version of time separability. For it, sets of timepoints are identified with indicator functions assigning the maximal outcome to that set and the minimal outcome to its complement, utility is normalized to be 0 at the worst outcome and 1 at the best, and then the time measure of a set of timepoints is the expected utility of its indicator function. The latter axiom I haven't seen before in the context of multiattribute utility, and it may be quite new. It amounts to additivity of the time measure over disjoint sets of timepoints. %}

{% %}

Neyman, Jerzy, & Egon S. Pearson (1928) "On the Use and Interpretation of Certain Test Criteria for Purposes of Statistical Inference: Part II," *Biometrika* 20A, 263–294.

{% **foundations of statistics**; This paper introduces their classical Neyman-Pearson model. In earlier paper they had introduced "principle of likelihood" which for simple hypotheses amounts to likelihood ratio and Bayesianism. (For composite hypotheses it does some, more or less ad hoc, upper bound taking of likelihoods before taking quotient.) Three things make NP take power and size, rather than likelihood ratio, as the basis of statistics. (1) Their desire for not using prior probabilities. (2) The frequentist interpretation that can be given to size and power. (3) The nice extension to composite hypotheses of size and power through uniformly most powerful tests in some important cases.

P. 293 and several other places refer to earlier Biometrika paper for

introduction of “principle of likelihood” (see at that reference).

This paper may have been the first that relates it to the size and, thus, makes all of humanity go wrong for a whole century, in my (Bayesian) opinion. They explicitly motivate their approach by the desire of not using prior probability.

Introductory, p. 291, chooses words to go towards where they want to go:

“Without hoping to know whether each separate hypothesis is true of false, we may search for rules to govern our behaviour with regard to them, in following which we insure that, in the long run of experience, we shall not be too often wrong. Here, for example, would be such a “rule of behavior”: to decide whether a hypothesis, H, of a given type be rejected or not, calculate a specified character, x, of the observed facts; if $x > x_0$ reject H, if $x \le x_0$ accept H. Such a rule tells us nothing as to whether in a particular case H is true when $x \le x_0$ or false when $x > x_0$. But it may often be proven that if we behave according to such a rule, then in the long run we shall reject H when it is true not more, say, than once in a hundred times, and in addition we may have evidence that we shall reject H sufficiently often when it is false.”

End of introductory, p. 293, on the principle of likelihood:

“It was clear, however, in using it that we were still handling a tool not fully understood, and it is the purpose of the present investigation to widen, and we believe simplify, certain of the conceptions previously introduced.”

P. 295, around Eq. 11: “Principle of likelihood.”

For simple hypotheses that means going by the likelihood ration which is Bayesian. For composite hypotheses, you take quotient of upper bound likelihood over H_0 and upper bound likelihood over H_1.

P. 296, again talking towards where they want to go:

“From the point of view of mathematical theory all that we can do is to show how the risk of the errors may be controlled and minimised.

The principle upon which the choice of the critical region is determined so that the two sources of errors may be controlled is of first importance.”

P. 296 explains, on the two errors in statistics: “in determining just how the balance should be struck, must be left to the investigator.”

P. 297, 1st paragraph (last 1.5 page of §II), then says that the probability of incorrectly rejecting H_0 can be controlled to be what they denote by ε (that’s the level of significance), and rest of paper then takes that as criterion. So, here is the dramatic moment when the 20th century statistics went the wrong way. P. 298, Eq. (15), displays the significance level criterion formally.

The same page says “as far as our judgment on the truth or falsehood of H_0 is concerned, if an error cannot be avoided it does not matter on which sample we make it." I disagree. First, the more extreme the sample, the more one will believe the incorrect hypothesis. Further, if there are several alternative hypotheses, I can imagine that the error of kind I (false rejection of H_0) is more serious as the sample suggests more that an alternative far remote from H_0 is true. I do not understand the footnote added by NP there. NP continue with "It is the frequency that matters" which is of course where they are heading for, so which may explain their assumption. They argue for the same point more explicitly in their 1933 paper in Proceedings of the Cambridge Philosophical Society 29, p. 497, where they write that errors of type I (incorrect rejection of H_0) are essentially different than of type II. They write that all incorrect rejections of H_0 are equivalent, no matter what the sample, but not so all incorrect acceptances of H_0 (then it will depend on alternative hypothesis that is true they say). They probably write this to justify their consideration of frequency of incorrect rejections of H_0. It seems quite implausible to me. The more extreme the sample is, the more one, incorrectly, believes in the alternative and, if there are more alternatives, the more remote is the alternative hypothesis now incorrectly assumed instead of H_0 so, the worse it seems to me.

P. 300, Eq. 24 derives lemma of Neyman-Pearson as it is called nowadays (1980-2023), that, for simple hypotheses, to have most powerful test at given significance level, one should maximize likelihood ratio. Then later it is extended to composite hypotheses. P. 301 points out, in the context of simple hypotheses, that also Bayesian approach would go by likelihood ratio: "In this case even if we had precise information as to the a priori probabilities of the alternatives H_1, H_2, ... we could not obtain an improved test."

P. 308 second paragraph discusses prior probabilities. "But in general, we are doubtful of the value of attempts to combine measures of the probability of an event if a hypothesis be true, with measures of the a priori probability of that hypothesis. The difficulty seems to vanish in this as in the other cases, if we regard the λ [λ is likelihood ratio criterion] surfaces as providing (1) a control by the choice of ε of the first source of error (the rejection of H_0 when true); and (2) a good compromise in the control of the second source of error (the acceptance of H_0 when some H_1 is true). The vague a priori grounds on which we are intuitively more confident in some alternatives than in others must be taken into account in the final judgment, but cannot be introduced into the test to give a single probability measure."

P. 313, on prior probabilities over composite hypothesis to take some average of size etc.: "We have, in fact, no hesitation in preferring to retain the simple conception of control of the first source of error (rejection of H_0 when it is true) by the choice of ε, which follows from the use of similar regions. This course seems necessary as a matter of practical policy, apart from any theoretical objections to the introduction of measure of a priori probability."

Rest of paper elaborates on many cases and examples.

Summary repeats criterion of first fixing level of significance and then optimizing power, calling it "A new basis has been introduced" %}

Neyman, Jerzy & Egon S. Pearson (1933) "On the Problem of the Most Efficient Tests of Statistical Hypotheses," *Philosophical Transactions of the Royal Society of London A* 231, 289–337.

{% **foundations of statistics**; This paper comes after the 1933 one in "Philosophical"

P. 493 is explicit on their desire not to use prior probability and also on them being seduced by the unfortunate coincidence of size having a long-run meaning: "Yet if it is important to take into account probabilities a priori in drawing a final inference from the observations, the practical statistician is nevertheless forced to recognize that the values of φ_i [the prior probabilities of the hypotheses] can only rarely be expressed in precise numerical form. It is therefore inevitable from the practical point of view that he should consider in what sense, if any, tests can be employed which are independent of probabilities a priori. Further, the statistical aspect of the problem will appeal to him. If he makes repeated use of the same statistical tools when faced with a similar set of admissible hypothees, in what sense can he be sure of certain long run properties?"

P. 502/503 points out that sometimes numerical measures can be assigned to the consequences of both types of error and then expectation of those measures should be taken.

P. 507, Definition D, in definition of most powerful test given significance level, uses explicitly the words "independent of the probabilities a priori." %}

{% **dynamic consistency**; **value of information**

What the author calls compound lottery concerns uncertainty to be resolved about future events. What she calls information structure refers to past (unknown) events. The information is carefully arranged to be noninstrumental. This means that by any rational theory it should be worthless. Subjects prefer to receive info

about past events early on, but prefer not to receive such info early on for future events. Because by rational theories, the info is worthless, minor psychological effects to select from indifference could drive the results. However, subjects are willing to pay for their preference. {% P. 205 nicely points out that analyses by DeGroot (1970) and Ledyard (1971) seek to characterize (finite, real-valued) expected utility maximization while the utility function is unbounded, but use that utility function itself to define the domain of prospects with finite expected utility, which does not count as a preference axiom. The latter should only use preferences as the empirical primitive. Wakker (1993 MOR) solved this problem with his truncation-continuity. %}

{% Explains immediacy effect and decreasing impatience by a model with constant discounting but time-dependent utility (as the author puts it: No constant marginal utility over time), including time-dependent background consumption. Reminds me of the hidden stakes for decision under uncertainty by Kadane & Winkler (1988). Has numerical illustration with power utility.
DC = stationarity: P. 2082 comes close but ascribes it to others: "… various experiments reject exponential discounting on the basis of dynamic choice data finding violations

of *dynamic consistency*.” [Italics from original] He then argues that it may instead be due to an optimistic bias in the expectation of future marginal utility, but I am not sure I understand. %}

Noor, Jawwad (2009) “Hyperbolic Discounting and the Standard Model: Eliciting Discount Functions,” *Journal of Economic Theory* 144, 2077–2083.

{% In his JET 2009 paper he took a discounting model with time-dependent utility. Here he takes outcome-dependent discounting. This is, of course, very unidentifiable, where we can always redefine a new outcome-dependent discount function as simply the product of utility and discounting, with then utility constant 1. He then observes that timed outcomes (only at one timepoint a nonzero outcome) do not identify discounting. Even if discounting is outcome independent then such a multiplicative representation indeed gives the utility and discount functions up to a joint power only, leaving power unidentifiable. Standard measurement theorems show that with more than one nonzero outcome, the power and the whole model become identifiable. The author shows how we can derive functional equations from preference, basically by translating into present value. He uses a variation of the Thomsen axiom to get discounting outcome-independent. %}

{% **foundations of statistics**: This paper argues for pregesistration of statistical analyses, and of all of them it seems. The authors nicely write nine challenges for preregistration, the main point being that, especially in exploratory research, often unforeseeable things happen at unforeseeable times during the study. They suggest solutions but those I usually found weak. A challenge not mentioned for preregistration combined with pre-journal-commitment is that for many studies they are only of high interest under particular results, and not under all. If a paper finds that a medicine against a disease (e.g., corona) works then that paper deserves wide attenion. However, if it finds that the medicine does not work, then the value of that finding is not zero but positive, but it is only slightly positive and needs to be known only to a few specialists.

For most studies, preregistration cannot be. Without it, it is unverifiable to what extent a researcher used prior or post prediction. This may explain why, for virtually all researchers who did not preregister, they do not even try to explain what was pre- or post-prediction. This is a problem for p-values, but not for Bayesian statistics reporting Bayes factors. I, as a Bayesian, think that the blame for these problems goes to the unsound concepts of classical statistics.

The term "revolution" is heavy and people should not just use it. I feel that here in this title it is overblown. %}

{% Information Technology (IT) project escalation can result from the deaf effect: If the agent fails to heed risk warnings communicated by others. This paper investigates how the MRR (messenger (= auditor)-receiver-relation) impacts the deaf effect. If the messenger is collaborative then the deaf effect is smaller than if she is an opponent. They test such things in experiments. I wonder if this could be corrected for trust and selective-reporting-by-the-messenger. For prospect theory, their hypothesis H3a matters. It predicts that the influence of MRR on the deaf effect is weaker for losses than for gains. The idea is that losses give more risk seeking and, hence, more willingness to pursue. I wonder how it is in not considering risk seeking/aversion, but the CHANGE of risk seeking/aversion. Even one level more, the deaf effect itself already is not about the absolute level of risk seeking, but about a CHANGE in risk seeking.

P. 5 1st para: In escalation situations, people rather add resources to a project after losses so as to recover. Let me add that this is a 2nd order effect because 1st order is that things with losses are bad and, hence, are avoided henceforth.

P. 7 1st column last para: "Student subjects were deemed to be appropriate for this exeriment because framing is a cognitive bias that should not be a function of work experience." %}

{% **probability elicitation**: applied to experimental economics; **proper scoring rules-correction**: Elicit subjective probabilities of beliefs about opponents' strategy choices in a 2 by 2 game. They also estimate such probabilities based on (recency-overweighted) observed choice frequencies of opponent's choices (fictitious-play beliefs). The subjective probability expressed by a player better predicts his strategy choice than the other probability. Although the authors emphasize this finding much, it is in fact trivial! (The authors mention it on p. 992, beginning of §3.1.6, but I disagree with their defenses.)

The subjective probabilities, depicted for instance in Figure 2 on p. 980, are too extreme and variable (and remain so, see top of p. 981), and often are 0 or 1. This suggests that subjects took these as proxies/justifications of what their own strategy choices would be (as per the referee's/editor's suggestion in footnote 20 on p. 986), and did not understand the **proper scoring rules**.

The subjective probability judgments predict the opponent's strategy choices worse than the observed-frequency estimations (§3.1.3 at pp. 985 ff) according to Brier scores. The linear distance, advanced by the authors in defense of subjective probabilities at the end of §3.1.3, is not proper and should not be considered. For instance, it favors always estimating a probability as 1 as soon as the true probability exceeds 0.5 and, thus, favors extreme judgments rather than true judgments.

Abstract 1st sentence claims novelty on something done before (elicitng beliefs from choices, well, in context of learning). Abstract $\ell\ell$. -5/-4 repeats it. The uninformative 3rd sentence of the abstract is characteristic of the self-enthusiasms of this paper: "What we find is interesting." (This sentence is repeated at the end of the first para of the conclusion, p. 1003.) P. 972 ℓ. -15: "Our original research plan …"

P. 976 writes that the quadratic soring rules formulas were given to subjects just like that. %}

{% **dynamic consistency**; Paper deals with **sophisticated choice** and naive choice, so it does not consider resolute choice and assumes that dynamic consistency in the strong sense is violated. It assumes constant zero discounting with one exception: The presence, the current period, receives higher weight (present-biased preference). It assumes that one action has to be chosen only one time (e.g. write a report), yielding a cost at some later time and a reward at some, possibly different, later time. §IV considers what the authors call welfare considerations, meaning the undiscounted total utility. This terminology suggests that the authors view zero discounting as normative, an assumption to which I am sympathetic.

For costs, sophistication counters the overweighting of the presence which is always good from the zero-**discounting normative** perspective (Proposition 3). For current reward, sophistication can do anything, also exacerbate the present-bias (Example 2). For example, the sophisticated person foresees that he will exhibit presence-bias in the future and therefore consume "too" soon, which decrease in future utility is just enough to make him completely give in to current presence-bias and consume immediately. He thereby lowers the normative undiscounted total utility.

P. 103 defines time consistency in the usual ambiguous way. (**time consistency stated ambiguously** %}

{% The authors study complexity aversion for risky choice, where they take number of outcomes in a lottery as complexity. This interpretation was criticized by Wakker (2023 JBEE), who argued that attribute splitting plays a big role here and not just complexity perception. The authors consider simple, two-outcome lotteries, and for each a corresponding seven-outcome lottery, corresponding in the sense of having same expectation, variance, and skewness. In Experiment 1, subjects have to estimate the mean (getting awarded for being close) for each, and express Willingness to pay (WTP), incentivized by Becker-DeGroot-Marschak (BDM). In Experiment 2, subjects have to do the same, but also do choice - making, each time between a simple and corresponding "complex" seven-outcome lottery.

In Experiment 1, the authors do not find complexity aversion. In Experiment 2, they do, and more for binary choice than for WTP evaluation.

My main criticism of the experiments is that the outcomes of lotteries were not listed naturally from high to low or low to high, but were listed in randomized order. For simple lotteries this does not matter much, but for complex it brings inconvenient extra complexity, and I think annoyance because of perception of either bad organization or deliberately making life unnecessarily difficult. A further drawback in the WTP measurements, surely in Exeriment 1 but maybe not done in Experiment 2, is that subjects were also asked to estimate mean, which is just more unpleasant for the complex lottery and, thus, negatively affects the WTP assessment. Thus, I think that the authors did not find complexity aversion in the sense of many outcomes, but in the sense of poor unnecessary complex presentation. Experiment 1 found no complexity aversion despite the handicapped presentation for complex gambles, which may be taken to suggest complexity seeking.

I disagree with some citations of the literature. On p. 2 ℓ. 5, Oberholzer et al. cite Sonsino et al. (2002) as supportive of *their* complexity aversion. However, Sonsino et al. (2002) was mostly about other concepts. Only their first experiment

speaks to number of outcomes (via event splitting), and they have only one, one!, data point on it, a switching that is only marginally significant. This is why Wakker's (2023) survey did not include this paper. Further, Mador et al. (2000), also cited by Oberholzer et al. there, considered other versions of complexity, as pointed out by Wakker (2003). Wakker's (2003) survey cites many other papers, mostly finding the opposite, complexity seeking, but those papers are not cited by Oberholzer et al. In particular the most advanced work on this topic, by Birnbaum, is not cited.

A further criticism is that subjects were paid in numbers whose unit was revealed only after the choices made. %}

{% %}

Oechssler, Jörg & Alex Roomets (2014) "Unintended Hedging in Ambiguity Experiments," *Economics Letters* 122, 243–246.

{% In a careful experiment, ambiguity is generated by balls falling through an irregular Galton box, just created by volunteer students hammering nails in it not knowing for what purpose. This box was used to determine the composition of Ellsberg urns. It is called mechanical ambiguity because it results from a process with no deliberate human beings involved (probably meant: No human beings who can rig the urn), and the experimenters not able to know. They compare with ambiguity that is generated by a human being which they call strategic (probably having in mind that this can involve rigging the urn and, hence, they do not control for suspicion and do not allow subjects to choose the color to bet on; **suspicion under ambiguity**), finding a null hypothesis of no difference (the choice percentages of 37.7% and 45.5% are not significantly different in a between-subject treatment of 53 subjects versus 121 subjects, suffering from the small power of between-subjects designs).

Each subject did only one choice, so as to have no income effects and no need for RIS (which is especially problematic for ambiguity because the risk involved in RIS interferes with ambiguity). The authors also correct for indifference, by letting the ambiguous option being slightly better (to be sure that unambiguous option chosen is really ambiguity aversion) and in another choice situation letting it be slightly worse (to be sure that ambiguous option chosen is really ambiguity seeking). They find some 40% ambiguity aversion but 25% ambiguity seeking (**ambiguity seeking**). The authors review many studies, showing that their finding is consistent with other findings. They find a null hypothesis of mechanical ambiguity being similar to strategic (human-generated) ambiguity. %}

{% **criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**: They provide so. There are a two-color ellsberg urn (B or Y), and a fair coin (H or T). It is made clear to subjects that first the color is determined and only then the coin is tossed, so that the order of events is properly as in the Anscombe-Aumann (AA) framework. Subjects can choose between two-stage options, where γ denotes a “good” positive prize that can depend on the act, not expressed in my notation. Subjects can either gamble on the color (BH: γ, BT: γ, YH:0 , YT:0), or on the coin, (BH: γ, BT:0, YH: γ , YT:0), or hedge (BH: γ, BT:0, YH: 0, YT: γ). The authors use better displays to make clear the ordering of events. According to AA we should have indifference between gambling on the coin or hedging, and under ambiguity aversion we should prefer gambling on the color strictly less. In reality, subjects had a clear preference for the coin gamble against hedging for instance. The authors had γ depend on the gamble in a way to confirm those strict preferences and rule out indifference. They argue that the preferences found are too strong to be due to random choice. %}

{% **utility elicitation**

p. 270: PE ("N-M") method does worst (**PE doesn't do well**); CE ("modified N-M") and Ramsey method (lottery equivalent with .5 probabilities, similar to Davidson, Siegel, & Suppes, 1957) give similar results;

P. 272: Ramsey method was superior in utility analysis;

utility of gambling: p. 259 argues that comparing risky to riskles gambles induces biases (due to utility or disutility of gambling)

P. 260 argues for CE (certainty equivalent) method and against PE method because subjects may not fully understand concept of probability (**PE doesn't do well**)

P. 263: "By keeping the number of participants small and by casting the study in a realistic and important decision context, we found it possible to evaluate the hypotheses of the study in greater depth."

P. 264, footnote 3: "Any obviously inconsistent answers were returned to the subject and ... were usually corrected"

P. 268, Table 2, gives five utility functions measured through PE (probability equivalents), CE, and SP (strength of preference), on interval [0, 3500]. These numbers are costs, not gains. The authors don't analyze it much. When I did, I found:

PE higher than others

1st subject: U_{PE}: inconsistent (decreasing after 2000). U_{CE}: convex; U_{SP}: concave

2nd subject: U_{PE}: linear. U_{CE}: linear; U_{SP}: concave

3rd subject: U_{PE}: convex. U_{CE}: concave;

U_{SP}: convex on [0,1800] and concave

on[1800,3500] (I drew the graph)

4th d subject: U_{PE}: concave. U_{CE}: convex; U_{SP}: concave

5th subject: U_{PE}: concave-convex. U_{CE}: convex; U_{SP}: convex; after normalization, U_{PE} dominates U_{CE} almost everywhere (on [0, 3100], except near 3500. %}

{% **time preference**; Pp. 216-217 gives an example where, even if a priori choice between some alternative consumption paths are not determined if intransitivity, the choices are determined if it can be done using backward induction where at each timepoint there are only two choice options. However, the authors suggest

that this may mean that intransitivity in general is no problem in case of backward induction.

They axiomatize (x,t) > (y,s) iff U(x) > eta(s,t)U(y). This allows intransitivities. They do this by imposing the Reidemeister condition on the 2nd coordinate while giving up transitivity. Their domain is in Re x Re, so, it is real-valued. They interpret the first coordinate as money and the second as time. Such intransitive additive representability reminds me of Vind's work. %}

Ok, Efe A. & Yusufcan Masatlioglu (2007) "A Theory of (Relative) Discounting," *Journal of Economic Theory* 137, 214–245.

{% **revealed preference**: A choice function is given on a general set of choice alternatives. The authors formulate revealed preference conditions (mostly acyclity conditions) that hold if and only if there exist a reference dependent model as follows: For each choice set, either one of the choice alternatives serves as reference point, or not. If not, then a utility function is maximized. If yes, then the utility function is only maximized over the choice alternatives that dominate the reference point for every attribute. Here both the reference point and the attributes (can also take as utility functions) are derived endogenously. The paper is targeted to/motivated by the attraction effect, where adding a dominated choice alternative makes the dominating choice alternative more attractive (the other one is ruled out here by taking the added alternative as reference point), and it reviews the literature on it.

The paper confines attention to two-point interactions, where the value of an alternative x chosen is increased by the presence in the choice-menu of one other alternative z (z is a potential reference for x), and not by bigger sets of other alternatives through multiple interaction.

The possibility to define attributes endogenously joint with the lexicographic processing gives much flexibility. If we want to rule out one alternative everywhere then we introduce an extra attribute where this alternative has value 0, all others in the set have value 1, and some proper reference point is chosen if needed. Contrary to what p. 301 ℓ. −1 writes, this is not parsimonious but increases fit rather than parsimonity. It reminds me of Suck (1990) who also derived attributes endogenously, and Epstein, Marinacci, & Seo (2007), who derive a state space endogenously (**state space derived endogeously**). %}

Ok, Efe A., Pietro Ortoleva, & Gil Riella (2015) "Revealed (P)Reference Theory," *American Economic Review* 105, 299–231. https://doi.org/10.1257/aer.20111046

{% A nice unification of two forms of incompleteness: Bewley (1986, 2002) kind with set of probability measures and preference only if unanymous EU, and Dubra-Maccheroni-Ok kind with set of utility functions and preference only if unanymous EU. The idea is that at the beginning, with your first preference, you are just free to choose indecisiveness one way or the other and they are on the same footing. However, once chosen indecisiveness one way you can no more have any in the other direction because the mix of the two will violate the independence-like axiom imposed. Do it in an Anscombe-Aumann setup.

P. 1794 concisely presents Bewley's theorem, with indecisiveness in beliefs.

P. 1795 has the Dubra, Maccheroni, & Ok (2004) dual, of indecisiveness in tastes (Theorem 1). The main axiom is reduction: it is a kind of local probabilistic sophistication, where the subjective probability can depend on the act.

P. 1796 Theorem 2 is the main result, with weak reduction as the main axiom. Now there need not exists act-dependent probabilistic sophistication yielding indifference, but only weak preference. %}

Ok, Efe A., Pietro Ortoleva, & Gil Riella (2012) "Incomplete Preferences under Uncertainty: Indecisiveness in Beliefs versus Tastes," *Econometrica* 80, 1791–1808.

{% This theoretical paper considers three reasons for probabilistic choice: Indifference, indecisiveness, and trying out for learning. As they write, these reasons are neither mutually exclusive nor exhaustive. For each of the three, it can be considered fully rational (although indecisiveness is debatable). They give theoretical tools for detecting the reasons and an underlying rational preference relation. %}

{% **coherentism**: Nice text on p. 421, intended only for descriptive applications:

"Though Savage insisted on the behaviouristic interpretation, from a modern vantage point this looks untenable. Almost all sciences introduce theoretical posits that go beyond, and are meant to explain, the data; few philosophers today are tempted by an instrumentalist or fictionalist attitude towards such posits. This is as true in psychology as anywhere else; since the 'first cognitive revolution', psychologists have been happy to posit unobservable mental states and processes, many of them inaccessible to consciousness, that are meant to explain behaviour. And in philosophy of mind, it is a commonplace to regard an agent's intentional attitudes, such as beliefs and desires, as internal causes of the agent's behaviour."

ubiquity fallacy: In the opening the paper, nicely, points out that many philosophers equate all of decision theory with EU: "Indeed many philosophers appear to use 'decision theory' simply to mean EU theory." (p. 410 $\ell\ell$. 2-3)

The author favors the mentalist approach, as I do, for descriptive applications. For me it is the same normatively, but for the author it is not and for normative he favors the behaviourist/representational view. This is because he, while he like me assumes that EU axioms are necessary for rationality, he, unlike me, also assumes that they are sufficient (**coherentism**). Pfff! After working 8 years in a hospital I have come to understand that there is more to rationality than the EU axioms. Anyway, this makes the author strongly criticize any author who does not leave the choice of utility completely free. P.425 2nd para: "But it is quite wrong to view the normative content of the theory as saying that an agent should maximize expected

utility relative to a psychologically real utility and credence function." P. 429 ℓℓ. 1-3: "It is evident that Briggs construes decision theory as telling the agent to maximize expected utility with respect to some independently defined utility function; which as I have argued is a misconception."

p. 421 penultimate para: "psychologist have been happy to posit unobservable mental states and processes, many of them inaccessible to consciousness, that are meant to explain behaviour."

P. 422 1st para about as if calculations:

"but this is quite standard in cognitive psychology." %}

{% **DC = stationarity**: Does not happen here, and the authors state the point carefully: "Present bias may lead to violations of dynamic consistency when choices at later points in time are also part of the analysis;" (p. 1450-1451).

tradeoff method: p. 1459 Axiom 11 is the tradeoff consistency axiom, which I introduced in Wakker (1984) and used in 2/3 of my papers, e.g. Köbberling & Wakker (2003), where my later papers also used that name tradeoff consistency. But, ☹, they do not cite me there. Fortunately, they do cite more of my papers (☺) than the average researcher does today, so I am still in a good mood.

The technique of measuring discounting without measuring utility by subjectively matching time intervals, used in this paper to identify β and δ, was introduced by Attema, Bleichrodt, & Wakker (2012 MDM) for the general measurement of discounting (from a different field; not cited) and was also used by Attema, Bleichrodt, Gao, Huang, & Wakker (2016 American Economic Review p. 1490).

P. 1462 footnote 9 cites Ramsey on pointing out a relation between time and belief. Ramsey apparently wrote: "the degree of belief is like a time interval; it has no precise meaning unless we specify how it is to be measured." But I conjecture that Ramsey did not think of subjective discounting here, but only of time as objective unit, and the analogy only concerned measurement of equal sets in general. Attema, Bleichrodt, & Wakker (2012 MDM p. 585) did point out the analogy between measuring subjective discounting without involving utility through matching time intervals and measuring subjective probabilities, a point reiterared by Attema, Bleichrodt, Gao, Huang, & Wakker (2016 American Economic Review p. 1490). %}

{% Assume a fixed prize, and t the time at which you receive it. This paper considers the case where, with the prize fixed, t is uncertain. Under the classical discounted EU, the commonly found convex discounting function would imply risk seeking w.r.t. t. Empirically, however, we find risk aversion. (The authors show it systematically, citing Chesson & Viscusi 2003 as the first finding of this kind.) As the authors point out, their finding gives nice evidence for risk aversion not being outcome driven but probability driven. An original idea! The finding supports rank-dependent utility. An alternative explanation is that the discounting function would be concave, with increasing rather than the commonly assumed decreasing impatience, but the authors do not favor this explanation. The authors cite Kacelnik & Bateson (1996) who find risk seeking instead for animal foraging behavior. Redelmeier & Heller (1993 MDM) also find risk aversion in an experiment very similar to the one here, but with aversive health outcomes instead of money. Then convex discounting is multiplied by a negative outcome meaning that the resulting function is concave, and common positive discounting gives risk aversion. Hence, what Redelmeier & Heller find is in agreement with common findings and not the paradox that this paper provides. %}

Prospect theory/Rank-Dependent Utility most popular for risk: beginning of §1.2 writes it.

GENERAL JUDGMENT

This paper has a very nice "mirror" treatment for lottery choices. It shows more clearly than before that risk attitudes are to a large extent driven by general principles of perception also found in other domains rather than by things typical of risk. Unfortunately, the author uses many terms differently than the literature does. In particular, he uses separative interpretations rather than Kahneman & Tversky's and also my integrative interpretations (explained below). In the integrative interpretation, his findings do not criticize risk attitude and probability

weighting, but give new insights into them, be it that those isights deviate less from what was known before than the author suggests. His deviating terms include preference, risk attitude, probability weighting, and loss aversion. The author gets carried away too much with claims such as "probability weighting is a misnamed phenomenon" (p. 29). The author's alternative explanation of complexity attitude, fashionable nowadays (2023), is noninformative for being too broad/unspecific, but on the other hand too narrow because factors other than complexity perception play a role.

SUMMARY

This paper lets subjects consider options concerning 100 boxes, such as

25 Boxes	75 Boxes
\$25	\$0

For the nonmixed cases, the outcomes are \$25 and \$0 or –\$25 and \$0. The number of nonzero-outcome boxes is 10, 25, 75, or 90 for nonmixed lotteries. One treatment concerns probabilistic mixing: one of the 100 boxes of an option is selected randomly, and its content is given to the subject. These options are called lotteries. The other treatment concerns physical mixing: the content of the 100 boxes is summed, divided by 100, and that amount is paid. In other words, under physical mixing subjects receive the average of the boxes for sure. These options are called deterministic mirrors of lotteries, mirrors for short. In the latter treatment, subjects have calculators available to facilitate calculating. The two treatments were within-subject with order randomized.

For the nonmixed cases, the paper elicits indifferences such as

25 Boxes	75 Boxes		100 Boxes
\$25	\$0	~	\$X

Under probabilistic mixing, this gives certainty equivalents. The results of physical mixing are called simplicity equivalents.

For the mixed case, the paper elicits equivalences such as

50 Boxes	50 Boxes		100 Boxes
–\$10	\$X	~	\$0

taking 10/X as loss aversion (recommended and justified by Wakker 2010 Example 9.4.2). And, similarly with –\$15 instead of –\$10.

Further, all indifferences are elicited using either choice lists (n = 184) or the

Becker-Degroot-Marschak (BDM) mechanism (n = 100). (For the mixed case, BDM is done a bit differently than described above.) This is between-subjects. For implementing losses, the author did the usual **losses from prior endowment mechanism**. There were N = 487 online subjects. They received $6 showup fee and for 1/5 of them the RIS was used. The experiment took some 26 minutes for subjects and they gained about $6.60 in total for choice lists, $7.50 for BDM. Means very little performance-contingent! The experiment being online adds to low motivation.

In the physical treatment, if we can ignore calculation costs, then everyone should calculate average and go purely by that. This did not happen at all. In both treatments, the usual four-fold evaluation pattern of prospect theory (PT) was found, to a similar extent, for group averages and medians. Subjects were more risk seeking for mirrors than for lotteries, something not discussed in the paper. Between-subject within-treatment heterogeneity was big, but between-treatment within-subject heterogeneity was small, the latter appearing from strong correlations between probabilistic and physical mixing (0.7). The differences between choice lists and BDM exceeded those between physical and probabilistic mixing.

AUTHOR'S INTERPRETATION:

The findings of PT do not reflect risk attitude (such as probability weighting), but a different thing: complexity attitude.

MY DEVIATING INTERPRETATION:

To prepare, I first note that risk attitude consists of (1) general perception phenomena plus (2) typical-of-risk-phenomena. Physical-mixing-attitude also consists of (1) general perception phenomena, plus (3) things typical of physical mixing. The latter, (3), can consist of dislike of the artificiality of not putting all money in one box for no reason that one can think of. The common (1) is large. But there are differences in the data still, with more pesssimism for gains under risk than for mirrors and large confidence intervals that do not reject considerable differences still. So, no good statistical support for the claimed identical results. (A small aside: further, the effects by (3) can happen to be similar to those by (2).)

My *main difference in interpretation with the author*: whenever things concern general perception in (1) above, the author writes that it is NOT risk attitude. I call this the separative view. I disagree: it is PART OF risk attitude still. I call this the integrative view. For example, that humans share 97% of their genes with (“other”) ape species, does not imply that our behavior would not be human.

Kahneman and Tversky, more than anyone else, brought the insight to the field that much of risk attitude concerns (1), i.e., general perception. The author cites them for it in Footnote 12 on p. 24 and p. 27, but other than that writes by the separative view. Typical is the author’s writing on p. 27: “Prospect-theoretic behavior can be interpreted, in large part, as an outgrowth of just this sort of insensitivity, an observation that goes back at least to Tversky & Kahneman (1992). *However*, as results like ours suggest, this kind of insensitivity is not special to risky choice but applies to complex problems more generally (e.g., in deterministic mirrors).” [italics added] He first acknowledges Tversky & Kahneman but then, by the word “however,” suggests that he deviates, which he does not at all.

My second difference in interpretation with the author: now (2023) it is fashionable in the literature to use the term complexity for many things. However, complexity plays a role in everything we do, but in million different ways, and it is commonly used in a completely vague unspecified manner, giving no predictive power. Hence, I find his interpretation by complexity attitude and his term “simplicity equivalent” not informative.

For the stakes in this experiment, the performance-contingent payments being lower than common in experiments, and Prolific adding noise, the effects of (2) and (3) above are similar. But for very large stakes, say 1000 fold, as in finance and health decisions, I predict that (3) almost entirely disappears and subjects will get very close to average maximization, but a considerable part of (2) (probability weighing and for large stakes also concave utility) will remain because it involves cognitive inability of people not understanding probability. Online Appendix A2 has a student group with probability of choice-contingent behavior being implemented being equal 1 rather than 1/5, but this is not enough of an increase in incentives. The author there claims similar findings but the lower half of Figure 6 displays big differences. He does acknowledge that loss aversion for mirrors was only half of that for lotteries.

FURTHER DETAILED COMMENTS FOR VERSION OF 4 June 2023

That the BDM is problematic has often been observed, so not very surprising that it deviates much. In general, that framing effects, preference reversals, violations of transitivity, and noise and factors unknown to us are strong, and stronger than the systematic deviations from EU, has been known long time. I agree with the author in calling the PT effects second-order. However, no other theory has as yet (2023) done better.

Fields similar to risk, such as intertemporal choice and welfare, are known to exhibit many phenomena similar to risk, sharing (1) above, general perceptual phenomena.

The last sentence of the abstract: "These findings suggest that much of the behavior described by prospect theory may be driven by the complexity of evaluating lotteries *rather than* by risk or risk preferences." [Italics added] It is again the separative view that I disagree with.

Intro: the author writes that the only difference between lotteries and their deterministic mirrors are that the former have stochasticity, i.e., (2) above. However, (3) above can also play a role: the deterministic mirrors can cause annoyance for the artificial inefficient disaggregated info for no good reason that one can think of.

P. 12: Whereas economists usually use the term preference to encompass everything, tastes, beliefs, discounting, and so on, the author apparently often uses the term preference for only taste and disjoint from, for instance, beliefs, a terminology common in finance for instance, unlike in economics. This leads to confusions and incorrect interpretations of other authors who used the terms differently. For instance, p. 12 writes: "Probability weighting, for instance, is classically interpreted as a description of how *taste* for risk changes as probabilities change.[6][Here footnote 6] However some recent treatments (e.g., Wakker 2010) have interpreted probability weighting *instead* as consisting of one component that is due to *preferences* ("optimism/pessimism," the elevation of the probability weighting function) and another that is driven by cognitive misunderstandings or misperceptions of the differences between probabilities ("likelihood insensitivity," the flatness of the probability weighting function)." [italics added] The author incorrectly ascribes the term taste to Kahneman and Tverksy (where footnote 6 cites their text that used the term "preference" in the general economic meaning rather than in the author's "taste" meaning) suggesting that they would preclude cognitive interpretations, which is really the last thing they would do. It then goes on to, incorrectly, suggest that my interpretation would be any different than

K&T's, by using a term preference for what I instead call motivational.

Something similar happens with loss aversion. Kahneman and Tversky, myself, and many others think that two factors contribute to loss aversion: (a) feeling; (b) attention. Regarding (a), losses are more felt than corresponding gains. Regarding (b), more attention is paid to losses than to gains (irrespective of what is felt). The author, however, takes it to comprise only (a), when writing on p. 12: "Loss aversion, likewise, is generally interpreted as a description of subjects' taste for losses relative to gains." Wakker (2010 p. 239 penultimate para) discusses (a) and (b).

Loss aversion in mirrors is 80% of loss aversion in lotteries.

P. 15, Figure 2, gives data on group averages. A difference displayed by the data is that for gains subjects are more optimistic (risk seeking) for mirrors than for lotteries, and for the mixed case also. For losses they may be a bit more pessimistic for mirrors, but now much. The author does not discuss these differences.

Results section: medians are the same for lotteries and mirrors.

P. 18, §3.1 2-to-last para: "our finding that lottery valuations *fail to* reveal risk preferences" [italics added] Again the separative view.

P. 18, §3.1 2-to-last para: Differences between choice lists and BDM are four times larger than between lotteries and mirrors.

P. 21: "Our experiment was designed to identify the relative roles risk and complexity play in generating lottery anomalies, but it was not designed to sharply identify exactly how complexity induces these anomalies." This sentence at the same time suggests an exact treatment of complexity and acknowledges that the paper does not do so. One of my main criticims concerns the latter. Footnote 1 on p.2 opens up with referring to complexity as defined in computer science, suggesting a specified treatment to come, but the paper does not do it.

P. 22, §3.3 provides much evidence such as relatedness with noisy behavor etc, supporting the view that subjects just did not want to do the effort of using proper calculations.

P. 22: "This strongly reinforces our conclusion that prospect-theoretic behavior in lotteries and mirrors derive from the same behavioral mechanism, and suggests that this mechanism has little to do with risk or risk preferences." The author uses the separative terminology.

P. 23, end of §3, cites much literature giving noisy processing models implying the PT patterns. Again, this need not be taken separatively but can be taken integratively.

P. 24, §4 2nd para: "This literature has, to a great extent, interpreted prospect theory as a description of risk preferences, encouraged by the *preference-based* interpretation advanced in the paper that introduced the theory (Kahneman & Tversky 1979). However the literature has long been ambivalent in this interpretation, and boundedly rational interpretations of some or all of prospect theory's components have been openly entertained as an *alternative possibility*." Again, the author takes the separative rather than the integrative perspective, again misunderstanding the term preference of K&T.

P. 25: "driven largely by constraints on information processing rather than preferences." Here, the author again uses the term preference differently than Kahneman & Tversky do.

All the phenomena in §4 (pp. 23-28) do not refute risk attitude, but give background to risk attitude.

P. 25, still §4, cites Benheim & Sprenger (2020) affirmatively on their, in my opinion incorrect, ideas on complexity aversion. Wakker (2023 JBEE §6) criticizes them, citing literature on event splitting. The author's Footnote 13 mentions event splitting but gives no references and does not explain why that would not be counterevidence.

P. 26: "We find similar elicitation effects in both lotteries and mirrors, indicating that elicitation effects themselves are phenomena of complexity, not risk. This result suggests that these effects have little to do with risk or risk preferences, but instead are likely expressions of the poorly adapted procedures subjects use when evaluating complex things." Again, the separative view, with again the unspecified "complex."

P. 27: "meaning loss aversion may be a species of a more general mechanism for processing positive relative to negative information." This is not a deviating insight but it is the very reason why Kahneman introduced loss aversion into prospect theory!

P. 28, end of §4, writes: "These results underscore and expand upon our interpretation of our results by suggesting that the patterns of insensitivity described by prospect theory may be generic to the evaluation of complex things — a mechanism that may unify a great number of anomalies in behavioral economics." This has been well understood by Tversky, Kahneman, and many others.

Pp. 28-30, in the discussion section, the author gets carried away in his separative perspective. He, for instance, goes overboard on p. 29: "This suggests, most importantly, that probability weighting is a *misnamed* phenomenon and is not, as in traditional interpretations, a description of the way tastes and preferences for risk change with probabilities." [Italics added] The italicized word "misnamed" is too much and very incorrect. Agsain, if human beings share 97% of their genes with apes, then "human being" is not a misnamed phenomonon.

cognitive ability related to likelihood insensitivity (= inverse S): that "complexity" contributes to inverse S supports it. %}

Oprea, Ryan (2023, 4 June) "Decisions under Risk are Decisions under Complexity," working paper.

{% Subjects express preferences between lotteries, displayed as 100 boxes containing monetary prizes, with one randomly selected and paid. Subjects also express preferences between "mirrors". Mirrors are displayed using the same 100 boxes as with lotteries, but now subjects get the average amount with certainty. That is, they get the expected value of the corresponding lottery with certainty.

For lottery preferences, probability weighting and loss aversion are found as usual and as predicted by prospect theory of Kahneman and Tversky (KT henceforth). Oprea calls this the common pattern CP, and I here use that term too. Remarkably though, mirror preferences don't go by expected value as they should normatively, but display the CP similarly. Two observations follow: The mirror preferences are clearly irrational, so that probably:

(1) CP in lottery preferences is irrational.

Further:

(2) Many phenomena for risky preferences, such as CP, occur similarly in other contexts, so are not very typical of risky-preferences-only but are based on more general principles of perception.

The two observations are not new but have been observed before, by Kahneman & Tversky (1979), Tversky & Kahneman (1981, 1986, 1992), and also by Wakker (2010) and many others. I repeat, emphasizing: all these works qualify CP as irrational and as much based on general perceptual properties. The contribution of Oprea is to show them with ingenious stimuli, prettier and clearer than ever before. So much that it deserves everybody's attention and a top publication.

Unfortunately, many misunderstanding have arisen. Many (if not all …!?) readers of Oprea's paper erroneously took it as a falsification and invalidation of

CP and prospect theory, rather than the corroboration that it is. Four causes of these misunderstandings follow:

(1) In Oprea's intro and §§I-II, he presents the above two observations without citing KT or any other predecessor, making readers erroneously believe that these are new insights. And, then, that KT must have missed them and hence must be wrong. Oprea's citation of KT on related material, only at the end of his §IV, does not convey their precedence:

> "… complexity: that it causes decision-makers to be insensitive to features of decision problems that matter for optimal choice. The classical pattern can be interpreted, in large part, as an outgrowth of just this sort of insensitivity, an observation that goes back at least to *Tversky and Kahneman (1992)*." [italics added] (p. 3808)

Intros should position the novelty of a paper, not the end of §IV. The text is confusingly surrounded by modern work on complexity as if contributing to only that, and uses vague words "outgrowth … just … at least". No reader will get from this text that the two above observations of the intro, put central throughout Oprea's paper, had long and thoroughly been presented before by KT and many others.

(2) Oprea's intro and §§I-II only emphasize similarities or even quantitative equalities between CP for risky and riskless preferences. They suggest complexity as the only relevant factor, suggesting that it can replace everything known before. Only his §§III-IV deviate and put things right. They acknowledge differences, sometimes even dramatic, between risky and riskless preferences, and that factors other than complexity can play a role. With that understood, the contribution of the paper becomes quite less sensational.

(3) Oprea uses the terms "preference" and "taste" in an unconventional manner. In his Footnote 1 he explains that in his terminology, these terms only refer to the rational ("welfare-relevant") part of preference, and that deviations from rationality are called mistakes and not preferences. This terminology deviates from the common convention in decision theory where preference refers to observed, revealed, choices so that preferences can be irrational. Sometimes Oprea adds "true" or "reliable" to the term preference. Now confusions arise from texts such as:

> "much of the behavior motivating our most important behavioral theories of risk

> derive from complexity-driven mistakes rather than *true risk preferences*." [iutalics added] (p. 3789; abstract):

By Oprea's footnote 1, "true risk preference" should be taken as rational. Then this text is just a restatement of the above first observation, made many times before by KT and many others. It then is strange that such claims are repeated throughout the paper, given that they are not new. If one, however, takes "true risk preference" in its usual meaning, as empirical, revealed, and comprising the usual irrationalities, then the text would amount to a refutation of "our most important behavioral theories", including prospect theory with CP (were it not that it then would be incorrect: that risky preferences share properties with other preferences does not mean they are not risky preferences), and be a sensational novelty rather than something well-known. Virtually all readers of Oprea's paper have, understandably, fallen victim to this misunderstanding, including Simonsohn (14 March 2025).

(4) Following up on (3), readers thinking that CP is falsified, think it must be in for replacement. And then the above cited text, and many such texts repeated throughout the paper, make them erroneously believe that complexity replaces CP. This is not so. CP is not in for replacement. Complexity is an important factor explaining and supporting CP (Armantier & Treich 2016; Spiliopoulos & Hertwig 2023; Zilker, Hertwig, & Pachur 2020), rather than replacing it.

Those were four causes of misunderstandings. Most papers assume that decision costs and bounded rationality are small enough to be ignored. If they are given a nontrivial role, then some of the terms above should be modified. Then "mistakes" in Oprea's paper may not be mistakes. Then the CP can even be rationalized sometimes (Enke & Graeber 2023). These changes do not affect the above analysis. Still (1) CP is not welfare-relevant and (2) risky and riskless preferences are related. Still, KT gave much attention to bounded rationality.

Banki et al. (2025) criticized Oprea's experiment. However, there has already been much evidence supporting the above two observations. I believe they can be done with stimuli as pretty as Oprea's, in experiments with good instructions, good incentives, and the right level of complexity of stimuli. My point is that such findings corroborate, rather than falsify, CP, prospect theory, and KT's

work.

{% **updating under ambiguity**: in the Anscombe-Aumann framework, the author imposes standard Anscombe-Aumann axioms (continuity, weak ordering, independence). He further considers updating and assumes consequentialism, event-collapsing (**coalescing**) (implicitly), and a weakened version of **dynamic consistency**: dynamic coherence. The latter means that if a set of events is informationally equivalent in the sense that given one, the complement of any other is null, then their updated preferences should be identical. He proves that these axioms hold iff: Bayesian updating for all events whose subjective probability exceeds a threshold ε. An observation less likely than ε is not trusted. Then the agent imposes a second-order probability distribution on his priors, updates that, and takes the most likely prior as new prior. How restrictive the last part, of maximizing likelihood, is, depends on how restricted the choice of prior is. What it is beyond preserving null I did not study.

Remarkable that American Economic Review took this purely axiomatic paper. %}

{% **paternalism/Humean-view-of-preference**: they propose heuristic but clever manner for correcting quantitatively for incoherencies in probability judgments. P. 1 and 2 give many refs to people trying to correct for incoherencies in probability judgments.

They ask subjects for judgments of probabilities of elementary statements and the set E of their logical combinations. These of course contain incoherencies. They then take state space S with 10 equally probable states.

STAGE 1. They stretch all probabilities of elementary statements by a random factor towards, randomly chosen, either 0 or 1.

STAGE 2. To each elementary statement they assign a, randomly chosen, subset E of S with ||E||/10 as close as possible to the "stretched" probability of the elementary statement. Thus, a probability distribution over E results.

STAGE 3. They calculate the absolute deviation between the probability over E of stage 2 and the direct judgments of probability

STAGE 4. They do the whole above process 30 times, and of these 30 times choose the one that has the minimal distance in Stage 3.

The probability distributions obtained like this better fit to objective probabilities, known to experimenters but not to subjects, than the direct judgements do. %}

{% N = 1047 subjects from the US and Germany answered hypothetical choice questions. There were affect-poor choices (lotteries over money) and affect-rich choices (lotteries over medical outcomes). Numeracy measures of the subjects were available. High numeracy and US give more EV maximization. (**cognitive ability related to risk/ambiguity aversion**) Remarkably, although the Americans on average had lower numeracy scores, they still did more EV maximization. Study 2 (N = 118 from Germany) shows that with affect-rich outcomes there is more neglect of probability (I guess, then more inverse S). %}

Pachur, Thorsten & Mirta Galesic (2013) "Strategy Selection in Risky Choice: The Impact of Numeracy, Affect, and Cross-Cultural Differences," *Journal of Behavioral Decision Making* 26, 260–271.

{% **PT falsified; probability weighting depends on outcomes**: They investigate this. Several studies have shown that affect-rich outcomes can affect probability weighting, the electric shocks versus moviestar kisses of Rottenstreich & Hsee (2001) being most well known. This paper shows the effect very thoroughly, also within-subject, and is the first to do so. The main finding is that affect-rich outcomes make people less, or even completely, insensitive to probabilities.

Process data with eye tracking support this claim. The authors interpret disregarding probabilities as something fundamentally different than bigger insensitivity (p. 75 last para of 1st column and p. 76 2nd column 2nd para), and follow that same interpretation in other papers. I disagree. It is an extreme case of insensitivity. Thus, what the authors take as evidence against inverse S, in my opinion is strong support. %}

Pachur, Thorsten, Ralph Hertwig, & Roland Wolkewitz (2014) "The Affect Gap in Risky Choice: Affect-Rich Outcomes Attenuate Attention to Probability Information," *Decision* 1, 64–78.

{% **cognitive ability related to risk/ambiguity aversion**: They measure PT and use real incentives. Subjects with high probabilistic insensitivity pay little time looking at probabilities, supporing the cognitive interpretation of inverse S.

P. 148: "Arguably the most influential descriptive model in the expectation tradition is cumulative prospect theory (CPT; Kahneman & Tversky, 1979; Tversky & Kahneman, 1992)."

(**Prospect theory/Rank-Dependent Utility most popular for risk**) They assume power utility with the same power for gains and losses, which, as explained by Wakker (2010, end of §9.6.1): "Thus, there is no clear way to define loss aversion for power utility unless the powers for gains and losses agree. Tversky & Kahneman (1992) coincidentally found such an agreement." Table 1 shows a strange finding: $\lambda < 1$, gain seeking.

P. 155: "CPT has a previously overlooked capacity to reflect aspects of the cognitive processing of specific attribute information."

Experiment 2 manipulates attention to gains and losses, and, unsurprisingly, more attention to losses increases loss aversion. %}

Pachur, Thorsten, Michael Schulte-Mecklenbeck, Ryan O. Murphy, & Ralph Hertwig (2018) "Prospect Theory Reflects Selective Allocation of Attention," *Journal of Experimental Psychology: General* 147, 147–169.
https://doi.org/10.1037/xge0000406

{% Consider how PT can accommodate five heuristics: Maxmin (maximize minimal outcome; the authors call it minimax), maxmax (maximize maximal outcome), least likely (identify the worst outcome of each prospect; take the one that assigns the lowest probability to its worst outcome; so, (0.1: -10^7, 0.9:-10^6) is preferred to 10^6 because the latter assigns probability 1 to its worst outcome, and the former only probability 0.1), most likely (equate each prospect with its most likely outcome, and choose according to those, which also readily leads to violations of stochastic dominance), and the priority heuristic (described in my comments to the Brandstätter, Gigerenzer, & Hertwig 2006 paper). A nice attempt at reconciliation!

They do not solve the problem mathematically, but by taking the parametric families of T&K'92 and fitting those to two-, three-, and five-outcome prospects.

Here are my mathematical speculations: For gains, maxmin (or maxmax) can be perfectly accommodated by a weighting function that is 0 (or 1) everywhere outside 0 (or 1), see my Wakker (2010) book Exercise 10.4.3. For losses this goes dually. Least likely and most likely are so far from any traditional theory satisfying stochastic dominance that it will depend entirely on the data set considered. The priority heuristic is more interesting but also more involved. Its overweighting of worst gain and best loss, and ignorance of intermediate outcomes supports pessimism + inverse S for gains and optimism + inverse S for losses.

I did not find clearly what stimuli were used in the simulations and experiments.

The authors consider hypothetical risky choices with monetary outcomes and with health outcomes. With health the probability weighting is more pessimistic and also more inverse S.

The heuristics models all have a context dependence that means they will violate transitivity. All the ones considered here are non-compensatory. Although algebraic models could be equipped with speculations on underlying cognitive processes and heuristics could be used without, mostly it is the other way around and this the authors write. The abstract takes diminishing sensitivity to outcomes and probabilities as psychophysical and not as cognitive. I like to take insensitivity (inverse S) probability weighting as (also) cognitive. The abstract calls risk aversion "and loss aversion" psychological.

P. 62 §8.1.1: "Algebraic models, with their focus on describing preference patterns, are mute about the cognitive processes underlying choice." P. 62 §8.1.2: "Prospect theory has psychophysical roots that Kahneman and Tversky (1979) highlighted, for instance, in the context of diminishing sensitivity" Again, the case of probability

weighting, I like to take that as (also) cognitive. I emailed with Thorsten Pachur on 23Feb.2018 and I think we converged on the following: The term prospect theory is used in different senses in the literature. Some economists prefer to take it Friedman-style purely as revealed-preference without any interpretation. Their claim of muteness refers to those. However, others, including Kahneman, Tversky, Rich Gonzalez (I would like to join in this group), like to speculate on cognitive interpretations and are not mute.

Nice is that the paper tries to relate and compare PT and heuristics in neutral terms. %}

{% My endorsement of the book:

"Rationality, central in economics and empirically abandoned in the "behavioral revolution," is, unfortunately, rarely discussed because of its slippery nature. This monograph, very very well building up, captures its essence, as of behavioral economics. Nuanced and in-depth. It thus serves two methodological purposes—a fortunate combination because one cannot be understood well without the other."

This, personal, monograph discusses rationality. It is not a collection of papers. It is one build-up of something that only a book can do. It is very well organized. Every chapter starts with some good citations, followed by a summary. Part I sets the stage, on homo economicus (Ch. 1), psychology (Ch. 2), scientific revolution (Ch. 3), and evolution (Ch. 4). Then follow 10 chapters on biases in behavioral economics. Finally, Ch. 15, called epilogue, brings all threads together and discusses arguments about rationality, without drawing clear conclusions, but this is OK for the slippery topic of rationality.

The preface ends with overblown language: "My aim is to get you to see the underlying meaning to the often mysterious ways we seem to live our lives." Well, to sell a book such quasi-nicely sounding sentences may be good and so be it. See the last sentence of Hawking (1988) and his comment on it, elsewhere in these annotations. Strictly speaking, it deserves the keyword: **ubiquity fallacy**.

Ch. 1: homo economicus

P. 2: "Analyses of citation flows show that economists export their results to other social sciences more than they import from them (Fourcade et al. 2015)." This can mean that economists are less open, or even more haughty, than others …

Pp. 3-5 discuss economic's simplifying rationality assumptions

Pp. 5-6 take Stigler & Becker (1977) “De Gustibus non Est Disputandum” more seriously than I do.

P. 10 writes, and I agree much: “Whenever we criticise the homo economicus, we should not ignore all the contributions of this “standard model” to economics and other social sciences. I will argue in this book that the way beyond the homo economicus is not to throw away the past insights and just state that people are “irrational”. On the contrary, it is the enrichment of this model which often offers the best insights into the rich and complicated patterns of human behaviour.”

Ch. 2 is on psychology of biases

P. 12 has nice texts on Ward Edwards, a pioneer with his impressive 1954 paper.

p. 13 nicely discusses Grether & Plott (1979).

Ch 3: Scientific revolution

P. 20 writes that behavioral economics lacks a unifying theory, but that evolution can provide such. Even that that is a central theme of the book. I would put it less central. Even though evolution is something like a religion to me, I think it is too abstract and complex to give concrete insights. Evolution can take place at every level, not only individuals but also habits (memes), genes, groups, language, and so on.

Ch. 4, pp. 22-34 is on evolution.

Then comes part II, on individual decisions.

Ch. 5 is on heuristics.

Ch. 6 on reference dependence and loss aversion.

§6.1.1 is on what Nobel-prize winner Kahneman calls Bernoulli’s error. That: Bernoulli did not incorporate reference dependence. I find calling this an error to be overblown and misplaced, and regret here as elsewhere that the author does not often take issue with ideas of high status but low value. §6.1.2 nicely points out that violation of asset integration is crucial.

§6.2.1 seeks to explain/rationalize reference dependence through limited perception, and §6.2.2 through motivation. Loss aversion is also discussed. I like to distinguish between basic and overall utility, and whether or not asset integration is violated, but did not find a central role for this in the text (may have missed it).

Ch. 7 is on probabilistic sensitivity.

§7.1 is on EU debates.

§7.2 is on probability weighting to give second-best solutions.

Ch. 8 is on random choice.

§8.1 discusses completeness from the indecisivenes perspective.

§8.2 discusses optimal sampling.

Ch. 9 is on intertemporal choice (impatience).

E.g., that we are always uncertain about the future.

Ch. 10 is on reciprocity.

On altruism, norms, rules.

Ch. 11 is on emotions and commitment.

Ch. 12 is on social identity.

§12.3.2 discusses group selection.

Ch. 13 is on imprecision.

§13.2 is on second-order beliefs, but this is to be taken between-persons and not for individual choice.

Ch. 14 is on delusion including overconfidence.

Part IV brings everything together in the final Ch. 15 entitled “Rationality”

Although this Part IV is called epilogue, it is the most important part of the book.

§15.1 discusses maximization. Is it rational to maximize happiness, instant pleasure, fitness, and there are citations by Socrates, Plato, Aristotle.

§15.2 discusses rationality as consistency (**coherentism**), and how the ordinal revolution contributed to bringing this about. Then pp. 227-228 discuss completeness, defending incompleteness due to indecisiveness. I never like such criticism, and more like criticisms of completeness due to unrealistic infinite continuum models, but never saw that discussed in the book. Pp. 229-230 discuss transitivity, with useful references, and leaving open if even that is rational. Pp. 230-233 discuss independence, taking history on for instance Samuelson from the valuable Moscati (2016). Pp. 233 ff. discuss independence of irrelevant alternatives. To me that is about the same as transitivity, but the book never seems to connect the two. Then a text has “Bayesianism” as its heading.

§15.3 is on rationality after the behavioral revolution. Pp. 240-241 is more optimistic than me on neuroscience by suggesting that it could make subjective experience observable.

I think Broome (1991), one of the biggest influences on my academic thinking, would have been a useful reference for this book. Broome in his discussion of rationality went further and argued that we may rather take the axioms as a choice of paradigm. So, if someone violates transitivity and take only the second-largest cake, we say that utility must be redefined. Broome discussed follow-up arguments on circularity and so on. %}

Page, Lionel & Robert T. Clemen (2013) "Do Prediction Markets Produce well Calibrated Probability Forecasts?," *Economic Journal* 491–513.

{% **risk seeking for small-probability gains**: well, this is risk aversion for small-probability losses.

"Overprotection stems partly from the skewed incentives for reviewing committees … are held accountable for failure but not rewarded for success. … the possible risks loom larger than the cost savings. This is because of the disproportionate weighting of rare extreme events — for instance, a risk increase of 0% to 1% may be seen as more alarming than one from 40% to 41%. Institutions may therefore opt to play safe, despite the low probability of such events. … As such, the costs of overprotection raise ethical concerns of their own." %}

https://doi.org/10.1038/544161d

{% **decreasing ARA/increasing RRA**: Shortly after 2011 Australian floods (Brisbane) interviewed home owners. They could choose payment of $10 for sure, or a scratch card costing $10 (sort of lottery game, well-known, and giving very high prize with small probability). People with serious damage to their house chose the scratch card more often. So, looks like they are more risk seeking. Well, probabilities of scratch card are unknown, so, then they are more uncertainty seeking. %}

Page, Lionel, David A. Savage, & Benno Torgler (2014) "Variation in Risk Seeking Behaviour Following Large Losses: A Natural Experiment," *European Economic Review* 71, 121–131.

{% Uses loss aversion as in Köszegi & Rabin (2006) to explain life-cycle consumption: (1) excess smoothness and sensitivity—consumption responds to income shocks with a lag (delay losses for expectation-adjustment.) (2) low consumption early in life (precautionary savings). Next, as uncertainty resolves, time-inconsistent overconsumption. Last, declining consumption. (3) At retirement, absent uncertainty, overconsumption drops, being associated with a sure loss in future consumption. Provides estimates from macro-data. %}

{% **dynamic consistency**; Writes that Adam Smith and David Hume already pointed out that we can have, besides instant utility, also utility from anticipated and remembered consumption. Suggests that Smith and Hume meant these concepts to be an internal reward system to avoid dynamic inconsistency. This would be reminiscent of the Machina-McClennen view on dynamic consistency without extraneous commitment device. It may also be that Smith and Hume only meant these emotions to serve good purposes in a general sense, without particularly thinking of dynamic inconsistency. D**C = stationarity** on p. 242, 248. %}

Palacios-Huerta, Ignacio (2003) "Time-Inconsistent Preferences in Adam Smith and David Hume," *History of Political Economy* 35, 241–268.

{% **decreasing ARA/increasing RRA**: many refs on power utility and the average power found, in the economics literature.

The paper is strange, incorrectly trying to criticize Rabin's (2000) paradox. Looking at the implausible implication of EU when combined with Rabin's plausible empirical assumption of $11_{0.5}$–10 $\prec$ 0 at various wealth levels, the idea to give up EU does not occur to the authors. Instead they, first, add evidence of the same kind as Rabin. That is, they cite many empirical estimations of power utility in the literature *that are all based on the EU assumption*, and then point out that these findings cannot be reconciled with Rabin's assumption of the above preference for a range of wealth levels. They do not conclude from this evidence, as does Rabin, that EU is in trouble, but, unable or unwilling to give up EU, they instead turn against Rabin's assumed preference and conclude that it must not be plausible after all.

This paper is typical of many economists' thinking. Rabin & Thaler show that, for a plausible assumption denoted PA here ($11_{0.5}$–10 ≺ 0 at various wealth levels), [EU & PA] $\Rightarrow$ implausible implications. They, correctly, conclude that EU is implausible. But many economists are just not able to make this step; they are not able to abandon EU. Instead, they enter their common way of thinking and come out with the conclusion that PA must be implausible.

It is also strange that, in citing findings on powers of utility from the literature, the point so crucial in Rabin's argument about how large the stakes are, is never mentioned by the authors. %}

Pareto, Vilfredo (1892) "Considerazioni sui Principii Fondamentali dell'Economia Politica Pura," *Giornalie degli Economisti*, Series 2, Vol. V, Aug. 1892.

{% Stigler (1950) says that on p. 307 (or p. 119 ff. says Stigler, 1950 in Footnote 201): First person in history to give empirical implication of additive decomposability it seems (according to Stigler, 1950). Mentioned that increase in price of any commodity then implies decrease in demand. Then says that demand is observable, that we can infer the implication just mentioned, and that therefore the utility of a commodity may be assumed to depend, approximately, only on the quantity of the commodity in question.

Seems to have noted problem of existence of utility function; i.e., seed of ordinalism.

Schumpeter (1954), §5 of Appendix to Ch. 7, suggests that Pareto turned to ordinalism only in 1890, and that “Wieser” preceded him. %}

Pareto, Vilfredo (1893) “Considerazioni sui Principii Fondamentali dell’Economia Politica Pura,” *Giornalie degli Economisti*, series 2, Vol. VII.

{% P. 47−48 (I think of Vol. I) used interpersonal comparison of utility for welfare purposes.

Distinguishes between utility bringing usefulness and fulfilling needs (in principle objective and observable), and utility fulfilling desires (ophelimity, subjective). Pareto seems to say that the two concepts should be identical for a rational person. So, then ophelimity is descriptive and usefulness is normative? Cooter & Rappoport, footnote 23, say that Pareto (1896 Vol. I) says that the two concepts should coincide for a rational person, don’t say where. Just before, they referred to p. 3 of Pareto’s work.) %}

Pareto, Vilfredo (1896/7) “*Cours d’Economie Politique*, Vol. I and II.” Rouge, Lausanne.

{% Seems to write: “It is an empirical fact that the natural sciences have progressed only when they have taken secondary principles as their point of departure, instead of trying to discover the essence of things … Pure political economy has therefore a great interest in relying as little as possible on the domain of psychology.” (I got this from Bruni & Sugden (2007), who cite Businо (1964) for it on their p. 154.) %}

Pareto, Vilfredo (1896/7) letter to Adrien Naville.

{% P. 214 (I guess of 1982 Reprinted text) seems to claim, as one of his main achievements, that "every psychological analysis is eliminated."

Seems to write:

"When, in order to establish the fundamental equations of pure economics, we start from the notion of pleasure and of its measurement, we come up against an insurmountable difficulty right from the start: there is no practical means of measuring this pleasure directly. We have just seen that such measurement is superfluous for attaining our end, which is the determination of economic equilibrium."

Pareto seems to assume that utility in a cardinal sense "exists" but is often unmeasurable. %}

Pareto, Vilfredo (1900) "Sunto di Alcuni Capitoli di un Nuovo Trattato di Economia Politica del Prof. Pareto," *Giornale degli Economisti* 10, 216–235; 511–549. Reprinted in 1982, "Oeuvres Complètes of V. Pareto," Droz, Geneva.

{% Seems that both the first article in Econometrica and in Review of Economic Studies was an article on Pareto.

Showed some implications of additive decomposability of utility, mentioned some economic phenomena that contradict those implications, but still defended it as an approximation.

Ch. 3, paragraph 29, utility is relation between man and thing. Paragraph 36b points out that only indifference curves matter, not anything of utility (called ophelimity, meaning it's what the subject chooses, so what apparently pleases him most, but need not be useful in some rational sense, e.g. such as taking heroine.

1927 translation in French seems to be first to define strength of preference on p. 19, according to Fishburn (1970 p. 81).

1971 translation seems to write, on p. 191, that strength of preference judgments by introspection are possible, though not with great precision.

Seems that in Ch. 3, §1, he writes on preferences only after learning:

"A man who buys a certain food for the first time may buy more of it than is necessary to satisfy his tastes, price taken into account. But in a second purchase he will correct his error, in part at least, and thus, little by little, will end up by procuring exactly what he needs. W*e will examine this action at the time when he has reached this state.* Similarly, if at first he makes a mistake in his reasoning about what he desires, he will rectify it in repeating the reasoning and will end up by making it completely logical." [italics added here]

conservation of influence: Seems to have written, on man maximizing something with us researchers being conspicuously vague on what is maximized: "to compare the sensations of a man in different situations, and to determine which of these he would chose. … [S]ince it is customary to assume that man will be guided in his choice exclusively by consideration of his own advantage, of his self-interest, we say that this class is made up of theories of egotism. But it could be made up of theories of *altruism* (if the meaning of that term could be defined rigorously), or, in general, of theories which rest on any rule which man follows in comparing his sensations. It is not an essential characteristic of this class of theories that a man choosing between two sensations choose the most agreeable; he could choose a different one, following a rule which could be fixed arbitrarily." (Ch.3, §11) %}

{% This book is considered a classic. Imagine that we observe only correlations, and find one between C and A. We don't know if C has causal influence on A or vice versa, because of symmetry. If we also get temporal info, and know that C preceded A, then it seems plausible that C has causal influence on A. (There is always problem of hidden common causes for C and A; soit.) For long time it was believed that with only info on correlations, and not for instance on temporal ordering, we cannot speculate on causal directions because of symmetry. It seems that Pearl discovered a way to speculate nevertheless: if C and B are mutually independent but both are correlated with A, then it is plausible that B and C have causal influence on A and not the other way around. Seems that he started writing on it at end of 1980s. This book collects several of his papers. %}

https://doi.org/10.1073/pnas.2401229121

{% An impressive study. For 1,507 (!) subjects, six elicitation methods were used to measure risk attitudes, taking essentially a whole day of each subject. Very little consistency was found, both between raw measures of risk aversion (only that; no raw measure of insensitivity) and between fitted parameters of expected utility or prospect theory. The authors conclude very negatively (P. 807 2nd column end of 1st para):

“What is clear, however, is that scientists’ common practice, namely, measuring risk preferences with one simple behavioural EM (for example, lotteries) and thus creating the fiction that they can capture consistent risk preferences, should stop.” They several times express the constructive view of preference. For example, abstract last sentence: “Instead, we interpret the results as suggesting that risk preferences may be constructed when they are elicited, and different cognitive processes can lead to varying preferences.”

My reaction: I will continue to work on finding consistent risk preferences. One reason is based on normative thoughts: There exists a normative proper risk attitude in every person, e.g. though utility in expected utility. We should do all we can to find it as much as possible. The more so as finding it is something like finding the holy grail. One can then take best decisions for people. This is also why the decision-theory concepts of risk attitude are way more interesting than introspective measures. Another point in my reaction: Subjects had to spend almost a day doing the experiment. My experience is that individual choice experiments can last no more than 45 minutes. After that subjects get bored. The subjects here may have gotten bored, so that almost only noise was measured.

The literature references in the paper are impressive.

P. 803, 2nd para: “Surprisingly, there is no consensus across science and industry on how risk preferences should be measured.”

P. 803: end of 1st para of 2nd column: many references that compare different measurement methods.

P. 804 penultimate para: The BART measurement deviated most from the others, and this is because, unike the other tasks, it had unknown probabilities, to be learned from sampling (DFE). P. 806 1st para: BART has very weird results, with risk seeking and loss aversion $\lambda = 0.43$, so, much gain seeking.

P. 804 2nd column 3rd para: They related choice inconsistencies to a cognitive intelligence measure, but found no relation. Report it only in online appendix (“Supplementary Information”).

P. 806, 2nd para: “However, numerous studies have demonstrated that individuals’ risk preferences often deviate from EUT and that CPT is often the best model for fitting aggregate choices even if some people are not best described by EUT and even though there may not be a single best model for fitting individual choices." (**Prospect theory/Rank-Dependent Utility most popular for risk**)

P. 806, 4th para: "Although on average CPT describes the choices better than EUT"

P. 807, 4th para: "Second, capturing risk preferences in terms of the non-normative components of risky choice (for example, probability weighting and loss aversion)". That is, the authors take expected utility as normative.

P. 807 para starting at bottom of 1st column is only one with a bit of positive results, although not much.

P. 807 2nd column 1st para reports the only positive result: "Second, the fact that all levels of analysis reveal exclusively positive correlations may hint at the existence of a general underlying construct."

P. 807 2nd column 1st para expresses the other constructive view of preference. It is not the view that all is arbitrary ad hoc construction and here is nothing down there. The second is that experimenters should influence subjects and construct their risk attitude together with subjects, as architects ("getting more out of fewer subjects"), when the authors write: "In addition, it may be of interest to examine whether decision aids, such as expert advice on how to approach specific decisions, may increase consistency in observed risk preferences." %}

{% I enjoyed this discussion, given to me by Gideon Keren, of the psychological factors underlying positive versus negative outcomes, distinguishing several biases or functional weightings. The authors separate affective from informational, and relate to approach-avoidance. It interested me because if gives psychological background to loss aversion. But sometimes it was hard to follow. For instance, on p. 37: "the tendency to expect the positive is allied with a strongly marked

sensivitity for aversive stimuli," if any part of this claim had been reversed it would have been just as plausible to me.

P. 54 middle: negativity effect (overweighting of negative outcomes, both affectively and informationally) is independent of probability at that negative outcome.

Yechiam & Hochman (2013) present a sophisticated model explaining loss aversion by attention rather than to utility, with a followup in Yechiam, Retzer, Telpaz, & Hochman (2015). Bilgin (2012) is also relevant, and so is Huber, Ariely, & Fischer (2001), who rule out any role of utility but still find loss aversion induced by weighting. Tversky & Kahneman (1981 p. 454 1st column penultimate para) explains loss aversion merely through utility.

Baumeister, Bratslavsky, Finkenauer, & Vohs (2001) is cited more than this paper but I like this paper more. %}

{% **dynamic consistency**? %}

Peleg, Bezalel & Stef H. Tijs (1996) "The Consistency Principle for Games in Strategic Form," *International Journal of Game Theory* 25, 13–34.

{% **dynamic consistency**; reviewed by Shefrin (1998); Goldman (1979, 1980) seems to be an important follow-up.

Paper first points out that for Strotz-Pollak solution (so, **sophisticated choice**; forgone-branch independence [often called consequentialism] is assumed for utility at time t) solution need not always exist. The counterexample is, if I understand right, based on the observation that the consumption chosen at time t is the result of a maximization and need not be continuous, therefore at time t–1 a noncontinuous function has to be maximized, if I understand right. Then one can approximate the optimal utility within each distance ε but the maximum need not exist. (This is in my opinion a technical complication that does not lead me to reject sophisticated choice intuitively.) The authors next proceed to study different approaches than Strotz-Pollak, and propose that the solution should be a subgame perfect equilibrium for the players which makes sense. They point out that being an equilibrium is necessary (I agree given sophisticated choice) but surely not sufficient, e.g., equilibria can violate Pareto. Note that sophisticated choice leads to equilibria. I'm not sure if the authors point that out.

P. 391 states the common assumption in economics that preference is not different than choice, but that preference is just binary choice: "An agent's preference ordering is nothing more than a summary of choices, when confronted with dichotomous alternatives."

P. 392, assumption that utility function at time t does not depend on past consumption, considered in §II, is like forgone-branch independence. I do not understand their claim, at the end of §III, that their definition of stationarity would preclude changing tastes. For example, let $U_1(x_1,x_2,x_3, \ldots)$ be $x_1 + x_2/2 + x_3 + x_4/2 + \cdots$. then I think that their stationarity leads to dynamic inconsistency and changing tastes; I didn't study it in much detail.

DC = stationarity: 2nd to last sentence of §III is on that topic. It defines stationarity as utility U_t at t being independent of past consumption and $U_t(a,b, \ldots) = U_1(a,b, \ldots)$. So, it is what I would call forgone-act independence (often called consequentialism) plus a sort of invariance (that DUR automatically has but DUU not) different than stationarity. They are wrong in suggesting that their stationarity would preclude changing tastes, there they seem to confuse things with DC (dynamic consistency). For example, let $U_1(a,b,c,d, \ldots) = a + b/2 + c + d/2 + + \cdots$, then DC is violated, at time 1 I may prefer (0,0,1,0, ...) to (0,0,0,1,0, ...) but at time 2 my preference reverses. %}

{% He introduced the Penney game, with intransitivity. Imagine a fair coin is tossed repeatedly, independently, giving H or T each time. Two players can choose a pattern of three results. Say Player 1 chooses THH and player 2 chooses HHH. If a pattern of a player shows up, before the pattern of the opponent did, the player

can claim victory. With the patterns chosen, 7 out of 8 times player 1 will win, so THH $\succ$ HHH. It turns ut that there are intransitivities, and there is not one optimal pattern. So, you can propose this game to someone, let that other first choose a pattern, and then you can always choose a pattern with the bigger chance of winning. %}

Penney, Walter (1969), "Penney-Ante," *Journal of Recreational Mathematics* 2, 241.

{% **questionnaire versus choice utility**;

Outcomes were monetary. Data were collected from 346 managers from small and medium size hog farms.

Risk attitude was measured by

(1) psychometric questionnaires regarding whether they would be open to new products etc.

(2) hypothetical CE (certainty equivalent), fifty-fifty, questions.

(3) same as (2) but corrected by taking it w.r.t. underlying scale that was derived from strength of preference (as they call it but it is direct assessment such as what is called VAS (visual analog scale) in the health domain; see p. 1341 beginning of §3.3.2), so, it was risk attitude à la Dyer & Sarin.

CE bias towards EV: most (60%) were risk seeking!

Risk attitude from questionnaire correlated significantly with (2) and (3), not with str. of pr. value scale.

Exponential utility fitted data better than power.

Attitude questions were best predicted by (1); i.e., psychometric questionnaire results. Actual behavior was, however, best predicted by (2) and (3). There was no relation between actual behavior and psychometric scales. This is a remarkable result, because most recent studies (this sentence is written June 2021; e.g. by Dohmen and co-authors) find that psychometric scales better predict behavior than decision-model quantities.

P. 1340 beginning of §3.3.1: Utility is measured of the price for slaughter hogs. Strictly speaking, a price is a different thing than money. P. 1341 beginning of §3.3.2: what the authors call strength of preference is in fact only a subjective intrinsic absolute evaluation ("VAS"), and not really a strength of preference between objects. %}

Pennings, Joost M.E. & Ale Smidts (2000) “Assessing the Construct Validity of Risk Attitude,” *Management Science* 46, 1337–1348.

{% **PT, applications**, loss aversion, buying strategy of hog farmers; **CE bias towards EV**: p. 1254 reports only 55% risk averse in CE (certainty equivalent) questions.

50-50 CE questions were asked to 332 Dutch hog farmers. 149 had an “open” production system, where piglets and feeds are bought, piglets are raised to slaughter hogs in three months, and then sold. 183 had a closed system that is similar, only do they breed the piglets themselves instead of buying them. In the open system where people buy the piglets, the buying price provides a natural reference point. Of these 149 people, 83 indeed show the S-shaped utility function of PT around that price, with convexity below, and 66 have concave utility. Of the other group of 183, 163 have concave utility without reference point or convex part, and 20 have ref/point concavity. An exceptionally nice illustration of how reference points come about because of small psychological aspects of framing.

In the open group with the natural reference point, for gains we have c = 3.53, and for losses c = –0.77 (Pennings, personal communication, email of Friday 23 July 2004.)

P. 1261: with log-IPT fitting (contrary to what the paper writes, it is not the IPT family but the log-IPT family, as Smidts, November 2003, personal communication, let me know), the inflection point (reference point!?) of utility is endogenous

P. 1272: argue that farmers may not transform 50/50 probabilities because they know them very well from everyday experience.

There are many elaborate details on parametric fittings. When the authors write global shape, they refer to the extent to which the function exhibits an S-shape. When they write local shape, they refer to the extent to which the function is concave or not. When they say organizational (strategic) behavior, they mean whether or not the production is open or closed and they relate it to whether or not utility is S-shaped. When they say trading behavior they mean other actions studied in another of their papers, and they relate it to risk aversion/concavity.

Given that the choice of production must be complex, and driven by many factors, risk attitude can at most be a minor causal factor. Therefore, I think that the choice of production is the cause of the utility function measured, and not what the authors suggest throughout, that it would be the other way around. I interpret this paper, therefore, as a nice illustration of how framing can drive utility measurement. %}

{% **game theory can/cannot be viewed as decision under uncertainty**: (see also: Game theory as ambiguity). Applying usual revealed-preference techniques in game theory has a problem. Imagine we want to derive preferences over and utilities of strategies for player 1. We do the typical revealed-preference measurement: Assume player 1 has has only actions 1 and 2 available, and not strategy 3. What will he prefer, strategy 1 or strategy 2? Problem is that removing strategy 3 and possibly other strategies changes the whole game, including the behavior of the other players, so that an essential ceteris paribus assumption is violated. Aumann & Drèze (2009) used the following thought experiment: "imagine player 1 does not have strategy 3 but the others don't know so and think that he has, and player 1 knows this." Such thought experiments are far-fetched and not very satisfactory. This paper proposes an alternative approch: "do not change the available strategies. Instead change the conceivabe beliefs." Then still utilities can be derived. A nice new approach. (Although I do not know to what extent this already was in Gilboa & Schmeidler 2003 GEB, a paper cited by the authors.) It uses techniques similar to case-based decision theory (CBDT) of Gilboa & Schmeidler, where preferences depend linearly on memories, much like here preferences depend linearly on beliefs.

This paper considers preference relations conditioned on subjective probability measures, denoted small p. It considers how variations in those subjective probabilities lead to variations in preferences, and derives utilities and so on from that. This is similar to Gilboa & Schmeidler's case-based decision theory (CBDT), where memories play roles similar to the subjective probability measures considered here. The author, indeed, cites a Gilboa & Schmeidler (2003) paper as very close. That paper did not use CBDT but related techniques. This is an interesting alternative approach to decision under risk, taking different empirical inputs.

Assume a finite state space S, and a finite set of (choice) alternatives C. (The paper uses different symbols and the unfortunate term choice for alternative.) In Savage's (1954) framework, states and so-called outcomes are primitives, and alternatives, called acts, are derived from those, as functions from S to outcomes. This is not the only way. The keyword "**criticisms of Savage's basic framework**" in this bibliography gives discussions of it. One can also take states and alternatives as primitive, and derive outcomes as pairs (s,a), so that the outcome set is a product set of the state space and the alternative space., and this is in fact what the paper does, more or less implicitly. The aforementioned set of (subjective) probability measures is the set of all probability distributions over S.

The paper considers expected utility, defined as maximizing

$a \mapsto \sum_{s \in S} p(s)u(a,s)$

over alternatives a given the probability measure p. First assume only two alternatives, C = {a, b}. Define by $\mathcal{P}^+$ the set of probability measures giving strict preference for a, and $\mathcal{P}^-$ and $\mathcal{P}^0$ similar. Only utility differences u(a,s)–u(b,s) are meaningful, and $\mathcal{P}^+$ is the set of p's with

$\sum_{s\in S} p(s)\big(u(a,s)-u(b,s)\big) > 0.$

Given that a and b are fixed, we can reinterpret this as preferences over the p's, where we only know which p's (the set $\mathcal{P}^+$) are strictly preferred to a neutral q with EU(q) = 0, which are indifferent to q, and which are preferred strictly less. Assuming usual weak ordering and continuity, independence is still necessary and sufficient for EU, where independence here is never more than betweenness. This is the first result of the paper.

When we have three or more alternatives, and C = {a,b,c,…}, then we need more than betweenness. Betweenness only implies linear indifference sets, but they need not be parallel as needed for EU. The paper imposes a "uniform preference increase" axiom, which involves assumptions about parallel hyperplanes. If there are no weakly dominated alternatives, then strong transitivity and a line property, referring to a particular line, can replace the uniform preference increase axiom. The extra axiom is similar in a mathematical sense to the diversity axiom of CBDT, as the author points out. It is also similar to the decomposition of independence in Burghart (2020, *Theory and Decision*), where homotheticity is used to get the indifference sets parallel and is similar to the uniform preference increase axiom. %}

{% %}

Peters, Hans J.M. & Horst Zank (2005) "The Egalitarian Solution for Multichoice Games," *Annals of Operations Research* 137, 399–409.

{% A detailed general criticism of the author's work is given at his 2019 Nature Physics paper. It is a case of **ubiquity fallacy**, where the author's expertise is ergodic theory. The author argues for his expected growth rate criterion for intertemporal choice. It implies, *under several assumptions*, maximization of expected logarithm of wealth. Bernoulli also argued for such maximizationn, be it for very different reasons. The author argues that his justification is superior to Bernoulli's, completely unfounded. As explained in my annotations at Peters (2019), it is because this author is not aboe to think of anything other existing than ergodic processes.

Pp. 4914-1915: The author argues that expected utility/value is an "ensemble average." How he comes to this claim is explained by Doctor, Wakker, & Wang (2020b). There are only two kinds of averages that can have any meaning to this author, and those are averages over time or averages over ensemble, which is often taken to reflect only persons. Other averages he cannot imagine. He then thinks that averages, such as expected value/utility, must be interpreted as one of these two averages, where ensemble refers to an average over people, because otherwise he cannot relate to them so he thinks they must make no sense. Because for expected utility, different outcomes may arise, the author reasons that the several (?) persons involved in it must be replicas of the agent, and that this requires a belief in parallel universes. He then blames Bernoulli, and then all economists, for not seeing things his way, for instance on p. 4918 3rd para: "these behavioural regularities have a physical reason that Bernoulli failed to point out." Note that no economist or decision theorist ever wrote such things, and that it is only the author's imagination from which all this comes. Typical is the 1st para of §5 (p. 4918): "Fermat and Pascal (P. Fermat & B. Pascal 1654, personal communication between themselves) chose to embed within parallel universes, but alternatively—and often more meaningfully—we can embed within time."

P. 4918, §5 1st para: the author cannot relate to single decisions, and argues that we should consider everything as a process over time.

Pp. 4919-4920: "Conceptually, however, the *arbitrary* utility (*arbitrary in the sense that it depends on personal characteristics*) is replaced by an argument based on the physical reality of the passing of time and the fact that no communication or transfer of resources is possible between the parallel universes introduced by Fermat." [italics added] Illustrates that the author finds the study of interpersonal dependence a waste of time, and instead we should all only be studying intertemporal variations as in ergodic theory. His strange idea of parallel universes, and incapability to relate to averages other than if over time or persons, is described in his §5a, p. 4920, and beginning of §6.

P. 4926: "Inadvertently, by postulating logarithmic utility (left-hand side of equation (7.1)), Bernoulli replaced the ensemble-average winnings with the time-average exponential growth rate in a multiplicative non-ergodic stochastic process (right-hand side of equation (7.1)). Bernoulli did not make the time argument," shows again the author's way of thinking: As everyone should always do only ergodic theory, so should Bernoulli, and if he didn't it was his mistake and he must have been doing it inadvertently.

P. 4929, penultimate para, explains why the author often calls utility circular: "The framework is self-referential in that it can only translate a given utility function into actions that are optimal with respect to that same utility function."

P. 4930 ℓ. 2: "For example, some fraction of $w may already be earmarked for other vital use." This sentence shows some awareness that we do not only optimize entire wealth at the end of our life, but that intermediate consumptions play a role. However, the author treats this as a little aside and not as what it should be: something that severly restricts his analyses. Here, in his early papers, he would still sometimes bring in some nuancces. But his apparent marketing successes rewarded him for dropping nuances, and they disappear in later writings. %}

Peters, Ole (2011) "The Time Resolution of the St Petersburg Paradox," *Philosophical Transactions of the Royal Society A* 369, 4913–4931.

{% The opening sentence "This study focuses on the simple setup of self-financing investments, that is, investments whose gains and losses are reinvested without consumption or deposits of fresh funds, in assets whose prices are undergoing geometric Brownian motion." shows that the author understands that intermediate consumption should be ruled out to make his criterion of expected growth factor relevant. It implies that his criterion can only refer to longterm investment decisions. In later papers he will omit these restrictions, and claim relevance for all of economics, getting more and more the taste of overselling.

P. 1593 2nd column writes: "While in the terminology of modern portfolio theory, the latter ansatz can be interpreted as the assumption of logarithmic utility, in section 1.1 the Kelly result is shown to be equivalent, in the present setup, to an application of Ito's formula of stochastic calculus. In this sense it is not the reflection of a particular investor's risk preferences, but a generic null hypothesis. Considerations of personal risk preferences can improve upon this hypothesis but they must not obscure the crucial role of time." It shows that he already has his preoccupation with time, thinking that ergodic properties are more important than anything else. But here at least he still acknowledges that considerations of interpersonal variations, e.g. regarding risk attitude, may also be of use, be it secondary to ergodic theory. Such relatively "positive" views on the value of risk theory will disappear from his later papers.

P. 1594 1st column seems to acknowledge that in finance not only returns (or their ln, which is equivalent to expected growth factor, the sole criterion of Peters' ergodic economics) but also volatility and even higher moments can matter.

P. 1596 1st column argues again that risk is in a way irrelevant because not all possible outcomes will actually be realized, whereas all outcomes over time will be.

Pp. 1596-1597 writes: "This is different from Bernoulli's treatment, where the logarithm is a utility function and would be inside the sample average, obscuring the conceptual failure of the ensemble average. It was Kelly (1956) who first pointed out that the time average should be considered instead." The author is suggesting here that Kelly is with him in arguing that time is more important than risk and that Bernoulli was just confused, but I cannot believe that Kelly would ever have suggested something so silly.

P. 1601 2nd para writes: "The use of leverage is not fundamentally constrained by the prevailing framework of portfolio selection, which relies on a necessarily and explicitly subjective notion of optimality, dependent on utility, or risk preferences. This has become problematic because asymmetric reward structures have encouraged excessive leveraging." Here he is also criticizing finance.

P. 1601 last para of 1st column opens with: "In conclusion, utility functions were introduced in the early 18th century to solve a problem that arose from using ensemble averages where time averages seem more appropriate." Showing again that for him time is more important than risk.

In several papers, Peters' imagination fabricated a history that from the 17th to the 19th century people worked with expectation, should have made the ergodicity assumption, but ergodic theory did not exist yet and, therefore, mankind was in a state of confusion, not able to distinguish averages over time from averages of uncertainty, and always confusing them. Only then ergodic theory came along and only then mankind was able to properly distinguish averages over time from averages over uncertainty. Needless to say, such fantasies have nothing to do with reality. %}

Peters, Ole (2011) "Optimal Leverage from Non-Ergodicity," *Quantitative Finance* 11, 1593–1602.

{% I am not neutral in the sense that I co-authered a criticism of this paper: Doctor, Wakker, & Wang (2020, *Nature Physics;* link). My views can best be inferred from my 12-minutes lecture for nonspecialists at
https://www.youtube.com/watch?v=FDvBrcytU7Q&t=52s.
Here is a link to many citations from this paper and criticisms of those:
http://personal.eur.nl/Wakker/refs//pdf/citations.eee18jan2021.pdf
I add some observations below.
The author is supported by Nassim Nicholas Taleb (who also supported president Trump). Furher, this journal wrote a supporting editorial, Nature Physics Editorial (2019).

The author has two basic problems:

(1) [economics by imagination] He knows little of economics, picks a few points from the economic literature, adds many details based only on his imagination, this leads to unsound frameworks, and then he starts blaming economics for that unsoundness. But the unsoundness came only from his own wrong imaginations, and not from economics.
(2) [**ubiquity fallacy**] The author's expertise is ergodic theory and he thinks it is the only thing existing. It is a subfield of measure theory, which is a subfield of mathematics, about the dynamic development of systems over time. It is a subfield in mathematics among dozens of other subfields.
Just some examples of decisions where time is not central (Peters is not aware of such):

> (1) [Choice of applicant] If we choose one from some similarly aged Ph.D. students, then we weigh the pros and cons of their high and low grades, the uncertainties about their motives/qualities, and their strategic interests E.G. when putting deadlines. All these ubiquitous aspects are relevant. But progression in time, while present (ubiquitous), is not considered or analyzed because it gives no insights into the choice to be made. It does not distinguish between candidates. P.s.: this could be considered a situation where a kind of generalized ergodicity holds in the sense that growth over time goes similarly for all candidates.
> (2) [Choice of restaurant] I don't just maximize entire wealth over my life, but think for the salary received this month, where I want to spend one evening in a fancy restaurant, which restaurant to choose. There are pros and cons such as service and travel time, uncertainties, impact for my company that evening, but progression over time plays no role in my decision.
> (3) [Choice of travel mode] If commuting to my work, I consider cycling or walking, where I prefer walking if there turns out to be black ice, and cycling otherwise. I think about probabilities of black ice and severeness of inconveniences, but not of growth of consequences over time.
> (4) [etc]

The author's mistake of thinking that growth over time can answer all questions is what I call the **ubiquity fallacy**. It is closely related to what Kaplan (1964) called the "law of the instrument." Kaplan seems to write

"I call it the law of the instrument, and it may be formulated as follows: Give a small boy a hammer, and he will find that everything he encounters needs pounding." (p. 28)

He also seems to write: "It comes as no particular surprise to discover that a scientist formulates problems in a way which requires for their solution just those techniques in which he himself is especially skilled." (p. 28)

Carrel (1939) seems to write: "Every specialist, owing to a well-known professional bias, believes that he understands the entire human being, while in reality he only grasps a tiny part of him." (§2.2)

I sometimes use the example of a dietician who thinks that all problems can be solved, no more wars etc., if we have a good diet.

P. 1221 presents ergodic economics as an, in the author's terminology, null model. I did not know this term, but from other papers by Peters inferred that it is a kind of first-approximation model, capturing the main characteristics, but open to refinements to capture things of secondary importance. So, here Peters seems to be more permissive to the rest of economics apart from ergodic phenomena: they are not completely useless, but can have secondary importance as long as it is understood that anything ergodic should be of primary importance.

The author, strangely, thinks that expected utility for one-time decisions requires belief in multiverses. David (1986) has a theory assuming this. %}

Peters, Ole (2019) "The Ergodicity Problem in Economics," *Nature Physics* 15, 1216–1221.

{% I am not neutral I the sense that I criticized this author. I find this reply weak. I take his "I'm not sure where the disagreement lies" literally: He does not understand any of our criticisms, does not react to any, but just repeats some of his views. He then goes into his ergodic model as if it captures all of life. His "Classical economics puts forward a different decision theory. Here, expectation value maximization is declared a natural aim" ignores the justifications, e.g. through normative preference foundations and/or empirical evidence, that economists give and that our paper mentions. His "Declaring expectation value maximization an a priori natural aim is, simply put, an error in the foundations of economics." is haughty.

His "From this perspective, the simplest decision theory is this: entities will often act to maximize the long-term growth rate of their wealth (or other resources)." commits the **ubiquity fallacy** w.r.t. time, of saying that everyone should always study time.

His "Declaring expectation value maximization an a priori natural aim is, simply put, an error in the foundations of economics. The error occurred because economics began working with mathematical models of randomness long before the ergodicity problem was discovered." makes the error of thinking that EU needs ergodicity. %}

Peters, Ole (2020) "Reply to: Economists' Views on the Ergodicity Problem," *Nature Physics* 16, 1169 (2020). https://doi.org/10.1038/s41567-020-01108-9

{% My comments concern version of January 12, 2018.

The abstract takes utility curvature as irrational

P. 2 writes: "We ask precisely how the failures of neoclassical economics may be interpreted as a flaw in the formalism that can be corrected. Such a flaw indeed exists, buried deep in the foundations of formal economics: often expectation values are taken where time averages would be appropriate. Such a flaw indeed exists, buried deep in the foundations of formal economics: often expectation values are taken where time averages would be appropriate. In this sense, formal economics has missed perhaps the most important property of decisions: they are made in time and affect the future." Showing the state of mind of the authors.

P. 3 "Secondly, we postulate a specific form of rationality, that is, we state an axiom. Our axiom is that humans make decisions in a manner that would optimise the timeaverage growth rate of wealth, were those decisions to be repeated indefinitely."

The authors then give theorems showing how maximization of EU w.r.t. a utility function U arises as maximizing expected growth rate w.r.t. a particular infinite stochastic process.

P. 9: "A well-established but false belief in the economics literature, due to Karl Menger [16, 17], is that permissible utility functions must be bounded."

P. 9 Discussion: "Expected utility theory is an 18th-century patch, applied to a flawed conceptual framework established in the 17th century that made blatantly wrong predictions of human behavior." %}

Peters, Ole & Alexander Adamou (2018) "The Time Interpretation of Expected Utility Theory," London Mathematical Laboratory, London, UK.

{% A nice family of weighting functions: Take the normal distribution function Φ. Take the inverse $\Phi^{-1}(p)$. Translate it, say by multiplying by a positive τ and adding a real λ, into $\tau(\Phi^{-1}(s)+\lambda)$. Then go back: $\Phi\big(\tau(\Phi^{-1}(s)+\lambda)\big)$. This way we transform mean and variance. This idea also appeared in Hou & Wang (2019).

They discuss probability weighting. Argue that we should bring in time and that it is a mistake not to do so, as always argued by Ole Peters. %}

Peters, Ole, Alexander Adamou, Mark Kirstein, & Yonatan Berman (2020) "What Are We Weighting for? A Mechanistic Model for Probability Weighting," working paper.

{% Here is a link to many citations from this paper and criticisms of those: http://personal.eur.nl/Wakker/refs//pdf/citations.eee18jan2021.pdf

Here are some further comments.

P. 5 2nd column: "In modern terms, Huygens suggested to maximize the ergodic growth rate assuming additive dynamics." I am pretty sure that Huygens did not think anything in the direction of ergodic growth.

P. 7 bottom of 1st para writes: "However, based on formal arguments, Menger drew conclusions for the structure of the permissible formalism, namely, he ruled out linear and logarithmic functions as models of behavior, and, equivalently, additive and multiplicative processes as models of wealth. Because of the central role of these dynamical models, the development of decision theory suffered from this restriction, and it is satisfying to see that formal arguments against these important models are invalid, as intuition would suggest." Shows one more time how far the author's imagination can lead him astray, as to claim that Menger would deny the existence of additive or multiplicative growth processes!?

P. 7 §D 1st sentence, and then p. 8 3rd para of 1st column: "Karl Menger revisited Bernoulli's 1738 study, and came to the incorrect conclusion that only bounded utility functions are permissible. … Despite a persisting intuitive discomfort, renowned economists accepted Menger's conclusions [that utility has to b bounded] and considered them an important milestone in the development of utility theory." The author continues in his imaginatory world about economics.

P. 8 1st column: "To implement this notion in the formalism of decision theory, it was decided to make utility functions bounded." The author continues in his imaginatory world about economics, erroneously thinking that they require bounded utility. %}

{% INTRO

It is impressive that computers with machine learning can already develop theories, and this general direction shown by this paper (more clearly than predecessors) is valuable and impressive, making this one of the most valuable papers I read for a long time. Yet, on the negative side, the concrete conclusions they draw on risk theories have, I think, value 0, because of a big mistake in the experiment (not implementing losses) and, I guess (being nonexpert), that prediction exercises with large calibration sets too much favor high numbers of parameters and overfitting. Thus, the main and very simple finding of the paper is: the more parameters the better.

SPT instead of OPT: p. 1210 2nd column ℓ. 1. What the authors call 1979 prospect theory in fact is not that, but is separable prospect theory (Wakker 2023 Theory and Decision). I will nevertheless use the abbreviation OPT for it. For new 1992 prospect theory I use the authors' abbreviation CPT, although I would prefer the abbreviation PT.

The authors collected a very large set of experimental choices between risky lotteries, being 14,711 subjects each making 20 choices randomly selected from 13,000 choice pairs, totalling 294,220 choices. Well, if I understand right, then for each individual each choice pair was repeated five times. Then it would amount to 1,47,100 risky choices. They used choice pairs from Erev, Ert, Plonsky, Cohen, & Cohen (2017). These are mostly lotteries with few outcomes, but some have more like 6 or 8 or so outcomes. They involve most of the well-known paradoxes so that in this sense the stimuli are not relevant for general choices but have paradoxes overrepresented. Then prediction exercises were done, taking a calibration ("training") set to next do out-of-sample prediction for a prediction set. Although the paper does not write it clearly, the authors combined all choices into a representative agent model. (One modification, an individual replication is discussed below.) They used a Luce-type probabilistic choice model, with dominating choices treated separately.

When the authors call a model neural, such as neural EU, they mean that they selected the best utility function from a very large class, using splining techniques. They also considered many parametric families. Because in this paper the more parameters the better, neural models are found to work best.

PROBLEMS REGARDING RISKY CHOICES:

(1) The authors use the random incentive system but if the outcome is a loss, the subject need not pay (their Figure 1, left upper panel). This is very unfortunate. First, it means that choices between loss lotteries were hypothetical. In general, I am not against hypothetical choice, but in an experiment where other choices are incentivized, by contrast effect hypothetical choice is no good. Second, and more seriously, mixed lotteries (giving both gain- and loss-outcomes) are warped and destroyed. Subjects are willing to risk just any loss just for optimizing a chance at a gain. Thus, the estimates on loss aversion in this paper have no validity, and many other results are distorted by it.

(2) Supposedly, a prediction task corrects for number of parameters, as often claimed, and the authors claim so on p. 1210 left column 2/3 ("All theories are evaluated on their cross-validated generalization performance, meaning that model complexity is already implicitly accounted for in our analyses") They resolutely take predictive power as the almost only and absolute criterion, although they do reckon some with psychological interpretability, but not much. However, in my only experience with prediction exercises, Kothiyal, Spinu, & Wakker (2014), it came out clearly that the more data, the higher the nr. of parameters give the optimal prediction. Makes sense because even with the most silly parameter, capturing a heuristic adopted by only 1/1000 of subjects, given enough data, errors will cancel out (usually) and something systematic, no matter how small and silly, will be picked up. Looks to me that prediction exercises do not sufficiently correct for overfitting. Overfitting gets a bigger problem as the calibration set gets bigger. I think that this is also a big problem in this paper, where more parameters are

always better. A model with almost everything depending on almost everything (using the term that psychologists like so much: Context dependence, implying that transitivity is violated) is found to be best in this paper. The model is too complex, with too many parameters with too little meaning, to be of much interest.

(3) In Figure 4B, lower panel (Figures S4-S6 in Online Appendix p. 24 for probability weighting), the common findings of utility and probability weighting are reproduced miraculously well, although the authors use the PT formula and not the CPT formula, but this is only because the authors used parametric families that do not allow for other patterns. Figure 1B the right lower figure gives probability weighting optimized under PT "neurally," i.e., without parametric restrictions and then, strangely enough, almost get the identity function. This is strange but is not discussed by the authors. It suggests that the parameters of PT beyond EU do nothing. Then how can PT predict so much better than EU? I do not understand. Figure S7 in Online Appendix p. 25 gives the best-fitting probability weighting function under CPT, but strangely enough it only gives light underweighting, mostly for small (one would expect more for large) probabilities. These figures are extra-hard to interpret for me because it is not clear to me to what extent they come from gains or losses or, maybe, both?

SMALLER PROBLEMS:

Something unavoidable here as in most experiments: we are not so much observing preferences but rather heuristics of subjects to get the experiment done easily. In this big study it is very central though: The winning model in this study has numerously many parameters, but they are mostly picking up and predicting every silly heuristic that subjects may adopt. They mostly measure coherent arbitrariness (Ariely, Loewenstein, & Prelec 2001).

I regret that the authors did not really pay the outcomes stated, but only 10% of it (their Figure 1, left upper panel, and Online Appendix p. 24 Figure S5).

In Figure 1, left lower panel, the authors erroneously let EU and EV NOT be a subset of CPT. EU and EV should have been in the (nonempty!) intersection of PT and CPT. The online appendix, p. 14, does write that CPT contains EU and EV.

The authors focus on differentiable theories, but provide no definition in the paper. Rank-dependent theories such as CPT are not differentiable in usual meanings, and several others considered will neither be. OPT is not even continuous, neither in probabilities (at $p = 0$) nor in outcomes (when collapsing). The authors mean differentiable in the sense of how the error measure depends on parameters chosen, as used for finding optimal fit. Peterson (19 Sep 2022; personal communication) explained: "that we could take derivatives with respect to model parameters, which is helpful for fitting models, large neural networks in particular. This perhaps only works if one can tolerate mapping gamble values to choice probabilities, as opposed to focusing on hard decision preferences, because doing so allows us to maintain a smooth (differentiable) error function when we fit models to human behavior."

Swollen language: end of p. 1212, and some other places, writes on "human ingenuity" for nothing other than theory building.

They claim several times that Erev et al. (2017) is the largest data set on risky choice to date, where they then have > 30 times more data. But this is not so, and they miss relevant literature. From the top of my head, l'Haridon & Vieider (2019) have 3000 subjects, certainty equivalents for 28 lotteries of risky choice, with about 25 choices per certainty equivalent, amounting to a total of 2939*44*25 = 3,232,900 risky choices. Over twice as much as this study! There have been several metastudies on risk attitudes that will also have had more. For instance, Brown, Imai, Vieider, & Camerer (2022), in their mata-analysis of loss aversion, counting only the papers reporting the number of subjects, have 305,514 SUBJECTS in the meta-analysis. Estimating loss aversion will involve several choices. Thus, their data set is similar in size to this paper. There will be other such studies. I think, frankly, that the authors should have anticipated that their unfounded claim has little chance of survival.

GENERAL COMMENTS

As for OPT versus CPT, for limited calibration sets as common in experiments, CPT clearly outperforms OPT (Figure 2B left part, yellow vs. red curve). For larger calibration sets they are very similar but OPT is somewhat better. This may be explained by overfitting: in CPT, weights should add to 1 but in OPT they need not, giving some more flexibility to OPT. (E.g., Loehmann, 1998, p. 299 last line: "Thus, the assumption that subjective probabilities sum to one has a strong effect on subjective probability estimates.") As written, for large data sets there is

no good correction for overfitting and it is the more parameters the better, the more so as we are getting heuristics of subjects more than true preferences here.

There was a replication study of 300 subjects each doing 300 choices (60 choice pairs, each repeated five times) and then separate fitting for each individual, so that heterogeneity between individuals can be inspected. I am afraid that this was much with boredom and fatigue. Heterogeneity is not reported, but only predictive performance. They replicated the main findings although, unfortunately, they did not consider an analysis of CPT but only of PT. I regret this and expect that with this more limited set, CPT would do much better.

The authors played with mix-models, where either a first or a second model is used, and it depends on features of the lottery which one, and they performed well.

It is interesting that Erev et al.'s (2017) BEAST model clearly outperforms all other standard models in predicting (Figure 3), and to have this confirmed by an independent team. I expect that the model winning in this (Peterson et al.) paper is not at all stable w.r.t. stimuli set chosen, and had they chosen a somewhat different set of 13,000 choice pairs to choose from, the parameters of the winning model would have been quite different. %}

{% **loss aversion: erroneously thinking it is reflection**: P. 2170 top line discusses a potential role of loss aversion in an experiment with purely losses. This is reiterated on p. 2177: "Experiment 3 suggests that even while favorable information is being overweighted, individuals in our ambiguity task show risk-seeking behavior consistent with loss aversion." (The authors use the term risk seeking also under pure ambiguity.)

Did Ellsberg experiments, where probability intervals are given to subjects, and maxmin EU is used. Consider both gains and losses. Providing extra info that is favorable has much positive effect, not only through its favorableness but also through reducing ambiguity. Providing extra info that is unfavorable has just a bit negative effect, because its unfavorableness is counterbalanced by its reduction of ambiguity.

Experiment 4B does not take Ellsberg urns, but guesses on naturally occurring quantities (say temperature). Events concerned whether the quantity was below or above some threshold. Whether the winning event was above or below the threshold was randomly determined, and this was told to subjects. It means that objective risk comes in. Further, subjects can have extra info about such events so that there is no control for beliefs. The central question, what the effect of info provision is, is a comparative question that is not much affected by the aforementioned complications.

The authors are enthusiastic about their findings and conclude the paper with: "Thus, our results have the potential to enhance both a psychological understanding of behavior as well as economics models with importance at the micro and macro levels." %}

Pfanzagl, Johann (1959) "*Die Axiomatischen Grundlagen einer Allgemeinen Theorie des Messens.*" Physica-Verlag, Vienna. Elaborated in Pfanzagl, Johann (1968) "*Theory of Measurement.*" Physica-Verlag, Vienna.

{% Pfanzagl is absolutely brilliant, and so is this paper, with mature and deep writing on measurement. Advanced results on the bisymmetry axiom, how that axiomatizes subjective expected utility etc. Everything is then restricted to two-outcome acts.

When reading p. 284 on the operation o in a o b (also denoted as F(a,b)): imagine an event E is given. a o b then denotes a certainty equivalent, being the sure amount equivalent to the prospect (E:a; not-E:b). So,

a o b = F(a,b) = CE(E:a; not-E:b)

a o b ~ (E:a; not-E:b)

Then Theorem 1 is a characterizations of subjective expected utility. a --> a* denotes the utility function. More precisely, it is Theorem 1 together with the assumption of reflexivity on p. 285 3rd para (to normalize probabilities). So, Pfanzagl was one of the first to characterize subjective expected utility, and the first to do it with continuity of utility, which in economics is natural!

For intertemporal choice: imagine two fixed timepoints, say today and tomorrow. a o b relates to the consumption of a today and b tomorrow and is, more precisely, the constant consumption c such that c today and c tomorrow is equivalent to a today and b tomorrow. It is the constant-consumption-equivalent. Then the theorems you see there amount to characterizations of discounted utility.

Pfanzagl in his 1968 book only uses topological connectedness, not top. separability, so, immediately understood that top. separability can be dispensed with. This insight was lost for some time after, because of Debreu (1960) and Gorman (1968) and others who did assume topological separability, but it was rediscovered by Krantz et al. (1971), and was propagated by people including me.

Theorem 2 considers bisymmetry (event-commutativity as Chew (1989) called it) for two-outcome acts with different events involved, characterizing that they have the same utility function so that it really is RDU-with-symmetry (SEU for fixed event but additivity of probability need not hold otherwise) when restricted to only binary acts that may relate to different events.

Pp. 287-288 discuss what I consider most interesting, DUU, where Pfanzagl then essentially is giving Savage's (1954) SEU for two states of nature, even for all binary acts.

biseparable utility: P. 287 has it, but (see end of 3rd para) only for symmetric nonadditive measures and probability transformations, (w(p) = 1−w(1−p)), so that no rank-dependent restriction needs to be added. He calls w(p) subjective probability. **binary prospects identify U and W**: writes: "In spite of that, they permit us to derive all relevant results concerning the scale of utility." Then he goes on to do biseparable utility for uncertainty, for the special case of a symmetric maybe nonadditive measure although he does not say this explicitly. P. 287 bottom goes on to do the same thing done before for probabilities, now doing it for an event. P. 288 gives all the axioms that axiomatize biseparable utility with a nonadditive symmetric measure. He does not write the model itself, but it is evident from replacing probabilities on the previous page by events. The bottom of the page shows that a violation of symmetry, discussed only for a fifty-fifty event, violates his axioms.

Pfanzagl is overly pessimistic in claiming that the construction of utility then is impossible. Nowadays (1996 and after) we know that comonotonic versions of axioms will still hold. Wakker & Deneffe (1996) showed that the construction of utility then can still be done.

P. 288 already describes the nice dynamic interpretation of bisymmetry if the events can be repeated independently that is also in Segal (1993, JME, "order indifference"), Luce (1988, JRU 1, Eqs. 22 and 23), and Luce (1998, JRU, "event commutativity").

Pp. 289-290 discuss constant absolute risk aversion (called consistency) and the crucial role of what is taken as a fixed or variable status quo (he uses this term status quo). There are several discussions of empirical and psychological studies, Mosteller & Nogee (1951), Stevens, etc.

Para on pp. 289-290: Pfanzagl tries to discuss the role of initial wealth or, maybe, reference dependence. Unfortunately, the text is incomprehensible because of the many undefined terms such as “money in front of the subject,” “available amount of money,” “money held by the subject,” “money in his pocket,” “money immediately involved in playing,” and in next para: “status quo,” “net outcomes.” In general, we have

W = R+ c

where W denotes final wealth, R denotes reference outcome, and c change w.r.t. reference outcome. Usually R is taken as a real number, as I will do, and not as a random variable or anything. Usually, in one choice situation, R is fixed there but c and W can take several values within and between lotteries, but I will write singular W and c mostly. If one investigates dependency on one of these variables, say c, by varying c, one has to specify which of the other two variables covaries and which is kept constant (if any). Authors commonly do not do that, leading to many ambiguous texts. Reference independence means that changes in R with c covarying and W kept fixed do not affect preferences, i.e., preferences depend only on W. Kahneman & Tversky (1979) assumed that changes in R and W, keeping c fixed, do not affect preferences (but only approximately so if the changes in R are not big, as they point out). Then preferences depend only on c. The para also discusses whether utility (curvature) changes, but then it is relevant to know if c or something else is argument, and if c is, whether W (mostly) or R covaries with c, and which of W and R is constant. Pfanzagl discusses the role of constant absolute risk aversion, or consistency as he calls it. I assume that he assumes here that preferences depend only on final wealth, i.e., reference independence. Then it means that adding constants to W, R, and c (keeping the equality) do not affect preferences. In particular, if we know only c and not R/W, then that is fine.

Theorem 3, p. 290, characterizes linear/exponential (CARA) family through constant absolute risk aversion. This was done before in mathematics, not related to decision theory, by Nagumo (1930 p. 78, stating sufficiency, but proof also stating necessity) and Hardy, Littlewood, & Pòlya (1934, Theorem 84, for log-power utility). %}

Pfanzagl, Johann (1959) “A General Theory of Measurement—Applications to Utility,” *Naval Research Logistics Quarterly* 6, 283–294.

{% Characterizes a functional as being a conditional expected value, with no utility involved ("linear utility"). %}

Pfanzagl, Johann (1967) "Characterizations of Conditional Expectations," *Annals of Mathematical Statistics* 38, 415–421.

{% I could only see the abstract, but it suggests the following. First, he points out that to measure subjective probabilities people usually use objective probabilities. Either to derive utility for instance using standard gambles, or to use matching probabilities. But Pfanzagl can do it using the bisymmetry technique of his 1959 paper, without assuming objective probabilities. %}

Pfanzagl, Johann (1967) "Subjective Probability Derived from the Morgenstern-von Neumann Utility Concept." *In* Martin Shubik (1967, ed.) "*Essays in Mathematical Economics in Honor of Oskar Morgenstern*," Princeton University Press, Princeton, NJ, 237–251.

{% An elaborated version of his 1959 book, translated by himself, with help (also in content) by Volker Baumann and H. Huber.

§1.10 distinguishes between fundamental and derived measurement: "… we can define fundamental measurement as the construction of scales by mapping an empirical relational system isomorphically into a numerical relational system. Derived measurement, on the other hand, derives a new scale from other given scales."

Lemma 3.5.9: an ordered set is connected w.r.t. order topology iff it has no gaps (a ≺ b but (a,b) is empty) and is order-complete (each nonempty subset with lower bound has infimum, or, equivalently, each nonempty subset with upper bound has supremum).

Corollary 5.4.2: if X is connected and an operation * is cancelable and continuous, then autodistributivity ((a*b)*c = (a*c) * (b*c)) implies bisymmetry. Cancelability is something like antisymmetry plus strict monotonicity. Formally, it means that a*b is 1-1 (injective) in each of its variables, at whatever level the other variable is fixed.

P. 107: the only weak point I discovered in this phantastic book so far: he writes Archimedian instead of Archimedean.

criticizing the dangerous role of technical axioms such as continuity: §6.6

(pp. 107-108) has a good discussion of, and even formal theorems on, the dangerous empirical status of technical (Pfanzagl says objectionable if finite observations cannot falsify) axioms such as continuity and solvability, often overlooked. (Remark on p. 111 gives another nice statement.) Definition 6.6.3 gives a definition of "technical" as Pfanzagl calls it. In the presence of other axioms, they do have empirical content but it may not be clear what that content is. See also §9.1 of Krantz et al. (1971). A strengthening of Adams, Fagot, & Robinson (1970, at the time of Pfanzagl's book unpublished) is given. §9.5 will explain that continuity is dangerous in adding empirical implications. Theorem 9.5.5 suggests that continuity w.r.t. connected topology does not add further dangerous implications to strong solvability.

tradeoff method: Def. 8.6.8 is in fact a version of the $\succcurlyeq^*$ relation defined in my book Wakker (1989) and used in what I call TO consistency nowadays (after 2005). The definition of F_{12} implies that

$(c_1, F_{12}(c_1)) \sim (d_1, F_{12}(d_1))$, and this together with $(a_1, F_{12}(c_1)) \leq' (b_1, F_{12}(d_1))$ ($\leq'$ denoting reversed preference) makes Pfanzagl write $a_1b_1 \leq' c_1d_1$, where I would write $a_1b_1 \leq'^* c_1d_1$ in my 1989 book and $a_1b_1 \leq'^{t} c_1d_1$ in my 2010 book (were it not that in the latter I only consider indifferences $\sim'^{t}$). Note that Pfanzagl's solution condition entails a strong solvability condition.

Pfanzagl pleas for this approach with tradeoffs (called distances in his terminology). Remark 9.4.5 ends with: "We are of the opinion that the indirect way over distances makes the whole approach more intuitive." (**tradeoff method**)

Ch. 12 does DUU in a multistage setup. Sure-thing principle is formulated as monotonicity, together with a "lack of illusion" condition that apparently entails **RCLA**, it entails the known things.

Axiom 12.5.2 assumes that for each event there exists another independent event, where independence means that conditioning does not affect preference.

biseparable utility: Corollary 12.5.8 (p. 211) has it only for additive measures S, with additivity proved in Theorem 12.5.9, and later conditions given that subjective probability agree with objective if existing. The text is restricted to repeatable events and compound gambles, although it could have been restricted to static gambles and certainty-equivalent substitution. %}

{% My comments concern the 1957 English translation. Funny examples of "conservation errors" in physics. Suppose liquid is poured from one form into another. Children under 7 will not recognize that the amount was unchanged.

conservation of influence: p. 213 2nd para: "without conservation of totalities" (about children up to seven years of age). Throughout the book, the term irreversibility is used as something crucial for randomness, but I hardly understood more of the term than that it means randomness. First children have to get a concept of implication, then that implication does not work 100%, so there is unpredictability, then they can get some awareness of chance. §X.2, p. 216 etc., argues that in many ways babies, like even the most primitive animals, can exhibit behavior adapted to chance, but this is animal spirit not real awareness. P. 217 2nd para: “But it would be idle to draw from these functional analogies a structural identity and to attribute to the nursing infant operative structures, whether deductive or probabilistic.”

Stage I is from 4 to 7, stage 2 from 7 to 11, stage/level 3 after 11. Stage I is subdivided into level I A and I B. Stage I consists of levels I A and I B, stage II also consists of levels II A and II B, stage III/level III is not subdivided I guess.

Ch. VI (pp 131-160):
“The Quantification of Probabilities.”

P. 131: “On the other hand, the progress supposes the gradual ability to establish a relationship between the individual cases and the whole distribution;” For the frequentist understanding of probability, the heads coming up on different tosses of a coin, different individual events, must indeed be grouped together and the child must be able to do that mentally.

P. 132 2nd para gives a nice description of the growing awareness of numerical probability. Also on p. 133 last para (on level I B: “or there is an intuitive comparison deriving from the perception of striking disproportionalities”).

Level I A understands that things can be unpredictable (“chance”). See, for example, §X.2, p. 218, “From the functional point of view, there is certainly at this time a notion which performs the function of the possible, and this is precisely the idea that the near future is made up of events which one is not certain that he can anticipate.” P. 138 last para, on level I A: “If the child had the least bit of quantified probabilistic intuition,” I think that somewhere else there is a text that the child neither distinguishes quantitatively nor qualitatively. A little bit of differentiation between different levels of likelihood arises at level I B, see p. 133 last para (on level I B: “or there is an intuitive comparison deriving from the perception of striking disproportionalities”). Level II knows that 4 out of 7 is more likely than 3 out of seven or 4 out of 8, but cannot compare 4 out of 7 to 2 out of 6. Note that the perception is not just a function of objective probability because 1/2 = 5/10 need not be understood. P. 228, 2nd para, on level II: “This again is easily explained as a function of operative development.”

Level III can distinguish numerical probabilities well. So, level I A is **principle of complete ignorance** (three-valued logic) where there is, in the terminology of decision theory, true, untrue, or possible.

My claim seems to be contradicted by several writings by Piaget & Inhelder that children at stage I cannot differentiate between the possible and the necessary. For example, this is the title of §X.2 on p. 216. However, the second half of the second para on p. 218 shows that Piaget & Inhelder consider possibility only understood if some logical operations like complementarity and their interaction with possible are also understood. So, he uses the term possible in a more restrictive sense. See also third para of p. 214 and the last para of §X.3, on p. 230. %}

{% **three-doors problem**: The author tries to discuss it but, ironically, does not understand it himself. Here is his incorrect description of the problem in his

opening para:

“One of the most famous television game shows from the heyday of the genre from the 1950s to the 1980s was Let’s Make a Deal. Its host, Monty Hall, achieved a second kind of fame when a dilemma in probability theory, loosely based on the show, was named after him. A contestant is faced with three doors. Behind one of them is a sleek new car. Behind the other two are goats. The contestant picks a door, say Door 1. To build suspense, Monty opens one of the other two doors, say Door 3, revealing a goat. To build the suspense still further, he gives the contestant an opportunity either to stick with their original choice or to switch to the unopened door. You are the contestant. What should you do?”

People well-versed in probability theory and statistics know that to determine a conditional probability one should not only be informed about the value observed, but also about what information one would have received in other, counterfactual, events. That is, one should know the whole random variable one is informed about. In this case, one should know the strategy of the quizmaster Monty. In particular, in the counterfactual event that the prize (car) had been behind door 3, could Monty have opened that door still? As a first and strongest counterexample to Pinker’s analysis assume that, whenever one of the remaining doors contains a prize, the quiz master will open that door, showing the contestant that the initial door chosen is wrong. Only if none of the remaining doors contains the prize, will the quiz master open one of those two. Under this quiz master strategy, the contestant definitely should not switch! For a second counterexample and most plausible case, assume that the quiz master just randomly opens a door, and it is coincidence whether or not it contains the prize. Then switching is no use and the door chosen, Door 1 does have probability 0.5 of having the prize. This is the most plausible interpretation of Pinker’s text in the absence of other info and, hence, the answer that Pinker qualifies as incorrect is in fact the most plausible answer.

In the Monty Hall problem things are different from the above two examples of quiz master strategies. Here the quiz master strategy is to always open a door with no prize behind; he has the info to so so. Only if one knows this (and that 50-50 randomization if the two doors not chosen both have no prize) can one solve the problem, and see that switching is good. Pinker’s account does not state Monty’s strategy and is faulty. He repeats the mistake later in his example of divine intervention, showing that he really does not understand the aforementioned fact of probability theory and statistics.

I commonly use one sentence to explain the case of Monty Halls's problem to people: "If one switches one wins the prize whenever one started at a wrong door." %}

Pinker, Steven (2021) "Why You Should Always Switch: The Monty Hall Problem (Finally) Explained," https://behavioralscientist.org/steven-pinker-rationality-why-you-should-always-switch-the-monty-hall-problem-finally-explained/

{% **Dutch book**; **ordered vector space**

Considers a preference relation on a product set X^I with I an infinite set, implying infinite dimensions. And then additive representations, many without an Archimedean axiom and with nonstandard real numbers. The paper gives a valuable collection of references to related works in intertemporal choice, decision under uncertainty, welfare, and so on. This paper considers additive representation with symmetry. It considers preferences between sequences that differ only on finitely many dimensions, so that the overtaking criterion can be used ($x > y$ iff SUM_i$\big(U(x_i)–U(y_i)\big) > 0$). U can take values in extended versions of $\mathbb{R}$, in Abelian ordered groups. Cites Hahn's embedding theorem (p. 56) mapping it into a lexicographically ordered vector space.

Necessary and sufficient conditions for additive representation are joint independence (= separability = sure-thing principle) and symmetry. At first I was surprised that this can be done with no richness such as connected-continuity or solvability in the outcome space or state space. But then I realized that the infinite symmetric coordinates generate additions of any length. We can calibrate U(x)/U(y) versus the rational number m/n by considering the preference between n states with x and m states with y. So, this gives an equivalent of richness in the state space.

P. 32, **criticizing the dangerous role of technical axioms such as continuity**: the author explains this.

P. 35 Example (ii): if infinitely many states are equally likely (by symmetry), and acts differ on only finitely many of them, then acts differ only on null sets.

Proposition 5(a) is Theorem 1.1 of Wakker (1986, Theory and Decision).

P. 40 gives Hölder's theorem. %}

{% Axiomatizes discounted utility when intertemporal profiles have to be continuous in time; this can be only on subsets of the time axis. A natural setup and amazing that it wasn't done before. %}

Pivato, Marcus (2021) "Intertemporal Choice with Continuity Constraints," *Mathematics of Operations Research* 46, 1203–1229.

{% The author axiomatizes maximization of Cesàro Averages of utility (CA). Let (x_1, x_2, …) be an infinite sequence.

$$\mathrm{Lim}_{n\to\infty} \sum_{j=1}^{n} u(x_j)$$

is the CA. The author only considers a restricted domain of "regular totally bounded" sequences and imposes invariance under "Levy" permutations, which can handle infinite sequences. He also imposes continuity w.r.t. a connected metric copology. I conjecture that the results of Kothiyal, Spinu, & Wakker (2014) can be used to handle completely general outcome sets X, with no continuity needed, as follows. Identify any finite sequence (x_1,…,x_n) with the

infinite sequence consisting of infinitely many repetitions of it. This way the domain of Kothiyal et al. is isomorphic to the subdomain consisting of all "periodic" sequences. The theorem of Kothiyal et al. gives necessary and sufficient conditions for maximization of CA (Cesàro average) here in full generality. Remains addition of a preference condition, capturing some sort of denseness, to extend it to the whole space. %}

Pivato, Marcus (2022) "A Characterization of Cesàro Average Utility," *Journal of Economic Theory* 201 105440.

{% Following up on Harsanyi (1955), when the individuals may have subjective probabilities that are different. Mongin (1995) gave an impossibility result, but Gilboa, Samet, & Schmeidler (2004) gave a possibility result by weakening Pareto to the case of identical beliefs. This paper examines such situations with new info arriving and updating. (**updating: discussing conditional probability and/or updating**:) Then "eventual" (long-run) Pareto gives eventual utilitarianism. %}

Pivato, Marcus (2022) "Bayesian Social Aggregation with Accumulating Evidence," *Journal of Economic Theory* 200, 105399.

{% This paper considers sets of preference relations and topologies on them. Relevant for instance if you are not sure about what the true preference relation is and want to talk about small deviations, a neighborhood of some preference relation. The paper links local continuous quasiorders to continuous strict partial orders. %}

Pivato, Marcus (2023) "Compact Spaces of Continuous Preferences," working paper.

{% They generalize a nice result of Mongin & Pivato (2015) on weighted utility in matixes. Say that uncertainty and persons are involved, that x_{ij} is the outcome for the ith person if the jth state of nature is true, and that utilitarian expected utility is maximized, necessitating the same subjective probabilities for every person. They formulate this as an impossibility theorem, in the sense that it is impossible for the persons to have different subjective probabilities, as in the classic Mongin (1995). They now allow for nonmonetary outcomes and non-Archimedean representations into Abelian groups. This is empirically and conceptually preferable but has the drawback that most researchers are not familiar with these concept, unfortunately. They also allow for state- and person-dependence of utility, in fact handling general additive composability, generalizing what has sometimes been called the theorem of aggregation (Nataf 1948). They generalize continuity into solvability, albeit unrestricted solvability which will imply two-sided unboundedness of the various utility functions. I expect that this could be avoided by taking restricted solvability. They also assume the existence of certainty equivalents. They also relax completeness somewhat, although the solvability axiom then is very restrictive. %}

Pivato, Marcus & Élise Flore Tchouante (2024) "Bayesian Social Aggregation with Non-Archimedean Utilities and Probabilities," *Economic Theory* 77, 561–595. https://doi.org/10.1007/s00199-023-01509-w

{% Consider aggregation over two components: states of the world and persons. That is, when welfare and uncertainty are both concerns, where there is ambiguity nonneutrality. They consider weakenings of weak separability/monotonicity, e.g., only when almost objective uncertainty. Then consider aggregation-(im)possibility as with Mongin (1995) and others. %}

{% **free will/determinism** %}

Pleasants, Nigel (2018) "Free Will, Determinism and the "Problem" of Structure and Agency in the Social Sciences," *Philosophy of the Social Sciences* 49, 3–30.

{% The authors argue and extensively document that in real-life decisions for gains the correlation between probabilities and outcomes usually is negative: High probabilities occur with low probabilities. P. 2013 ff. argues and documents that for laboratory experiment of risk attitudes there is no such relation. This effect can contribute to ambiguity aversion, and this becoming stronger as outcomes get higher. An experiment, study 3, p. 2010 ff., confirms it. I think that this finding is of special interest to DFE, but the authors do not discuss it.

On p. 2008 ℓ. −3 (reproduced below) and elsewhere (e.g. p. 2001) the authors incorrectly suggest that the dependence between probabilities and outcomes that they have found be inconsistent with common theories such as Savage (1954), who assumed that probabilities of events are independent of outcomes. But Savage's independence was mathematical, which is completely and totally different than empirical/stochastic independence. The authors are simply concusing these two concepts and, on the basis of this confusion, criticize common theories such as Savage's and claim novelty. Savage's independence concerns a mathematical independence *once the event capturing all relevant uncertainty has been completely specified*, and is a completely different concept. It would be absurd if Savage had claimed that high outcomes empirically occur as often with high probabilities as with low probabilities, but yet this is what the authors in fact claim.

The confusion is suggested by their text on p. 2002 when the authors write:

"It is these properties of intercue relationships and substitutability [empirical dependence of probability on outcome] that we suggest offer a *new* perspective on how people make decisions under uncertainty. Under uncertainty, cues such as the payoffs associated with different courses of actions may be accessible, whereas other cues—in this case, the probability with which those payoffs occur—are not. This missing probability information has been *problematic* for choice theories as typically both payoffs and probabilities are used in determining the value of options and in choosing" [italics added]

The confusion becomes completely apparent on p. 2008 when the authors write:

"The risk–reward heuristic envisions that when faced with choice under uncertainty people infer that the probability of an event is negatively related with the magnitude of the payoffs. This view conflicts [??] with other hypotheses about the relationship between these two variables during decision making. For instance, according to subjective expected utility theory (Savage, 1954)—the normative account of how people ought to make these decisions— payoffs and probabilities are two *independent* [this is mathematical independence, and the authors are confusing it with empirical independence] factors that determine the value of an alternative and, ultimately, choice. That is, the utility of an alternative that yields outcome x if the event A occurs otherwise 0, (x, A), is

$$u(x, A) = p(A)\cdot u(x) + p(\sim A)\cdot u(0) = p(A)\cdot u(x) \qquad (4)$$

where event A is a subset of possible states of the world S, $A \subset S$. The u is the utility function describing the subjective value of those consequences. The p is a probability measure on the state space S and reflects the decision maker's subjective beliefs about the likelihood of different states of the world occurring. However, note that the probability is based on the event only and not on the consequence of the event. Consequently, in subjective utility theory, payoffs and probabilities are ultimately compensating but not interacting [again, this is mathematical independence but the authors are confusing it with empirical independence] factors in determining the value of the alternative. Thus, if subjective expected utility theory is taken at first approximation as a descriptive theory of choice, then a consequence of this independence assumption is that the probabilities people use to make decisions under uncertainty must be estimated independently of the magnitudes of the payoffs." [italics from original]

The authors add here a footnote 10, which displays the same confusion and does not help:

"It is important to emphasize that Savage's (1954) subjective expected utility theory is a theory of choice. Utilities and probabilities are derived from preferences over acts. It does not explicitly state how probabilities are to be calculated. It does assume payoffs and probabilities are two independent constructs that determine the value of the construct. For this reason, we have stated the independence prediction—that probabilities be estimated independently from the magnitude of the payoffs—as a consequence that follows from the theory." %}

{% Many papers have demonstrated loss aversion and the endowment effect, finding loss aversion parameters of 2.25 etc. These studies have usually been designed to be optimal for the presence and detection of the effect, where framings must be properly chosen and, given the irrationality of the effects mentioned, subjects are not understanding things at a high level of rationality. It is first-gut preferences that are being examined in such studies. Nowadays (1980-2023), many studies have come to overstate their case, as if loss aversion were ubiquitous. Then it is useful that there come a counterreaction, showing that loss aversion need not arise under proper framing and instructions. Although the latter point is in fact trivial, it is useful that it be demonstrated very explicitly in these days. This paper provides such a demonstration.

As the loss aversion papers have sometimes gone too far, this paper goes too far in the opposite direction by claiming that loss aversion is only misconception and, "hence," not worth studying, and that prospect theory and the endowment effect are, consequently, not valid theories. This, obviously, is an overstatement. Prospect theory and the endowment effect are theories about misconceptions

(which contradicts the claim of Plott & Zeiler (2005) in several places, e.g. p. 531 2nd column second para, of such theories not existing) occurring in gut-feeling preferences. These exist, affect economic phenomena, and or worthy of study also by economists just as well as the sophisticated preferences that are Plott's primary interest. For prescriptive purposes the sophisticated Plott-interest-preferences are more important than the gut-feeling Kahneman-interest-preferences. I am, accordingly, more interested in the Plott-preferences, but both kinds are interesting and worth being studied.

random incentive system: p. 534 footnote 5, bringing the old Holt (1986) argument, shows that the authors, as so many other experimental economists, are not up to date on the random incentive system, the incentive system used by Holt & Laury (2002, American Economic Review), Harrison, Lau, & Williams (2002, American Economic Review), and many others.

Pp. 537-538 is nice statement of how subjects who do not understand the instructions can behave strategically even if irrational in WTP-WTA.

The conclusions of this paper are based on acceptance of null hypotheses under big variance, which is overstated several times (e.g. p. 542, end of §III, "allows us to reject strongly the hypothesis that …"). P. 541, 2nd column, top, to the contrary, nicely has a rejection of loss aversion exceeding 2.

Seem to criticize BDM (Becker-DeGroot-Marschak). %}

{% **updating: testing Bayes’ formula**: Urn with 20 balls has X yellow balls, with X unknown to subjects. Subjects are asked to guess X, receiving rewards if their guess is right. So, they should choose the most likely value X. All values of X have the same (2^{nd} order) probability 1/21 of being that. So, in principle subjects can calculate the optimal replies, using Bayes formula, in what follows. But, as is well known, they don’t.

Subjects observe a sample and then guess X. Next they get extra info about X being ≥ 10 or < 10, and can readjust. If the new info contradicts their original estimate, the extra info improves their guess. Paradoxically, if the new info confirms their original estimate, it worsens their predictions. %}

{% This paper considers revealed preferences between lotteries, so, probability distributions over money (only ≥ 0) with known probabilities (risk). Choice sets are compact sets. I think that in the main results those sets are what is called comprehensive in bargaining game theory: with every lottery, they also contain all lotteries stochastically dominated by that lottery in the sense of worsening outcomes (the use the term downward extension). It is important that they don’t consider only choices from linear budget sets, as often done in other papers, but general compact sets. (Because of it, they can’t use first-order conditions as other

papers do.) This is very desirable. Many papers consider linear budget sets, only because those are so familiar to economists working on consumer choice in markets with prices. But such sets are not at all very natural in other contexts. For risky decisions, they do appear in financial markets, but this comprises only a small part of human decisions under risk. Further, those linear budget sets do not give good discriminatory power to distinguish theories and, for instance, usually cannot identify nonconvex preferences. The authors mention this on p. 1787.

What the authors call the GRID (Generalized Restriction of Infinite Domains) method is based on their Theorem 1. Basically, it says that we have to consider only outcomes that occurred in a lottery chosen as best in some choice situation.

We assume a continuous preference functional assigning to each lottery $(p_1;x_1,\ldots,p_n;x_n)$ the value $\Phi(p_1,u(x_1),\ldots,p_n,u(x_n))$, where Φ has a number of free (subjective) parameters still to be determined, u (utility) being one of them. For instance, Φ is expected utility and then there is no other free parameter besides u. Or Φ is disappointment aversion theory and then there is $\beta\in\mathbb{R}$, the disappointment aversion parameter, as extra parameter. Or Φ is rank-dependent utility, and then the probability weighting function w is an extra free parameter.

Essential for Theorem 1 is that u can be any strictly increasing continuous function. We assume strict stochastic dominance, with Φ strictly increasing in each $u(x_j)$. The authors discuss the pros of this generality, of, for instance, also allowing for convex utility. There are both pros and cons to generality. Assume we observed finitely many, k, choices, from compact choice sets, maximizing Φ. Here each choice is singleton, and concerns only one element selected from the subset of best elements, which is nonempty because of compactness (and assumed continuity).

For Theorem 1, define X as the union of the support of the k lotteries chosen from some choice set (with added the minimal outcome 0, something which I ignore for now). So, it contains all outcomes that appeared in at least one chosen lottery. X is finite. L_X denotes the set of lotteries contained in at least one choice set that have support in X. Then there exists a Φ representing all choices if and only if there exists one when we only consider L_X. The authors provide a mathematical proof in the appendix, with induction with respect to the maximal number of outcomes in a lottery. I next give a verbal account of the gist of the proof, skipping technicalities: Take the solution restricted to L_X, and u restricted to X, where it is strictly increasing. We have to extend u to $\mathbb{R}$. All we have to do is let Φ be as bad as possible for all lotteries not yet covered, making sure that they were never chosen. We thus first take u*, the minimal nondecreasing extension of f to $\mathbb{R}$. That is, $u^*(\alpha) = \sup\{u(\beta): \beta \in X, \beta \leq \alpha\}$. Strict increasingness and avoidance of $u^* = -\infty$ will be discussed later. Using u* in Φ, all choices are properly represented: if a lottery was not covered before (support not in X), then its Φ value is equal to the best element of L_X dominated, and that was not chosen.

Technicalities remaining in the above proof are to moderate u* slightly to make it strictly increasing and to avoid values $-\infty$. For the latter, we must avoid the "driven-to-infinity" problem, which would happen for instance under EU if we had $1 \succ (1-p{:}2, p{:}0)$ for all $p > 0$, with all those lotteries contained in some compact choice set. This is handled by the authors' assumption that there is a minimal outcome 0 and that it is already contained in X.

P. 1783 writes, on nonparametric fitting: "This is empirically important because if we happen to find that a dataset is incompatible with a given model, then we can safely conclude that this incompatibility is attributable to the model itself rather than a poorly selected parametric form."

P. 1785 suggests that the GRID method can also be used for uncertainty.

The authors use their method to reanalyze three existing data sets.

They use Afriat's index to measure distances and for fitting. They find that most subjects satisfy GARP, i.e., transitivity & stoch. dominance. Of those, about half can be fitted by EU. Disappointment aversion does not give more fit, but RDU does, The good performance of EU may be because it is taken very general, allowing any utility function, and the stimuli have not been targeted to discriminate theories. In particular, no very small or large probabilities were involved. %}

{% Analyze the famous deal-or-no-deal show, where there are risky decisions with real incentives for hundreds of thousands of dollars. Qualitatively, they find that subjects become more risk seeking both by prior losses (break-even) and by prior gains (house-money effect).

They find expected utility rejected (p. 57 ℓ. –6). Prospect theory with some

assumptions about reference points (e.g. p. 61 2nd para) explains the data well. For simplicity, they do not incorporate probability weighting (p. 62 3rd para). Reference points are path-dependent in the sense of being affected by prior gains or losses. Had the authors analyzed only the shows of one country, they could not have concluded this because prior gains or losses are then inextrically correlated with remaining stakes. They, however, analyzed different countries and did separate experiments that use different stakes so that they could compare people who face the same future stakes but some with prior gains and others with prior losses.

There are some weird sentences stating that they do not accept or reject EU or any other theory (p. 40 penultimate para, p. 67 bottom), where EU is defended by the possibility of choosing strange utility functions (with convex segments and depending on prior gains, the latter being in fact prospect theory framing with reference dependence and not EU). However, there are oceans of literature, since Friedman & Savage (1948) showing that such functions are no good, so the statements are absurd. One of the authors told me they added these claims reluctantly because one referee insisted much on it. Another illustration that referees have too much power in the present system.

decreasing ARA/increasing RRA: they find it confirmed (p. 45 bottom, p. 46)

§4: in EU analysis, they use expo-power utility with initial wealth just as additional free parameter (p. 52 end of 1st para).

NonEU in dynamic situations is done through backward induction. %}

Post, Thierry, Martijn van den Assem, Guido Baltussen, & Richard Thaler (2008) “Deal or No Deal? Decision Making under Risk in a Large-Payoff Game Show,” *American Economic Review* 98, 38–71.

{% Subjects are daily investors in stock trading floors of brokerage houses in China. Consider two outcomes, good (U=1) or bad (U=0). For risk, they assume EU. For ambiguity, let us assume the whole set of probabilities, so that a gamble is valued by (1−α). If they find the objective probability p of getting the good prize that is equivalent, then immediately we have 1−α = p, so we, can measure α without having to measure risk attitude. It can similarly be done if the set of priors is a set other than the set of all known probabilities, e.g., [0.20, 0.70], as done in this paper (p. 199 sugests [20,70] but other parts suggest [30, 70]). Finding the p is in fact finding a matching probability. The authors give a somewhat complex derivation (§3), but it can be as simple as just stated (easily extended to [0.20, 0.70]). Dimmock, Kouwenberg, & Wakker (2016, Theorem 3.1) showed more generally that matching probabilities are easy tools to measure ambiguity attitudes. I regret now that we did not know about this paper, which I read only in March 2019, because I would have liked to cite it for partial priority here.

Risk aversion is measured through the CRRA index. **correlation risk & ambiguity attitude**: find a weakly positive relation (p. 209).

Anxious subjects are more risk averse. Subjects with higher school education are both more risk averse and more ambiguity averse. Income and wealth and gender have no effect. %}

correlation risk & ambiguity attitude: Although they have data, they do not report on this point. Seems they found women also to be more ambiguity averse, but I could not find it stated clearly. %}

Powell, Melanie & David Ansic (1997) "Gender Differences in Risk Behaviour in Financial Decision-Making: An Experimental Analysis," *Journal of Economic Psychology* 18, 605–628.

{% They gathered six focus groups with 30 members of the UK adults to come together three weekends, and discuss evaluations of health states. They focused the discussion on the question of whether one better consult the general public using hypothetical health states, or patients who experienced the health state. They conclude that the UK public is against evaluations by the general public using hypothetical health states.

The paper is in the spirit of the constructive view of preference, as I like it ("get more out of fewer subjects" by more interviewer influence). But it does not focus on what the evaluations of health states then can be (which would be the central topic of utility measurement using the constructive approach or whatever, and is my central interest), but instead on the meta-question of how the general public thinks about the measurement/policy question of which method to use. This study is still useful in weakening the argument, often put up for using the general public with hypothetical descriptions because they are paying (through taxes), that the general public does not seem to feel it that way. %}

{% **inverse S**; **tradeoff method**: in Appendix 1;

Introduces some parametric families for probability transformations.

The most interesting, and by far most popular, family is the two-parameter CI. (compound invariance),

$w(p) = [\exp(-(-\ln p)^{\alpha})]^{\beta}$, $0 < \alpha < 1$, $\beta > 0$.

Expected utility results for $\alpha = \beta = 1$. The smaller α the more inverse S-shaped it is, the higher β the lower (more pessimistic) the curve. It is an affine transformation at the level $-\ln(-\ln(p))$.) It satisfies subproportionality making it suited for very small probabilities, but also performs well, giving nice inverse S-shape, for not-very-small probabilities. Remarkably, this good empirical family also has a preference axiomatization. It also has other nice analytical properties.

Big drawback is that the parameter α, meant to capture insensitivity, also impacts optimism/pessimism. Garphical illustrations can show this. The following calculations also can: Set the pessimism index β at its neutrality level $\beta = 1$, and α at its empirically prevailing level of $\alpha = 0.65$. Then for all nonextreme probabilities $0.05 \le p \le 0.95$, we have $1 - w(p) - w(1-p) > 0$, with a maximal value 0.09 at $p = 0.50$, showing pessimism. For the extreme probabilities $|p| \le 0.04$ slight optimism is generated.

Unfortunately, Prelec promotes the one-parameter family with $\beta = 1$. I think that the two-parameter family is the most important one.

Definition 1 (compound invariance) should be restricted to nonzero outcomes and probabilities. $x = y = x' = 0 = p = q = r$ and $y' = 1 = s$ and $s = y' = 1$ provide a counterexample to the condition with 0 probabilities. (Restricting to only nonzero outcomes or to only nonzero probabilities will also work.)

(First version: Prelec, Drazen (1989) "On the Shape of the Decision Weight Function," Harvard Business School, Harvard University, Cambridge, MA, USA.)

In the CI family, the two parameters are not very well separated. The α parameter, supposed to capture insensitivity, also somewhat affects elevation. This can be seen from Wakker (2010 Figure 7.2.2). For the figures with $\beta = 1$, the fourth (outer right) figure with $\alpha = 0.35$ has the curve on average lower than the second figure with $\alpha = 1$ (EU). So, with β fixed, lowering α led to some decrease of elevation. In this regard the Goldstein-Einhorn (1987) family is better (Wakker 2010 Figure 7.2.3). %}

{% **DC = stationarity**, p. 512 top, but bottom properly mentions the assumption of time invariance “and who resets the zero on the discount function when the next decision arrives”

Footnote 1 p. 513 lists empirical violations of stationarity; p. 516 bottom: Hybrid model. Considers Pratt-Arrow concavity of log of discount function as index of impatience. The paper throughout treats stationarity and dynamic consistency as if equivalent.

P. 526, end of §VI, suggests that time perception may be driven by the numerosity effect. It does not use the term numerosity effect, and refers only to Rubinstein’s similarity model, but it is in fact a general argument for the numerosity effect. %}

Prelec, Drazen (2004) “Decreasing Impatience: A Criterion for Non-Stationary Time Preference and “Hyperbolic” Discounting,” *Scandinavian Journal of Economics* 106, 511–532.

{% Prelec (personal communication) credits Shane Frederick for having invented the term truth serum to describe **proper scoring rules**.

probability elicitation. A large group of people all start from the same state of info (common prior à la Harsanyi 1988; logical view of probability à la Carnap). The only difference between people is which one of m possible signals each received. $t^r_i = 1$ means that person r received signal i (so, t can stand for True signal). Then $t^r_j = 0$ for all $j \neq i$. Each person is asked to report his signal, where they can lie if they want. $x^r_j = 1$ means that person r reports signal j. Then $x^r_i = 0$ for all $i \neq j$. $x\acute{}_k$ (denoted x_bar_k in the paper, but here on internet I cannot implement the bar notation) is the portion of the group reporting signal k; i.e., it is the average of the x^r_k over r. Every person is also asked to report an estimate of the $x\acute{}_k$. y^r_k is the estimate of person r of $x\acute{}_k$. Every person is rewarded for the y anwers and for the x answers, in the following way, where I treat only the case of $a = 1$ in Eq. 2 of Prelec. We will assume hereafter that the group is so large that a single-person’s answers do not influence the group averages. For the single-person optimization problems below, consequently, the group averages are treated as constants.

Person 1 (and every other person alike) is rewarded for his y answers through the usual (well, averaged) logarithmic proper-scoring rule reward:

$$\Sigma_k\, x'_k ln(y^1_k). \qquad (*)$$

(The *ln*'s are all negative, so, he has to pay here.) Given that the x'_k are the true population averages, it is well known that the optimal result is obtained by setting $y^1_k = x'_k$. Person 1 does not know x'_k and must use subjective estimates. It is well known that the person (under subjective expected value maximization) best gives the true subjective estimates of the x'_k's.

Person 1 also receives a positive constant amount:

$$-\Sigma_k\, x'_k ln(x'_k). \qquad (**)$$

Before we turn to the reward for person 1 for his x answer, first a notation: y'_k is the *geometric* average of y^r_k over r. That is, $ln(y'_k)$ is the average of $ln(y^r_k)$ over r. Now the reward for person 1 for his x answer is

$$ln(x'_k/y'_k) \text{ where k indicates the answer given.} \qquad (***)$$

That is, $x^1_k = 1$ and $x^1_j = 0$ for all $j \neq k$. The person should therefore seek to answer that k for which, in proportional terms, the population will mostly underestimate the true proportion. (Where they will be most surprised by the true proportion.) This paper assumes that person 1 expects the biggest underestimation by the population, so, the biggest surprise x'_k/y'_k, at his true answer of true signal k. In other words, *starting from the info that person 1 has about the others' opinions, he assumes that his private signal moves closer to the truth*. Then incentive compatibility trivially follows. The required assumptions are often not satisfied, (e.g., speaking for myself, if I like a politician then it usually is one that will receive only few votes), and this paper is to be applied only where they are. Often in case of violation something can be done such as embedding the question in more complex questions. Anyway, under the assumptions made you should honestly report your true signal.

In total person 1 receives (*) + (***), plus also the constant (**). Because the y-answer of person 1 does not affect (***) and the x-answer does not affect (*), these constitute two independent optimization problems. The one for y-answers serves only to get the true y-answer estimates from each individual, to be used in (***).

Several assumptions in this paper are questionable from the practical perspective. The assumption that apart from the private signal received and asked

in the question, everything else is common knowledge and is the same for all people, is very very restrictive. But given that, the basic idea is impressive and valuable. The rewards make people tell the truth without requiring that the events in question become observable before payment takes place. This is an impressive achievement distinguishing this paper from traditional proper scoring rules or decision-based elicitations. In principle, we can observe everything of people this way, how happy they feel, and so on. Also, it does not require observability of any prior distribution, resolving a major restriction to the application of proper scoring rules. The paper achieves these things by assuming a group process for the signals and the corresponding subjective probabilities depending on the true beliefs that make the true beliefs observable after all, because the difference between the private signal and the assumed group average is assumed to be in the direction of the believed truth. The paper applies its technique not only to observable questions/signals, where the application is clear-cut, but also to questions such as what people think is "the" or "best" probability estimate, given all the info of mankind, that mankind will survive the coming century. Such concepts of probability are not easy to imagine or think about, so that the application is less clear-cut here.

Johnson, Pratt, & Zeckhauser (1990) and others also study truth-revelation mechanisms, but a big difference seems to be that their mechanisms assume the common prior to be known, and Prelec does not need this info. %}

{% **inverse S**, intersecting diagonal at about .2 (for utility linear). Probability transformation seems to be .42 at .50!

Certainty equivalents were obtained from bidding games, each time between two persons, where the highest bidder got the prospect. This encourages subjects to bid less than the fair price and, hence, we get an overestimation of risk aversion, and strategic behavior as a horrible confound. The tendency to overbid, and winner's curse, lead to biases that reduce risk aversion.

questionnaire versus choice utility: p. 184 footnote 3: "Also by purely social scientists (e.g. J. von Neumann and O. Morgenstern, Theory of Games and Economic Behavior, 1944, 1-641). … It is interesting to note that these writers appear to hold the understanding of economic phenomena without recourse to psychological theory as a worthwhile ideal (a familiar theme for those acquainted with the efforts in psychology to understand psychological phenomena without recourse to physiological theory)."

Likelihood-sensitivity (inverse S) ordering: Unsophisticated men exhibit least, then sophisticated subjects, then women, in the sense that the first category has least overweighting of small probabilities and least underweighting of high probabilities (see Table II) (**gender differences in risk attitudes**). That sophisticated men deviate more from linearity than unsophisticated is strange, and deviates from the authors' suggestion on pp. 191 line 1 ("while it may reduce them [effects]"). It makes me wonder if the unsophisticated-men and sophisticated-subects have been interchanged in Table II.

linear utility for small stakes: They use linear utility. They justify this by pointing out that for small probabilities there is risk seeking, for large there is risk

aversion, irrespective of what the prizes are (pp. 187-188; **inverse S**). A strong argument deserving more attention also now, in 2015! %}

{% **cognitive ability related to risk/ambiguity aversion**: has the data but does not seem to report this.

correlation risk & ambiguity attitude: has the data but does not seem to report this.

Follow-up on Abdellaoui, Klibanoff, & Placido (2015) and Halevy (2007). Better score in arithmetic test $\Rightarrow$ better RCLA. Framing also affects relation RCLA and ambiguity aversion. No clear relation is found.

Ambiguity is generated by starting from known composition, and then letting students randomly take out some things, unknown to all. This is in fact 2nd order probabilities. (**second-order probabilities to model ambiguity**). The thing it is to be related to. Use certainty equivalents (through choice list and RIS) to measure all attitudes. Ambiguity neutral likelihoods were always 0.5.

Index of risk aversion is risk premium normalized by dividing by maximum outcome, and ambiguity aversion index is difference between that and its analog for ambiguity. So, ambiguity aversion is indeed how much uncertainty *deviates* from risk, which is my preferred definition. For between-subject comparisons, the main purpose of this study, the indexes are OK. But they are not very well suited for comparisons to other studies, for one reason because dividing by the maximum outcome provides overcorrection, implementing local risk and ambiguity neutrality. Yet such measures are widely used in the literature. %}

random incentive system between-subjects (paying only some subjects)**.**

The author writes precisely and accurately about concepts in a clear way that often is not psychologist s'strongest point. A pleasure to read!

suspicion under ambiguity: The author does the Ellsberg experiment where subjects cannot choose the color to gamble on. However, here it is not a mistake as it is in sloppy experiments, but here it is done deliberately so as to investigate suspicion about rigging the balls. In one treatment ambiguity is nothing but second-stage probability (**second-order probabilities to model ambiguity**) and there is no reason to suspect the experimenter has rigged the balls except when the experimenter did outright lying (which often happens especially in psychology where it sometimes cannot be avoided). In the other treatment no info is given and there is more reason to suspect rigging of the balls.

The author concludes (p. 1086, end of penultimate para): "Future researchers, using the two-colour Ellsberg urns task, with a specified target colour to be drawn, should also consider the issue of trust in the experimenter not to rig the urn, as this needs controlling for if pure ambiguity aversion is to be measured." (**suspicion under ambiguity**) %}

First they derive a general additive representation V(x,z) + V(y,z) for (x,y) for each fixed level of z. Then they use that to generalize many results in the literature, such as Rohde’s (2010) preference foundation of the Fehr-Schmidt welfare model, rank-dependent utility, linear representations in mixture spaces, and other things. %}
Qin, Wei-zhi & Hendrik Rommeswinkel (2024) “Conditionally Additive Utility Representations,” *Theory and Decision* 96, 555–595. https://doi.org/10.1007/s11238-023-09962-8

{% **tradeoff method**: Use it like Abdellaoui (2000), for gains. Replicate the Abdellaoui (2000) non-parametric measurement method with N = 124. **inverse S:** Strangely enough, find convex w more than concave or inverse S. It shows that probability weighting is volatile. (I would say that basic utility is most stable, then probability weighting is second, and loss aversion is the least.) A nice addition that this paper gives: Even though conceptually and theoretically, probability weighting is a new component, it would not be very worthwhile if it was strongly related to utility curvature statistically. This paper finds that it is not strongly related, so that it does explain additional variance in the data. They also

reanalyze the data of Bleichrodt & Pinto (2000), finding the same result. They could not reanalyze the data of Abdellaoui (2000) because those are lost.

Utility deviates from linearity and is concave. %}

Qiu, Jianying & Eva-Maria Steiger (2011) "Understanding the Two Components of Risk Attitudes: An Experimental Analysis," *Management Science* 57, 193–199.

{% The authors measure multiple priors, but take the term in an unconventional sense. On the one hand it refers to two-stage probabilities, on the other hand to single priors entertained by other students in the experiment. The latter is equated, for an event, with its matching probability. They equate these two, calling this equation a leap of faith (p. 57), but giving arguments. Thus they get the two-stage structure of the smooth model. For the smooth model they allow using information about 2nd order distribution, but for α maxmin not, and then smooth fits data better. %}

Qiu, Jianying & Utz Weitzel (2016) "Experimental Evidence on Valuation with Multiple Priors," *Journal of Risk and Uncertainty* 53, 55–74.

{% The reasoning on p. 1282, 3rd para, is, for EU with concave utility:

Assume expected utility with concave utility U, and consider the following ASSUMPTION. A person prefers a sure amount $M to a gamble (.5, $M+11; .5, $M−10), for each level of wealth M.

Then u´(M+11)/u´(M−10) < 10/11 for all M. In other words, u´(x+21)/u´(x) < 10/11 for all x.

Then u´(11)/u´(–10) < 10/11, u´(32)/u´(11) < 10/11, etc.

The assumption implies that U is very concave for large amounts of money, and is unsatisfactorily concave. For example, U´(x+21)/U´(x) is at most 10/11 and, therefore, U´(x+2100)/U´(x) is at most $(10/11)^{100}$ = 0.00007; etc. Compare this with constant absolute risk averse (CARA) implying linear-exponential utility, which is also overly concave for large amounts. CARA is a condition of

the kind "for all lotteries and all probabilities …". That is, it is a mathematical condition whose empirical (un)reasonableness is not transparent. Rabin's condition, imposing the invariance w.r.t. M only for one natural preference with moderate stakes, makes the empirical restrictiveness of the Assumption more tangible and shocking. In footnote 2, Rabin points out that the basic idea was presented before by Hansson (1988). Hansson's presentation was, however, way less convincing. (Prelec, personal communication, called Rabin's attention to Hansson.) The conclusion is that expected utility advocates should abandon the displayed assumption. However, the Assumption can be restricted to bounded intervals for M where it is empirically convincing and still implies concavity of utility too extreme to be plausible.

linear utility for small stakes: this is the basic message of this paper.

It has been well known that utility is approximately linear for small stakes. This statement is a mathematical fact without much empirical relevance yet because "approximately" and "small" have no clear meaning. Rabin mentions concrete numbers and, thus, makes it clear that this point is empirically relevant.

People who really want the displayed assumption, may want to adopt a nonEU theory. For example, prospect theory with M as status quo and then loss aversion may explain much of the empirical realism of the above assumption.

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): footnote 3, p. 1282, says that he finds the psychological interpreting of vNM utility the natural way to think about vNM utility.

If the amounts 10 and 11 in the assumption are replaced by $10/\lambda$ and $11/\lambda$ for positive λ, then the concavity of U gets larger as λ gets larger and becomes infinite if λ goes to infinity (so, the betting odds 10:11 are not accepted no matter how small the stake). That is, U then kind of explodes. EU advocates cannot have this. This point reflects that a concave U is almost everywhere differentiable, so is approximately linear for small amounts of money.

Empirically, it will matter a lot if people psychologically integrate M into the outcome (final wealth) as expected utility requires or do not in the Assumption. Prospect theory says they don't and then loss aversion can explain the findings. Rabin recommends loss aversion as main factor to explain in the last para of the main text, pp. 1288-1289.

The result can be reinforced by assuming that a person only declines this 50–50 +11 versus −10 gamble at the current state of wealth, but has concave utility and decreasing ARA (absolute risk aversion) so that he also declines the gamble for all smaller initial wealths. This point is alluded to on p. 1283-1284, with no mention of decreasing ARA, unfortunately.

Kahneman & Tversky (1979, p. 277): "The certainty equivalent of the prospect (1,000, .50), for example, lies between 300 and 400 for most people, in a wide range of asset positions."

Christiane, Veronika & I: P. 1287 discusses relation between small-stakes and large-stakes risk attitudes. In particular, footnote 10 points out the related difficulties for the coefficient of relative risk aversion.

P. 1282: "From such observations we should conclude that aversion to modest-stake risk has nothing to do with diminishing marginal utility of wealth."

Samuelson (1963) also showed that risk aversion in the small can imply implausible risk aversion in the large. Rabin's argument is, however, more convincing. Its preference assumption is less extreme (rejecting $11_{0.5}(-10)$ versus rejecting $200_{0.5}(-100)$), its domain-assumption is less demanding (Samuelson needs invariance of his assumed preference over a large wealth range [−10,000, +20,000]), and its conclusions are stronger (See Rabin's footnote 11, p. 1288).

P. 222 explicitly brings up that the preferences are assumed for all wealth levels.

P. 223, erroneously, writes for Samuelson's colleague that, under EU, rejecting the $200_{0.5}(-100)$ once should imply rejecting independent repetions, but it is very well known that this is not true (Liu & Colman 2009 p. 278). It is only true if [$200_{0.5}(-100)$ once] is rejected at every wealth level that can occur during the process, something that is implied for instance by constant absolute risk aversion.

Pp. 227-228 discusses money pumps. You can get people into small books when there are small transaction costs, e.g. people who, when subscribing to the phone company, in one blow take wiring insurance.

{% Replies to Ellsberg's violation of the sure-thing principle. On p. 694, Raiffa considers a fifty-fifty mixture of two ambiguous gambles and a fifty-fifty mixture of two preferred unambiguous gambles. His "strict dominance" argument requires that the second mixture be preferred. It is similar to Luce's consequence

monotonicity or Segal's compound independence. His "objectively identical" claim is based on reduction (for events) and leads to the conclusion that the two mixtures are identical, and therefore equivalent. Because of the contradictory preferences that have resulted, Raiffa suggests that the original preference for the unambiguous gambles be changed. Of course, his argument has used all components of the vNM independence condition.

P. 690, on Savage's theory: "It is a theory which purports to advise any one of its believers how he *should* behave in complicated situations, *provided* he can make choices in a coherent manner in relatively simple, uncomplicated situations."

P. 690/691 states that a normative theory can be useful only if it sometimes !deviates! from actual behavior: "If most people behaved in a manner roughly consistent with Savage's thory then the theory would gain stature as a descriptive theory but would lose a good deal of its normative importance. We do not have to teach people what comes naturally." The same point is stated, but disliked, by McCord & De Neufville (1983), p. 281.

P. 694 is implicitly assuming independence-like conditions. %}

Raiffa, Howard (1961) "Risk, Uncertainty and the Savage Axioms: Comment," *Quarterly Journal of Economics* 75, 690–694.

{% **risk averse for gains, risk seeking for losses**

Good elementary textbook for getting to understand construction of decision trees, backward induction, and v**alue of information**. Ch. 3 on cost of sampling may be less central. Ch. 6 is kind of Anscombe-Aumann and can be skipped. Ch. 7 is a bit much on economics of sampling, and value of info. Ch. 8 is on risk sharing for groups. These could be skipped by someone interested only in individual decision under risk.

Preface p. ix-x: says book is about rational decisions as if this is all decision making, then brings only aggregation of uncertainty, and then casually mentions that uncertainty is a central topic.

risk averse for gains, risk seeking for losses: p. 75: in Fig. 4.18 Raiffa suggested that people prefer $-100_{0.5}0$ to -45; i.e., they are risk seeking there.

§4.9, pp. 81-82:

"If people always behaved as this prescriptive theory says they ought to, then there would be no reason to make a fuss about a prescriptive theory. We could then just tell people, "Do what comes naturally."

P. 85: in Allais paradox, one 0 outcome may be different from another.

decreasing ARA/increasing RRA: pp. 91-94 suggests that decreasing absolute risk aversion is plausible, I didn’t see RRA being discussed.

P. 110: judgmental probability of event E is p: $\$100_{p}0 \sim \$100_{A}0$; i.e., it is the matching probability. §4 discusses that these need not be additive.

P. 112: Raiffa’s famous ’61 argument against Ellsberg.

P. 146, principle of substitutability: is in fact like Anscombe & Aumann (1963), two-stage with states of nature and objective probability mixing of acts, but with prior mixing not posterior. For two states of nature.

P. 161-168 seems to discuss bisection for eliciting probability.

P. 287: Experimentor continuing until he has a result pleasing him, does good research. My handwritten notebook p. 639 %}

Ramsey, Frank P. (1929/1978) "Theories." *In* David H. Mellor (ed.), *Foundations: Essays in Philosophy, Logic, Mathematics and Economics* 101–125. Humanities Press, Atlantic Highlands, New Jersey.

{% This text by Ramsey is one of the best in all of decision theory, with refined and deep understanding of all relevant issues found nowhere else in the literature.

Brought to the attention of Arrow, Econometrica, (1951, p. 423), by Norman C. Dalkey, RAND-corporation; Arrow (p. 424) called Ramsey's work "none too clear."

Pp. 158-159 on frequentist probability (strongly criticized later in the paper, to my joy), that even if existing there are always situations of partial belief.

Pp. 160-166 criticize the logical interpretation of probability, advocated by his teacher and protector Keynes, and I found nuances lacking in this discussion. P. 161 has the nice concept of psychogalvanometer to directly measure degrees of belief.

Pp. 166-169 is a nice text on measurement in social science, with scale types and framing (that models hold only approximately).

Pp. 169 last para ("We are driven therefore") - p. 174 penultimate para ("no memory of the previous ones"): is a superb discussion of the dispositional nature of preference, as of virtually any property in natural sciences and elsewhere. It is the best discussion of this point that I ever read. All modern issues such as introspection and hypothetical choice are put right there. It is unbelievable that Ramsey immediately, even before our field was born, understood these things to an extent that most researchers will do never in their life (unless they were as fortunate as I was to have been exposed to Ramsey's text at a young age). For understanding why we need the random incentive system in experimental economics to implement real incentives, this is the best text. Ramsey wants subjective probability to be entirely revealed-preference based.

coherentism: P. 171 writes: "Suppose, however, I am wrong about this and that we can decide by introspection the nature of belief, and measure its degree; still, I shall argue, the kind of measurement of belief with which probability is concerned is not this kind but is a measurement of belief *qua* basis of action."

Used **just noticeable difference** for cardinal utility: p. 171 puts it forward as a basis for measuring beliefs/probabilities, but then properly criticizes it as just a different cardinal scale.

P. 172 beginning of 3rd para: "It is clear that we are concerned with dispositional rather than with actualized beliefs;" That is, subj. probability is not belief now had, but only as it would be had if we had to act on it. As Tversky would put it in support theory: it is in our mind, not on our mind.

P. 172 writes that a **Dutch book** can be made against nonEU. Does not define it, apparently considering it to be well known. However, it is the first mention of Dutch book in the literature that I am aware of. Pp. 182 & 183 will do it again.

P. 172 bottom: measuring belief may automatically affect it.

P. 173 penultimate para: "we seek things which we want, which may be our own or other people's pleasure, *or anything else whatever*, and our actions are such as we think most likely to realize these goods." [italics added here]
Ramsey here points out that from the representation it follows that we are maximizing something, utility (or its expectation), but does not commit to anything that that might be.

Para on pp. 173-174 nicely states how utility is a different, kind of exchangeable, scale differently than the scales we commonly use such as hours of swimming.

P. 174 3rd para nicely points out that normative here is something different than in ethics. The term ethically neutral event emphasizes this point.

linear utility for small stakes & **marginal utility is diminishing**: p. 176: "Since it is universally agreed that money has a diminishing marginal utility, if money bets are to be used, it is evident that they should be for as small stakes as possible. But then again the measurement is spoiled by introducing the new factor of reluctance to bother about trifles."

P. 174: in repeated choices to measure subjective probabilities there should be no learning to make this interpretation work. When Luce worked with repeated decisions in the 1990s he overlooked this point. I, exposed to Ramsey at young age, wrote Luce an email about it. He acknowledged me for it on p. 10 (footnote) in Luce, R. Duncan (2000) "*Utility of Gains and Losses: Measurement-Theoretical and Experimental Approaches*." Lawrence Erlbaum Publishers, London.

P. 176 2nd para: The formal analysis of his preference foundation starts. Will be until p. 184. It starts with what is called an ethically neutral event. (Ramsey uses the term proposition instead of event.) This is an event that carries no value in itself. That is an event in a Savagean sense. An event that carries a value in itself is a bit like a consequence in Savage (1954), although may be also like a Savagean event, and it is not very clear how to model this, a bit Jeffrey-type maybe. At any rate, Ramsey then assumes an ethically neutral event that you just as much like to gamble on as against. Under EU it means that it has subjective probability 0.5. Then observations (0.5:x, 0.5:z) ~ y show that y is the utility midpoint between x and z. In this way, we can measure utility to any desired degree of precision. With utility available, we can measure subjective probabilities. This is how Ramsey does it.

Savage's definition of acts, states, consequences, distinguishing them, is not clearly present in Ramsey's writing. Davidson & Suppes (1956) can be taken as a full formalization, although it may not be what Ramsey had in mind.

updating: discussing conditional probability and/or updating: discussed on p. 180. Nice that actual receipt of info can alter things and requires an assumption for invoking Bayes' formula.

(P.s.: simultaneity in the penultimate para refers to the discussion of Einstein on p. 169.)

P. 183 last para writes that, essentially, we should get by with finite models. A point also central in the Shapiro (1969) (& Richter) quasi-characterization of subjective expected utility.

P. 184 - end is philosophical, on induction and so on.

P. 188, on objective/subjective probabilities: "And in a sense we may say that the two interpretations are the objective and subjective aspects of the same inner meaning,"

P. 189, on finding equally probable basic events:

"it is a matter of physics rather than pure logic."

His suggestion that Keynes would think differently is hard to believe and is probably driven by his young desire to disagree with his befriended teacher. One also sees that top of p. 167. Whenever Keynes is involved Ramsey becomes unreasonably negative.

coherentism: Ramsey doesn't need more than one sentence to, for once and for all, refute coherentism: p. 191: "we want our beliefs to be consistent not merely with one another but also with the facts."

P. 193 and also preceding texts: "the highest ideal would be always to have a true opinion and be certain of it;"

Pp. 204-205 has text on statistics.

Pp. 206 ff. is on the meaning of probability, criticizing frequentism. The opening: "there are no such things as objective chances" is reminiscent of de Finetti's "probability does not exist."

Ramsey died before completing the paper. Then a friend finished the paper. (It may have been by the editor of this book, Richard Braithwaite, as suggested by Fienberg 2008, p. 21; Braithwaite provided the same valuable service to Johnson (1932).) Probably Ramsey himself had finished the text up to p. 184, which is all of the highest possible level. Braithwaite finished starting p. 184 and then there are, besides strong parts, also parts of less interest. Braithwaite has given a wonderful service to us by finishing this paper. %}

{% **decreasing/increasing impatience**: seems to find increasing instead of the common decreasing.

One typically finds:

$A now ~ $B in one year,

$B in one year ~ $C in two years,

but $A now ~ $C−X in two years for a positive X. The author calls this subadditivity. It in fact entails intransitivity. Such effects may be underlying studies that find hyperbolic discounting. Such studies typically look at [$A now ~ $B in one year] in combination with [$A now ~ $C − X] in two years. They, thus, compare time intervals of different lengths.

I discovered March 5, 2014, that p. 25 Eq. 16 proposes a variation of exponentional discounting where we take t to a power s. This is what Ebert & Prelec (2007) call constant sensitivity, Bleichrodt, Rohde, & Wakker (2009) call CRDI, and Bleichrodt, Kothiyal, Prelec, & Wakker (2013) call unit invariance. Read claims that the formula implies no declining impatience but this depends on the parameter s, and is not so for $s < 1$. %}

{% This paper criticizes traditional tests of transitivity that assume a deterministic theory and classical statistical tests of it. It thus strongly criticizes statistical analyses based on majority choices (e.g. p. 46 1st column). It favors using probabilistic choice models with what Loomes & Sugden call the random preference model (p. 47) and what can also be called a mixture model. The paper opens with an example where an agent randomly has one of three preference relations, each transitive, but observed majority preferences violate transitivity. Advocates of classical deterministic theories can argue that this is a type I error, which is known to happen sometimes. The paper has done an enormous work by analyzing over 100 classical data sets, and adding an experiment. It derives a triangular inequality for the mixture model, argues that this is a strong test of transitivity (p. 44). Acceptance of the null of the triangular inequality is taken as evidence for transitivity. P. 45 1st column argues that deterministic theories are reasonable only if not very much noise.

The paper also strongly argues against 2-alternative forced choice (2AFC) studies, which cannot measure indifference (e.g. p. 54 2nd para). %}

{% **tradeoff method's error propagation**: This paper assumes asymmetric errors in the tradeoff method, with arguments that this is reasonable because answers are bounded from one side (because of monotonicity) and not from the other in the method. They show that their assumed errors lead to biases making TO utility more concave. Possible remedies are: (1) use choice lists instead of direct matching, so that upper bounds for answers can be imposed; this may reduce but does not remove the problem; (2) quantify the errors and then correct for them. (3) use answers normalized in the money dimension, such as $(x_i-x_0)/(x_4-x_0)$ instead of $x_0, \ldots, x_4$, for instance, as I usually let students do when I teach on this. Again, this reduces but does not remove the problem. It is in general a better method. Further in defense of the TO method: it usually gives less concave, close to linear, utility, more than other methods, suggesting that there is no big error in the direction of concavity. The keyword used here gives several simulations that suggested that the error propagation probem is not big. %}

Richard, Thibault & Valentin Baudin (2020) "Asymmetric Noise and Systematic Biases: A New Look at the Trade-Off Method,"

{% Argues against the PE (if I remember well, he calls it SG) as gold standard for utility measurement because, first, EU is empirically violated (I agree) and, second, EU is neither appropriate normatively (I disagree) (**PE doesn't do well**). He prefers the TTO.

I agree with virtually all of pages 7-10, in particular that the author emphasizes that the PE cannot be a gold standard in view of violations of EU. I disagree more often with the texts following p. 10.

The footnote on p. 11 cites in an affirmative manner the, I think incorrect, criticisms of Allais and Pope on the mathematics of Machina.

P. 8, 2nd column, end of 1st para (referring to Gescheider 1988 for it): "As with other psychological concepts these attributes cannot be directly observed but only inferred. The concept itself is a construct and the functional relationship between the construct and external evidence must be embodied in psycho-physical theory."

P. 8 2nd column at about 2/3 of the page, on the ordinalist move in economics: "While removing the psychological connotations, this also reduced the value of the concept outside the framework of positive economics."

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): p. 9, 2nd column: "It is likely that the great appeal of N-M utility in the context of CUA [Cost-Utility Analysis] is derived from such a conflation of concepts [representational utility versus strength of preference]."

P. 10 discusses **utility of gambling** (later the term utility of risk is also used). For the author, however, it seems to entail regret etc., any global aspect that cannot be modeled through the utility of single outcomes.

P. 13 has a nice citation of Claude Bernard, taken from Allais.

P. 18 discusses the **HYE** in a critical manner. %}

Richter, Marcel K. (1980) "Continuous and Semi-continuous Utility," *International Economic Review* 21, 293–299.

{% This paper is written in the spirit of Richter's work, understanding very well how theoretical concepts should be related to observations and that deriving concepts from finitely many observed preferences is the thing to do. It shows how, under subjective expected utility with both utility and probability unknown, finitely many observations can reveal the info that subjective probabilities are in some interval [a,b] for any algebraic numbers a,b, and similar things. Algebraic means the solution to a polynomial equation with only natural numbers as weights involved. So, we can find out that p_1 is 2/3 or that it is squareroot of 2. We cannot find out that it is pi. At most we can find out that it is close to pi. Nice examples are given to illustrate this.

Unfortunately, there are some advanced results on necessary and sufficient conditions for polynomial sets for which utilities can always be found and more similar results which I did not find very interesting. %}

{% %}

Rieger, Marc Oliver & Mei Wang (2008) "What Is Behind the Priority Heuristic? A Mathematical Analysis and Comment on Brandstätter, Gigerenzer, and Hertwig (2006)," *Psychological Review* 115, 274–280.

{% Used data from as in other studies by these authors, e.g. Rieger, Oliver, Wang, & Hens (2015 Management Science). Here students from many countries were asked a variation of Ellsberg's 3-color urn, where there are 30 red balls and 70 black or yellow balls. The most ambiguity averse country was Thailand (80% choose Red), and the last was the US (42% or so choose Red). They correlated these percentages with equity premiums in the countries, finding correlation 0.5 (p = 0.008). Macro-economic controls do not affect the result. Problem: their question did not control for suspicion (**suspicion under ambiguity**) and hence it may have been suspicion rather than ambiguity aversion that drove the correlation.

They also correlated with Hofstede's (2001) uncertainty aversion index. It was positively correlated with ambiguity aversion, and explained the same variance in the equity premium puzzle as ambiguity aversion. %}

Rieger, Marc Oliver & Mei Wang (2012) "Can Ambiguity Aversion Solve the Equity Premium Puzzle? Survey Evidence from International Data," *Finance Research Letters* 9, 63–72.

{% Measure risk and ambiguity attitudes of 6912 subjects (students) in 53 countries, involving N = 6912 students. Section 2 reviews other international studies, which never involved as many countries.

Use WTP for gains but WTA for losses, doing hypothetical choice. Six gain lotteries and two loss lotteries, but no probability smaller than 0.1 or larger than 0.9, so, cannot really observe inverse S. Strictly speaking, the gain lotteries are not really gains because subjects pay their WTP, leading to net payment −WTP (negative, so, a loss) if the lottery gives outcome 0.

Use as index of risk aversion the risk premium divided by the absolute value of EV. Because no mixed lotteries here and no EV = 0 this can be done, although, as is not well known, this normalization is too much and makes moderate payments too risk neutral. An analysis of these data determining PT parameters is in the authors' 2017 paper in Theory and Decision.

For ambiguity have 30 of 100 balls red, and the other 70 black or yellow in unknown proportion. 4.1% of the questions violate weak internality, and 15.1% strict.

risk averse for gains, risk seeking for losses: is found in all 53 countries. Positively related to Hofstede's uncertainty avoidance index.

gender differences in risk attitude: p. 642 §4.2.1: women are more risk averse for gains and more risk seeking for losses.

Pp. 642-643: older people are less risk averse both for gains and for losses (**relation age-risk attitude**).

P. 642: For gains, risk aversion is increasing in wealth between countries. Given that the index that the authors is more a relative risk aversion index than an absolute one, this is consistent with common findings at the individual level. For losses it is not significant (p. 643).

reflection at individual level for risk: risk aversion for gains is negatively correlated with risk aversion for losses (p. 643).

P. 645: using only students reduces heterogeneity within countries, making between-country comparisons more reliable.

For 48 of 53 countries they have only one university. It is in itself good, if studying between-country variations, to have within-country homogeneity. Yet here typicalities of one particular university can much interfere with characteristics of the country. %}

Rieger, Marc Oliver, Mei Wang, & Thorsten Hens (2015) "Risk Preferences around the World," *Management Science* 61, 637–648. https://doi.org/10.1287/mnsc.2013.1869

{% The authors published on this data set in Management Science in 2015, using a-theoretical indexes of risk attitudes such as normalized risk premium. This paper calculates five PT parameters, the same as T&K'92, and then re-analyzes. The data of such a big study have to be noisy, and with eight questions per subject it is difficult to estimate five parameters of PT. Hence, they mostly take all answers per country assuming representative agent. One difficulty in this study is that for losses they only have prospects with one nonzero outcome, so that a common power of utility and probability weighting is unidentifiable. (Pointed out by the authors on p. 584.) Because the authors use a weighting function family, the one-parameter family of T&K'92, their data fitting gives a unique fit, but this is due to assumed functions and not based on data. For gains they have only one of six prospects with more than one nonzero outcome, which should fully determine the power.

gender differences in risk attitude: women do more probability weighting than men.

concave utility for gains, convex utility for losses: is found (p. 582). Utility for losses is more linear than for gains, but not much.

inverse S: is found for both gains and losses. But they only fit the one-parameter family of TK92. Closer to linear for losses than for gains (p. 583).

p. 583: Utility parameters are related to portfolio decisions, but probability weighting parameters are not. This fits with my hypothesis that probability weighting is more noisy than utility.

reflection at individual level for risk: p. 584 finds it, with a positive correlation between concavity of utility for gains and convexity for losses.

P. 587: their nonparametric analysis of probability weighting depends much on utility assumed to be logpower, because only then the third displayed equation implies a constant ratio of CEs.

P. 587: For losses, unlike for gains, the probability weighting parameter is not correlated with the nonparametric estimate, showing that the measurement for losses is more noisy than for gains. Of course, they have fewer observations for losses.

P. 589: of Hofstede's indexes, individualism and uncertainty avoidance enhance more probability weighting.

P. 593: Cites Hofstede (2001) on desirability, if studying between-country differences, to have within-country homogeneity of the sample. %}

{% The probabilistic dominance model works as follows. It is a regular Anscombe-Aumann framework. In (A,f), A is a set of acts containing f, where f has a special role: it is a status quo. The agent deemes as unacceptable all acts in A that have a probability of θ or more of yielding a utility loss relative to the status quo of λ or more. Here θ and λ are thresholds set by the agent. The unacceptable acts are removed from A. For the ones remaining, expected utility is maximized. A comparative condition of revealing more bias towards the status quo is defined (always having stronger preference for the status quo) that implies the same EU model but with θ and λ being more extreme. %}

{% Incentives: Do both with and without real incentives. Each subject did three choices, each of them paid under real incentives (income effect).

ambiguity seeking: If subjects are first endowed with the ambiguous Ellsberg gamble, and are asked if they want to exchange it for the unambiguous one, then most don't want that. In terms of final wealth, they then exhibit ambiguity seeking. The main conclusion can be that loss aversion dominates ambiguity aversion.

The authors use the term source preference differently than prospect theory does. In this paper it means whether it matters if subjects just got a prior endowment or had selected it.

An alternative title for this paper could have been:
"The status quo bias dominates ambiguity aversion."

suspicion under ambiguity: p. 181: They controlled for suspicion in Ellsberg choices both by letting subjects select color to gambe on, and by gambling on all colors. Unfortunately, in the latter case they really played all three choices, so that income effects and, in particular, hedging may have been going on.

reflection at individual level for ambiguity: experiment 1 gives no data.

Experiment 2 does not give it explicitly. Maybe it can be derived from the data given in Tables 5 and 6, but it was too complex to me (would have to read line by line) how the groups and treatments had been organized. This similarly holds for Experiment 3. %}

{% **risk averse for gains, risk seeking for losses**: They find it. They confirm common ratio, preference reversal, and reflection.

Teams are not closer to EU than individuals, but they do get higher EV at lower risk so, in that sense are better.

loss aversion: erroneously thinking it is reflection: p. 416 confuses reflection (what they do) with loss aversion, calling it reference point effect, and even explicitly stating the confusion: "the reference point effect (also referred to as loss aversion or reflection effect)." %}

Rockenbach, Bettina, Abdolkarim Sadrieh, & Barbara Mathauschek (2007) "Teams Take the Better Risks," *Journal of Economic Behavior and Organization* 63, 412–422.

{% They use RIS.

ambiguity seeking for losses: they claim so, but it is only mismodeling of outcomes and utility.

First two experiments mainly redo Fox & Tversky (1995) with joint and separate evaluation of prospects (separable prospect theory). They do not replicate the FT finding but find that separate evaluation still gives ambiguity aversion. They suggest too much that this is their own idea, citing FT too late and vaguely at the end of §3 p. 279. There are later related findings by Chow & Sarin (2001, 2002).

P. 271 argues that not just EU should be maximized, but sometimes also variance of utility should be considered, which is to be minimized if we are above our needs and is to be maximized if we are below our needs. The authors simply misunderstand utility. If there is a level of needs below which everything is very bad then this should be incorporated in our utility function, e.g. being steep or having a jump below that level of needs, and we still just maximize EU. What they say then is correct in terms of variance of outcomes, but not in terms of variance of utility contrary to what they say. Wakker (2010 Comment 2.6.5) criticizes such considerations of variance of utility.

In their experiments, ambiguity was generated by providing intervals, with center equal to objective probability. Unfortunately, subjects could not choose the color to gamble on, so that there can be suspicion. (**suspicion under ambiguity**; P. 283 explains that Rode 1996 had done it properly.)

Experiment 4: P. 289 end of §6 explains that they generate the same probability distributions over the same outcomes with only different reference points (they don't use the latter term). Those quasi-reference points are however presented as different levels of needs to the subjects where subjects need to attain that level for some important purpose (making it to a second stage of some nice prospect). So, it is not at all the same outcomes but it is just very different situations in which outcomes mean very different things, with very different utilities. This rather than any attitude to ambiguity explains their findings. %}

{% This paper proposes an index of decreasing impatience. Assume

(s,x) ~ (t,y)

(s+σ,x) ~ (t+τ,y).

It uses the tradeoff technique to obtain, in my 2010 book notation,

$s \ominus t \sim^t (s+\sigma) \ominus (t,t+\tau)$. It then takes as index $\frac{\tau-\sigma}{\sigma(t-s)}$, and analyzes and calculates it for popular discount families. I would be curious for which discount family it is constant. It shares with Prelec (2004) that it only considers the lengths of the time periods during which stationarity is violated, and for instance not the utility loss one is willing to suffer. There are pros and cons to this, depending on application and purpose. In an experiment, more increasing than decreasing impatience is found! (**decreasing/increasing impatience**) The index is not related to other personality questions. %}

{% **updating: discussing conditional probability and/or updating**: The basic novelty of the paper concerns the framework of decision under uncertainty that is most central today, Savage's. A state space S is given. Exactly one state is true, the others are not true, and it is uncertain which is the true one. An agent chooses between acts. Each act f maps the state space to an outcome space, say ℝ (money), to yield outcome f(s) where s is the true state. Because the true state is uncertain, it is uncertain what the outcome of an act is. In Savage's model the very only purpose of the agent is to get the best outcome (with highest utility), but because of uncertainty this is not easy and expected utility is maximized. This paper adds a novel aspect where we make the mostly satisfied assumption that the agent knows what act he chooses and what outcome x he receives. The paper observes that the agent then automatically also receives info, being that $f^{-1}(x)$ is a true event, i.e., contains the true state. It is assumed that this info can bring additional utility. The representation, called subjective knowledge utility representation, is:

$$f \quad \text{-->} \quad \text{SUM}_\alpha\, u(\alpha)\mu\big(f^{-1}(\alpha)\big) \;+\; \text{SUM}_\alpha\, h\big(f^{-1}(\alpha)\big)$$

Here the summations are over all outcomes α. The first summation captures regular expected utility. Thus, u denotes a regular utility function and μ a subjective probability measure. In the second summation, h captures the value of the information that event $(f^{-1}(\alpha))$ is true. μ is unique and u is an interval scale, as usual. However, h is unique only up to any measure. This means that only its deviaton from additivity matters. $h(A) + h(B) - h(A \cup B)$ captures how much extra value there comes from separating A and B; in general, it is allowed to be negative. P. 11 Proposition 1: Subadditivity means it is always positive, and characterizes preference for information. (**value of information**)

The paper modifies Savage's axioms to accommodate the added value of information, which is, essentially, that the axioms hold only under information neutrality, i.e., when the informational value can play no role by it being fixed. For instance, monotonicity in outcomes (their Axiom 3 on p. 7; Savage's P3):

$\gamma \succcurlyeq \beta \Rightarrow \gamma_E\mu \succcurlyeq \beta_E\mu$ only if $\mu \neq \gamma$ and $\mu \neq \beta$.

The same basic novelty is, independently, in work byYucheng Liang, as indicated by the authors on top of p. 3, with more details on p. 18. Liang used a more complex model with updating whole probability distributions, more advanced and formal but less accessible. The authors use an unconventional continuity axiom (Axiom 6; p. 9) that is very strong and readily implies Villegas' monotonicity condition. %}

{% **SEU = SEU**: says on p. 534 that transforming probabilities is still SEU.

Argues that Yaari's 1965 (QJE) result confirms overestimation of small probabilities, but need not reject the Friedman/Savage (1948) utility hypothesis if the subjects of Yaari's experiment were involved in other side gambles unknown to the experimentor (hidden stakes in Kadane & Winkler's 1988 sense). It is, however, generally accepted nowadays (1990-2023) to ignore hidden stakes,

mostly because of the isolation effect. Therefore, whereas Rosett is formally right, his point should not affect Yaari's finding. %}

Rosett, Richard N. (1967) "The Friedman-Savage Hypothesis and Convex Acceptance Sets: A Reconciliation," *Quarterly Journal of Economics* 81, 534–535.

{% **inverse S:** data support finding of Yaari which suggests inverse S probability weighting: sets of lotteries preferred to status quo is convex suggesting concave utility but decision weights, inferrable from tangent of convex set of lotteries, differ from objective probabilities and suggest overweighting of low probabilities.

Nice opening sentence:

" … are the modest final product of an initially ambitious attempt …"

real incentives: **random incentive system**

Highly remarkable is the last paragraph on p. 482. It shows that Edwards fixed-probability-transformation model (separable prospect theory) violates stochastic dominance for the special case of overestimation of small probabilties (so, it already has part of Fishburn 1978). This latter model is described as Yaari's hypothesis. Probability-weighted means weighting through "subjective probabilities" that are transforms of objective probabilities:

> Yaari's hypothesis is appealing as long as we confine our attention to gambles with only two outcomes. If we consider gambles with many outcomes we need to deal with the problems that all the probabilities may be small and if they are all subjectively exaggerated, their sum will exceed one. To trace the implications of this anomaly, it is necessary to specify the rule for calculating expected values. If, for example, expected utility is calculated simply by summing the probability-weighted utilities of outcomes, it should be possible to persuade a gambler that by giving away money he makes himself better off. If his initial wealth is X_0 and his utility is $U(X_0)$, it will be possible to find a set of pay-offs,
>
> $X_i < X_0$, $i = 1, \ldots, n$,
>
> such that $\Sigma p_i U(X_i) > U(X_0)$.
>
> This happens because $\Sigma p_i > 1$ and we can select the X_i to make $U(X_i)$ as close to $U(X_0)$ as we please.

Next he goes on to show that adding a constant to U can affect preference.

Conclusion points out importance of framing (“exact conditions of the experiment”) %}

{% **foundations of statistics**

This paper pleas for using Bayes factors, which are likelihood ratios.

One view is that researchers want to find and confirm equalities because they are informative. The authors use the term invariants for equalities, and p. 225 penultimate para nicely link those to conservation laws, although the concrete examples given are far-fetched in only stating functional relations. The paper points out that psychologists have [too] much the Popperian attitude of rejecting and falsifying things. P. 225: "the psychological field has a Popperian orientation, in which demonstrations of effects or associations are valued more than demonstrations of invariances (Meehle 1978)."

The opening pages, and also elsewhere, often argue that classical hypothesis testing has no way of supporting the null. But power analysis is a common tool for it, and showing that other nulls could be rejected so that the data is not just noise also helps.

The authors often write that the choice of priors affects the resulting Bayes factor (e.g., p. 229). I do not understand this because they are independent of each other. Probably the authors mean choice of alternative hypothesis/parameters, where they let that be influenced by choice of prior.

The authors give many examples of reasonable choices of priors and alternatives, calculating through their effects, and they favor choosing noninformative priors.

P. 235 3rd para: "in Bayesian analysis, the elements of subjectivity are transparent rather than hidden". %}

{% Propose a variation of Gul's disappointment aversion model where not all outcomes below the CE (certainty equivalent) are overweighted with weight θ, but only those below δCE, where δ is a subjective parameter to choose. This model is, obvioudly, only for positive outcomes, with the level 0 very empirically meaningful. Remarkably, this model is one of the few that is not rank-dependent when restricted to binary prospects because the minimum outcome of a prospect may exceed δCE for $\delta < 1$ and then it is not overweighted. It does have the multiplicative representation as usual for single nonzero outcome prospects. A preference foundation is, unfortunately, not in the paper (it is in a technical web appendix, but I prefer not to read such). As they point out on p. 1308, this model is a betweenness model. If we fix CE, then simply all utility differences below δCE are indeed increased, and then it is EU. Betweenness means EU within each indifference class.

The authors intuitively justify their model by the desirability to overweigh low outcomes, where low is relative to the prospect (they argue in favor of this aspect p. 1307 last para). Rank dependence also does that. They refer repeatedly to the value-at-risk model for motivation (p. 1307, p. 1329), but this is a rank dependent model (my prospect theory book shows this in Exercise 6.4.4, p. 181). They also justify their model by having countercyclical risk aversion (p. 1317 ℓ. –2 and p. 1329 opening sentence in Conclusion.

{% **intertemporal separability criticized**: Central in habit formation of course. A reference point is developed that is a linear combination of past consumption.

It seems that at each timepoint instant utility experienced at that timepoint can be replaced by an equivalent money amount, turning general consumption stream into money stream, and that for the latter no habit formation is assumed, so that it can be evaluated using classical models. In the transformation of instant experienced utility into money then all the effects of habit formation can be captured. Then money is a bit like instant utility in Kahneman, Wakker, & Sarin (1997).

{% **measure of similarity**; Model: in choice between (p,x) and (q,y), subjects consider probabilities or utilities identical if they are sufficiently similar, and then go by "nonidentical" dimension only. Otherwise they do something else. This is very similar to threshold models.

This paper considers single-nonzero outcome lotteries. It shows that similarity relations on p and x, compatible with ratios of functions g and u, respectively, can be combined with the preference relation defined from g(p)u(x). It also shows that a preference relation representable by functions g, u through g(p)u(x), can be combined with similarity relations defined from g and u.

These theorems are not really representation theorems because they don't start from (similarity relations +) preference relations, but from only one of these two, and derive the other not from observed preferences but from the functions elicited from the one.

In Proposition 2, the pref relation on top of p. 151 is not given beforehand, but defined there. So, it is not a representation theorem. %}

{% **decreasing/increasing impatience**: find counter-evidence against the commonly assumed decreasing impatience and/or present effect.

Kirsten&I: intro has countably many outcomes and timepoints. The alternative model, starting in §2, however, takes uncountably many timepoints. This is used in his similarity model. Theoretically, it could also be a countable but dense subset of the time axis, such as the rational timepoints. There can be several consumptions, as in the second experiment. Really the hybrid model, with outcomes evaluated separately discretely and not as flow per time unit.

Presents three intertemporal choice problems data (no real incentives) that violate constant discounting for future and not present consumptions, so that the quasi-hyperbolic discounting that only overweights current consumption is violated also. Tries to explain the data through Rubinstein’s (1988) similarity model, although it was not clear to me why some dimensions were more similar than others. An alternative explanation for experiments I and III at least can be that for choices with small differences subjects choose the least complex option.

The auther argues that greater brakeaways from traditional economic models may be desirable and concludes: “We need to open the black box of decision making, and come up with some completely new and fresh modeling devices.” %}

{% Personal view about Theoretical Economics, complaining many times that it is not useful.

Starts with a story about Adam in paradise, having time-consistent invariant preferences over apples, but preferring one apple today to two apples tomorrow and 2 today to 1 today and 1 tomorrow. Then he prefers 1 apple today to one apple each day from day 17 till age of 100. This is not desirable and is Adam's "first traumatic experience." The following traumatic experiences nicely illustrate the gradual development away from classical economics. Many claims, such as that against new models as much counterevidence will be found as against classical ones (e.g. p. 871 1st para), should be taken as subjective personal opinions backed up with little evidence.

P. 869 is very negative about Rabin's calibration theorem. Rubinstein's "solution" is that outcomes should be interpreted as changes with respect to a reference point and not as final wealth. He cites Kahneman & Tversky (1979) for it, and also Cox & Sadiraj in an affirmative manner. What Rubinstein does not realize here is that this "solution" is not a minor modification of expected utility, but a major breakaway, half of the breakaway comprised by prospect theory. What he does not realize either is that Rabin himself also agrees with this solution and puts it forward as a primary explanation (Rabin 2000, Econometrica, when putting forward loss aversion which entails reference dependence; see last para of the main text, pp. 1288-1289). Rubinstein mistakes economics for abstract mathematics. Feynman's lecture "What Differs Physics from Mathematics" is equally relevant to economics and explains that one cannot do that.

Rubinstein's time paradox attempts to suggest that Rabin's paradox is a routine exercise and, thus, to downplay it. %}

{% The panel, 13 people, was convened by the US public Health Service (PHS), met 11 times during 2.5 years (first in 1993), in order to improve standardization in Cost-Effectiveness studies. They take societal perspective.

P. 1175, top: health states worse than death have negative utility.

P. 1175: they take QALY, which has advantage of combining length of time and health quality

P. 1175: “Second, since the purpose of investing in health is to make people better-off, it seems appropriate to let them be the judge of what constitutes better or worse outcomes and of the relative magnitudes of health effects.” I disagree with the opinion suggested here and stated also elsewhere, that the utility of the general public having to be maximized, would automatically imply that the general public is best to decide on what that utility function is. Other people such as patients or doctors mauy be able to judge better. Tversky & Kahneman (1981) p. 458 2nd column 1st para argue for the opposite: “A predictive orientation encourages the decision-maker to focus on future experience and to ask “What will I feel then?” rather than “What do I want now?” The former question, when answered with care, can be the more useful guide in difficult decisions.”

P. 1175 discusses question of whether people in a health state judge it more favorable than others, and gives several references. Some find the effect but others don’t find it and find equal judgments. The issue is not clear.

P. 1176, that decision analyses often only consider part of the criteria, where this is only an ingredient for final decisions to be made by others. “But real-world decisions must balance health against other goals—fair access to services, help for those worst off, and values outside health affected by health decisions. Thus, it is seldom appropriate to apply CEA mechanically. The panel recommended that CEA be used as an aid to decision makers who must weigh the information it provides in the context of these other values.” %}

{% **utility elicitation**; They list five questions on utility measurement as their central topics; I am puzzled about the answers to Questions 3 and 5 below, which seem to be contradictory.

Question 3 asks if the utility of a health state depends on the time spent in that health state. They find that the utility of a health state falls “dramatically” (p. 703; i.e., a violation of Stalmeier’s proportionality heuristic) as the duration is longer.

Question 5 addresses the question of whether being in a health state affects its utility. They find that people in a health state (e.g., kidney dialysis patients) value their state higher than the general public does (which runs contrary to strategic answering). %}

{% This paper introduces a nice paradox for RDU that is a sort of analog of Rabin’s (2000) calibration paradox for EU. It is tested empirically in the follow-up paper by Cox, Sadiraj, Vogt, & Dasgupta (2013). It is discussed in Exercise 7.4.2 of Wakker (2010), who cites Cox et al. (2013 EE; well, their 2007 working paper version) for it. But this paper by Sadiraj has the priority. Assume RDU. For each i = 0,…,98, we write r_i = i/100. Assume that a subject exhibits risk averse preferences as follows:

$(r_i{:}6,\ 0.01{:}6,\ 0.01{:}0,\ (1 - r_i - 0.02){:}0) \prec$

(r_i:6, 0.01:2, 0.01:2, $(1-r_i-0.02)$:0)

and that, with $U(0)=0$, $U(6)/U(2)>2.1$. Then it follows that $w(0.5)<0.01$. %}

{% The paper assumes hidden acts by agents, not observable to researchers, and shows how then nonexpected utility models and ambiguity models can result from that. Reminds me of Drèze (1959).

P. 2 writes an argument that ambiguity aversion can result from evolutionary optimization: "The starting point of our analysis is an observation which dates back to a seminal paper by Robson (1996): Evolutionary optimality generates a preference for idiosyncratic uncertainty over common uncertainty, and ambiguity is closely associated with common uncertainty in many instances. Hence, natural selection favors ambiguity aversion."

I do not read enough to understand the point of "idiosyncratic uncertainty" and cannot understand. In general, being Bayesian, I do not think that evolution will favor ambiguity aversion. %}

{% A 2002 paper was called Discounting and Future Selves, and Weibull and I discussed it in Amsterdam.

General discounted utility says that $U = SUM_{t=0}^{n} f(t)u(x_t)$ is to be maximized, with u some instant utility, maybe hedonic. The case $f(t) = \delta^t$ is constant discounting. The authors rewrite it as a linear combination in their Eq. 2 on p. 258 (I only write it for time $t = 0$)

$$U_0(x) \quad = \quad u(x_0) + SUM_{t=1}^{n} a(t)U_t(x) \qquad\qquad (*)$$

where each $U_t(x)$ is a linear combination of $u(x_t)$ and the $U_j(x)$'s for $j > t$.

U_t is the total happiness experienced at time t. The authors impose conditions on the U_t's and analyze when then all a(t)'s can be nonnegative. It feels some like double/multiple counting where x_n affects the happiness at time n, then also that at time n−1 through altruism of self at time n−1 with time n, then at time n−2, and thus affects happiness at time 0 indirectly through all intermediate utilities.

In Eq. (*), if the left term involved U then the definition would be problematic, circular/emplicit. But now with u for present, why not u for all future times?

Constant discounting can be obtained as the special case where U_t depends only on x_t and U_{t+1} (reminiscent of recursive formulas) and is a boundary case (p. 260 end of §3).

Footnote 7 explains that altruistic utility can only be generated for future selfs and not past selfs because the latter "do not exist" anymore at the present time. I add here: if it could, funny spirals could arise where a small future consumption due to altruism makes the present self happier, but then through reversed altruism towards the past, this makes the future self more happy, which makes the present self yet more happy, and so on. %}

{% What they call "constant risk aversion" is constant absolute !and! constant RRA.

Theorem 1: Fréchet differentiable functional V over lotteries that satisfies constant absolute and RRA is an expected value functional.

P. 29 argues against the use of rank-dependence in axioms (similarly to Luce, 1996): "Since rank dependent functionals evaluate outcomes not only by their value but also by their relative rank as compared to other possible outcomes, axioms that presuppose attitudes that are based on outcomes' relative rank are arguably less convincing than axioms that do not make an explicit appeal to such ranks."

Theorem 3 characterizes the Yaari functional, so, RDU with linear utility, for a quadratic probability weighting function of the form $w(p) = p + cp - cp^2$. %}

Safra, Zvi & Uzi Segal (1998) "Constant Risk Aversion," *Journal of Economic Theory* 83, 19–42.

{% The authors argue, as do Safra & Segal (1998) and Luce, that axiomatizations of rank-dependent utility explicitly using rank-ordering of outcomes are unsatisfactory. I agree that it is interesting to have an axiomatization that does not explicitly use rank-dependence. I disagree, however, with the claim that an explicit use of rank-ordering be unsatisfactory: the rank-ordering of outcomes is directly observable (and there is an intuition to using it) and, hence, there is no reason not to use it explicitly. %}

Safra, Zvi & Uzi Segal (2001) "Rank-Dependent Preferences without Ranking Axioms," *Journal of Mathematical Economics* 35, 547–562.

{% The authors assume that the Rabin paradox (RP) preference $(0 \succ 11_{0.5}(-10))$ holds in isolation, but also when merged with a wide range of "background" risky prospects. With "merged" I mean that there is no isolated choice where the background risk is ignored, as is the common assumption in prospect theory, but the payoffs of the background risk are integrated with the gamble payoffs. Then, under RDU, the same implausible implications follow as in Rabin's analysis under EU. The authors argue that, therefore, RDU does not help explain RP.

One difficulty is that the background risk assumption is too strong to be empirically reasonable. A direct way to see this: The background risk can concern many independent replicas of the prospect in Figure 8.6.1. Then repeated application of the assumption together with transitivity implies rejecting many repetitions of the prospect, which violates the law of large numbers. This case also makes LeRoy's (2003) criticism of Rabin's paradox implausible. An indirect way to see this: with the background risk assumption, RDU reduces to EU. Unfortunately, I do not know a place in the literature where this was clearly written. I learned it from Quiggin (persona communication, and of 1990s). Quiggin (2003) was derived from it but, unfortunately, doesn't have the general result. A related result is in Barberis, Huang, & Thaler (2006). %}

Sagara, Namika (2013) “Representation of Preference Orderings with an Infinite Horizon: Time-Additive Separable Utility in Continuous Time,” *Journal of International Economic Studies* 27, 3–22.

{% Preference condition considered concerns choice with reference points. It is a no-regret condition of the following kind: Assume that, with some arbitrary reference point, you can choose between x and y, and you choose x. Then, so it is assumed, x becomes your new reference point (an essential modification and clarification of this point comes later). The paper then assumes that, with x as new reference point, y should never be preferred to x. So, a point should always become more preferred if it becomes a reference point, suggesting a status-quo preference. The paper shows that most theories violate this condition unless reference independence.

The essential modification and clarification announced above is that for a prospect x not x itself (a random reference point as in Sugden 2003; this paper is referenced in footnote 13, but as a betweenness paper, and not for his modeling of reference dependence; data of Roca, Hogarth, & Maule 2006 support that x itself, and not its certainty equivalent, is taken as reference point) is taken as reference point, but instead a constant outcome, being the certainty equivalent of the prospect.

The reference point above is defined in an implicit manner because the preference relation w.r.t. which the certainty equivalent is determined, depends on the reference point and hence on the certainty equivalent. The following example on prospect theory clarifies what is going on.

Assume that PT holds with linear probability weighting and linear utility for gains and for losses, and loss aversion factor 2. This means that prospects are judged relatively unfavorable, with certainty equivalent below expectation, if the reference point is somewhere between the outcomes of the prospect so that the prospect is mixed, and they are judged relatively favorable, with certainty equivalent being expectation as under risk neutrality if the reference point is below or above all outcomes of the prospect.

Now for each prospect the reference point is the sure outcome such that the absolute value of the expectation of the prospect below the outcome is half of its expectation above; this reference point is smaller than the expectation of the prospect.

Imagine that a current reference point is below a prospect’s lowest outcome. The agent must choose between that prospect and its expectation minus a very small positive epsilon. All outcomes being above the reference point and, hence, expected value governing preference, the agent prefers the prospect and takes it. Then, so it is assumed, the agent adjusts the reference point to the present situation, taking the reference point as explained above. In this new situation the reference point is between the outcomes of the prospect, loss aversion with overweighting of the lowest outcomes is effective and generates risk aversion, and the agent now prefers the expectation minus epsilon to the prospect, and regrets the previous choice. The phenomenon is generated by the reference point being the sure outcome and not the prospect. %}

General observations regarding theories and experiments.

Pp. 88-91 discuss Rabin's (2000) paradox, suggesting utility of income as solution, and I guess he missed the last para of Rabin's paper where Rabin suggests the same solution through the term loss aversion. %}

Samuelson, Larry (2005) "Economic Theory and Experimental Economics," *Journal of Economic Literature* 63, 65–107.

{% Seems to be his first publication.

marginal utility is diminishing: p. 158: "In general, economists assume on a priori grounds that marginal utility decreases with income in a monotonic manner."

P. 155 ℓ. −2 describes DC vaguely, but deliberately vaguely: "whose tastes maintain a certain invariance throughout the time"

P. 156 starts with a general "state-dependent EU" functional $\int$V(x,t)dt studied a.o. by Wakker & Zank (1999 MOR)

time preference; derives cardinal utility from additive (or integrated) utility of money over time, assuming discounting that is known a priori; (by the way, it could be done without knowing the discount factor by means of the **tradeoff method** of Wakker & Deneffe, 1996). P. 161: "ordering *differences* in utility by the individual. The advantage of our experiment is that it compels indidividuals to make just such judgments." [italics from original].

P. 160 2nd para carefully distinguishes calendar time from stopwatch time.

P. 160, last full paragraph, already describes, I think, Becker's idea, "theory of history," that one might incorporate all of history in utility, and calls theory of history a contradiction in terms, maybe for being too general.

risky utility u = transform of strength of preference v: This paper is not at all on risk, but on time preference. There it explicitly distinguishes (last paragraph of paper, on p. 161), the cardinal utility function of constant discounting from cardinal utility for welfare theory.

DC = stationarity? P. 160 third paragraph beginning describes, I think, forgone-act independence (often called consequentialism) (the 1940 sentence), and then after that DC (e.g., mentioning precommitment). So, he never explicitly mentions stationarity but it's nicely implied à la Han & I.

Top of p. 160 says that functions that allow unlimited interrelationships become so general as to be almost vacuous.

risky utility u = transform of strength of preference v: well, he says that time-pref. utility is not welfare utility, but that's the same kind of thinking.

risky utility u = transform of strength of preference v (?latter doesn't exist?): p. 161 discusses that additive time preference leads to cardinal utility and, hence, meaningful comparison of utility difference and writes:

"…we must invoke Pareto's Postulate Two, which relates to the possibility of ordering *differences* in utility by the individual. … The advantage of our experiment is that it compels the individual to make just such judgments. …Thus, with postulates one and two being fulfilled, it is to be expected that utility is uniquely measurable.

In conclusion, any connection between utility as discussed here and any welfare concept is disavowed. The idea that the results of such a statistical investigation could have any influence upon ethical judgments of policy is one which deserves the impatience of modern economists." [italics and paragraph break from original]

In the first sentence of the last para, Samuelson points out that one cardinal utility in one context need not automatically serve as cardinal utility in another. He does not go as far as conjecturing two different cardinal concepts of utility, but it is a similar point. %}

{% **risky utility u = transform of strength of preference v, latter doesn't exist**;

P. 344: "Secondly, there has been a progressive movement toward the rejection of hedonistic, introspective, psychological elements."

Derives, I think, some results of prices, equilibria, for consumer theory, showing that nothing more than ordinal utility is needed. %}

Samuelson, Paul A. (1938) "The Empirical Implications of Utility Analysis," *Econometrica* 6, 344–356.

{% **risky utility u = transform of strength of preference v, latter doesn’t exist**: Argues that cardinal utility in welfare economics is useless, p. 65: “Only those who consider general welfare as the algebraic sum of individual utilities require that utility be measurable in a cardinal sense. It is not only that we can get along without this cardinal concept, but literally nothing is added by its assumption.”

P. 66 shows that, under smoothness, same ordering of utility differences implies cardinal equivalence.

P. 70 shows, on strength of preferences, that $[X_1;X_2]$ ~* $[X_1';X_2']$ and $[X_2;X_3]$ ~* $[X_2';X_3']$ should imply $[X_1;X_3]$ ~* $[X_1';X_3']$ is the main condition required to have a utility difference representation. Claims that it is not a plausible condition. A theoretical study of Samuelson’s axiom, generalizing all existing characterizations of strength-of-preference through utility difference, is in Köbberling (2004, Economic Theory). %}

{% End of footnote 2 already predicts that different methods for **utility elicitation**, which should lead to identical results under expected utility, in reality can be expected to give different empirical results.

P. 120 gives the famous Samuelson saying that the axioms should satisfy themselves, ascribing it to a friend. Samuelson presents the most rational man that he knows, Ysidro (most probably Edgeworth), presents a nonEU functional for him, and then writes about him:

“When told that he did not satisfy all of the v. Neumann-Morgenstern axioms, he replied that he thought it more rational to satisfy his preferences and let the axioms satisfy themselves.”

Footnote on p. 119 nicely credits Marschak for working on preference conditions for risk. On later occasions Samuelson, in personal correspondence to Fishburn and me, wrote that he learned the independence condition from Marschak. In a 1965 postscript, Samuelson says that Marschak, in this work, enjoyed many discussions on the topic with Herman Rubin.

{% **revealed preference** %}
Samuelson, Paul A. (1950) “The Problem of Integrability in Utility Theory,” *Economica*, N.S. 17, 355–385.

{% P. 671: “I must refer the reader to the forthcoming book by L.J. Savage, which will represent a landmark in the history of probability theory.”

independence/sure-thing principle due to mutually exclusive events: P. 672: "Prior to 1950, I hesitated to go much further. But much brooding over the magic words "mutually-exclusive" convinced me that there was much to be said for a further "strong independence axiom." When I did a history search, jointly with Fishburn, in the early 1990s, reading the letter correspondence of Fishburn and Samuelson of which Friedman had kindly sent us paper copies, I added in handwriting to "brooding" that it had taken place in the summer of 1950. I do not remember now where I got this from. Moscati (2016) cites a letter by Marschak (May 1950) to Samuelson pointing out the mutual exclusivity, to which Samuelson then reacts in a confused manner. So, probably, Marschak (1950) wrote it to Samuelson, but Samuelson only digested it later.

independence/sure-thing principle due to mutually exclusive events: para on pp. 672-673:

"It is this independence axiom that is crucial for the Bernoulli-Savage theory of maximization of expected cardinal utility, and which is the concern of the present symposium. Within the stochastic realm, independence has a legitimacy that it does not have in the nonstochastic realm. Why? Because either heads or tails must come up: if one comes up, the other cannot; so, there is no reason why the choice between A_1 and B_1 should be "contaminated" by the choice between A_2 and B_2.[3] How different this is as compared to the two blends of gasoline, where we must reckon with physical and chemical interactions."

The footnote 3, on p. 673, starts with: "Around 1950, Marschak, Dalkey, Nash, and others independently recognized the crucial importance of the independence axiom." %}

Samuelson, Paul A. (1952) "Probability, Utility, and the Independence Axiom," *Econometrica* 20, 670–679.

{% **consequentialism/pragmatism**: I took from Machina (1989, JEL) that Samuelson (pp. 676-677 in Stiglitz's 1966 book) noted that separability across alternative consequences

"must always be applied to a definite set of entities—e.g., (1) single-event money prizes, (2) single-event vectors of goods, (3) single-event money prizes cum gaming and suspense feelings . . . [Separability] then has implications and restrictions upon choices among such entities; but, strictly speaking, it need not impose restrictions upon some different (and perhaps simpler) set of entities.

In what dimensional space are we "really" operating? If every time you find my axiom falsified, I tell you to go to a space of still higher dimensions, you can legitimately regard my theories as irrefutable and meaningless . . . From my own direct and indirect observations, I am satisfied that a large fraction of the sociology of gambling and risk taking will never significantly be discernible in terms of money prizes alone, as distinct from elements of suspense . .” %}

{% %}
Sarver, Todd (2008) "Anticipating Regret: Why Fewer Options May be Better," *Econometrica* 76, 263–305.

{% This paper presents an advanced economic model for intertemporal choice under risk, assuming basic knowledge of such models on the part of the readers. P. 1352: "The setting for the axiomatic analysis is the space of infinite-horizon temporal lotteries. This domain is rich enough to encode not only the atemporal distribution of consumption streams but also how information about future consumption arrives through time. For example, future wealth and hence future consumption may depend on the returns to investments which are realized gradually over a sequence of interim periods."

The model contains all preferences that satisfy a convexity preference

condition (p.1353 Axiom 1) w.r.t. probabilistic mixing, and in this sense is rich, general. The axiom means that if you are willing to sacrifice x so as to increase a probability from p to q, then you are only more willing to increase it from d+p to d+q for any positive d. It is some stronger than quasi-convexity in probabilistic mixing. Then in Definition 3 (p. 1354) it is specified as an optimal risk attitude (ORA):

$$V(c,m) = u(c) + \beta \sup_{\varphi \in \Phi} E_m\big(\varphi(V)\big)$$

where E_m denotes expectation w.r.t. probability measure m. I guess that m denotes both saved money and probability distribution over it. V is the representing functional, c is immediate consumption and u its utility, and V inherits randomness from its arguments c and m. φ is a transformation of the representing function V ($\varphi(x) \le x$ for all x required). The set Φ of functions φ considered is subjective. The author interprets different φ as different risk attitudes, and the agent then chooses the risk attitude giving her maximal utility. Of course, different interpretations are possible. Mathematically, the optimization over φ results from the quasiconvexity preference condition. As the author shows, the functional is general enough to accommodate all prevailing empirical findings related to risk aversion. One cannot accommodate everything of course, so inverse S and fourfold pattern cannot be accommodated.

P. 1353 defines certainty equivalents as general functions satisfying stochastic dominance and idempotence (CE(x)=x for all degenerate x), prior to specifying preferences. They follow in the ensuing para.

§4.3 analyzes the Rabin paradox and the role of background risk for it, citing Safra & Segal (2008) for the claim that RDU has difficulties. As my annotations at Safra & Segal (2008) explain, I disagree because their empirical assumption is not plausible. This paper shows that the model is general enough to accommodate Rabin paradox choices while maintaining differentiability (by taking functionals that are close enough to kinked but not really kinked) and that it can accommodate at least moderate background risk. However, p. 1367 writes, realistically, that RDU, a special case of the general model, may work best: "Finally, specification RDU1 [RDU], which exhibits first-order risk aversion, is perhaps the best suited for generating high risk aversion for small gambles and moderate risk aversion for larger gambles." (**Prospect theory/Rank-Dependent Utility most popular for risk**) %}

Savage, Leonard J. (1953) "Une Axiomatisation du Comportement Raisonnable Face à l'Incertitude." *Colloques Internationaux du Centre National de la Recherche Scientifique* (Econométrie) 40, 29–40.

{% The first five chapters are, I think, the greatest contribution to all of decision theory. The rest of the book is not very interesting.

As explained for instance by Fienberg (2008), when Savage wrote this book he did not know that his sure-thing principle amounted to the likelihood principle for statistics (later Barnard seems to have explained the likelihood principle to Savage), nor that it implies a breakaway from classical statistics. The whole second part of the book tries to do classical-like statistics and decisions, such as through minimax, and is not interesting.

On Savage's use of the term sure-thing principle, which has raised many misunderstandings: p. 22 2nd para:

"It will be preferable to regard the principle as a loose one that suggests certain formal postulates well articulated …". In his analysis, the principle is related to three formal postulates, P2 and P3 (page 21 and the rest of §2.7), and P7 (p. 77, the para preceding P7). Since, the terminology in the field has shifted. Nowadays (after 1990), it is commonly accepted to let the term sure-thing principle refer only to Savage's P2 and not, as he did, to P2, P3, and P7.

P. 17 seems to briefly mention the problem of indifference for observability of

revealed preference.

questionnaire versus choice utility: p. 17: "I think it of great importance that preference, and indifference, between f and g be determined, at least in principle, by decisions between acts and not by response to introspective questions."

P. 20 seems to say about the use of his axioms:

"to make complicated decisions depend on simpler ones."

Section 3.1, pp. 27-30, on general meaning of preference is nice.

questionnaire versus choice utility: pp. 27-28 argue that one should observe choice rather than do direct questioning. P. 27 writes: "direct interrogation has justifiably met with antipathy from most statistical theorists."

Pp. 27-28: "if the state of mind in question is not capable of manifesting itself in some sort of extraverbal behavior, it is extraneous to our main interest. If, on the other hand, it does manifest itself through more material behavior, that should, at least in principle, imply the possibility of testing whether …"

At the end of p. 28 it says that questioning "what would you do if" seems fine. This is an example where for normative purposes one deliberately uses hypothetical choice, so that this if of interest in its own right. (**real incentives/hypothetical choice**) P. 28 penultimate para says that for normative it is right. P. 29, by way of digression, discusses empirical observations for descriptive purposes. Top says that real incentives is problematic for high stakes and losses. Middle nicely discusses observability problem that choice f from {f,g,h} does not reveal preference between g and h, and the paradox that for transitivity testing you need to observe three choices but take each one as only choice. Income effect if observing more than one. Then it proposes, last para, the random incentive system (RIS), ascribing the idea to his teacher the statistician W. Allen Wallis but also writing that Allais used it. Lines −3/−2 point out that one needs a conditioning assumption (the point of Holt American Economic Review 1986) to justify the RIS.

Pp. 40-43, §3.4: For Savage, countable additivity was not central and it was only a pragmatic matter of convenience. He used all subsets of the state space (which excludes countable additivity) and not a sigma-algebra only for expositional purposes, actually preferring sigma-algebra other than for exposition. Savage did express a slight preference for not committing to countable additivity but, again, not out of principle but only pragmatically, and not committing clearly. (Probably to quite some extent so as not to get in conflict with de Finetti who was in a less refined league than Savage.)

§3.3, p. 37 of 1972 version, has Theorem 3 (so, Theorem 3.3.3 in Savage's notation) with item 7 stating solvability for P: for every event E and every $0 < \mu < P(E)$ there is a subset $B \subset E$ with $P(B) = \mu$.

§ 3.4, pp. 42-43: That his results all hold true on sigma-algebras, but that at least his proof does not work on algebras. Kopylov (2007) extends the result to algebras of events, and even mosaics.

Savage (1972, pp. 57-58): "To approach the matter in a somewhat different way, there seem to be some probability relations about which we feel relatively "sure" as compared with others. When our opinions, as reflected in real or envisaged action, are inconsistent, we sacrifice the unsure opinions to the sure ones. The notion of "sure" and "unsure" introduced here is vague, and my complaint is precisely that neither the theory of personal probability, as it is developed in this book, nor any other device known to me renders the notion less vague."

linear utility for small stakes: P. 60, on book making argument of de Finetti: "but it seems to me a somewhat less satisfactory approach than the one sponsored here, because it must assume either that the bets are for infinitesimal sums or … that the utility of money is linear."

linear utility for small stakes: P. 91: for small amounts, utility is approximately linear

risky utility u = transform of strength of preference v, latter doesn't exist: p. 91, "the now almost obsolete economic notion of utility in riskless situations, a notion still sometimes confused with the one under discussion." P. 94 (using Bernoulli's term moral worth for utility): "It seems mystical, however, to talk about moral worth apart from probability and, having done so, doubly mystical to postulate that this undefined quantity serves as a utility."

P. 94, on Bernoulli's logarithmic utility: "To this day, no other function has been suggested as a better prototype for Everyman's utility function."

P. 95, "Cramer therefore concluded, and I think rightly, that the utility of cash must be bounded, at least from above." Then Savage says there must also be lower bounds.

P. 96 (of 72 ed.) says that utility is ordinal if only to determine choice between riskless options, says that useful requirements may be discovered in the future that do make utility cardinal, says "That possibility remains academic to date".

P. 101, end of second paragraph: ... the law of the conservation of energy ...

new sorts of energy are so defined as to keep the law true. Whole p. 101 discusses point that theories can in principle explain everything, at the cost however of becoming tautological.

P. 103: example of car with or without radio.

Seems to say that individuals with same evidence can have different beliefs.

value of information: seems to write somewhere "the person is free to ignore the observation. That obvious fact is the theory's expression of the commonplace that knowledge is not disadvantageous."

derived concepts in pref. axioms: Using concepts derived from prefs in axioms: Back of front leaf has first defined concepts and then axioms using these, for virtually all postulates (P2, P3, P4, P5, P7), being preferences given events, null events, preferences over consequences, and qualitative ordering of events. Main text uses derived concepts in P3 (p. 26) and P7 (pp. 77-78).

biseparable utility: for his EU;

A criticism of the mathematical analysis is that Savage never clearly specifies what the domain of preference is. I think that in the main text we should take it to be ALL maps from states to consequences, where, as his §3.4 (pp. 40-43) explains, it can equally well be with a sigma-algebra of events (and a sigma-algerba on the set of consequences) and only ALL measurable maps from states to consequences. The difference between whether measurability and sigma-algebras are present or not, is not important for what follows and will be ignored henceforth. Fishburn (1970), in his clear account of Savage's (1954) theorem, does it this way, immediately writing "F is the set of all functions of S into X" (§14.1, p. 192). Whether the domain includes all maps, or at least all simple (finitely many values) acts, or at least all bounded acts, is left unspecified by Savage.

Continuing, I think that Savage surely needs all simple acts (he calls them gambles) in his proof. The proof of Theorem 4 in §5.3 (pp. 75-76) in its last para refers to the "convex set of all gambles" which suggests it quite. I conjecture that, because Savage did not know how to handle the set of all acts and, for instance, unbounded utility with integrals possibly hard to define, he deliberately wrote vaguely about it, to cover up that he did not understand. See for instance the following text on p. 42, §3.4: "All that has been, or is to be, formally deduced in this book concerning preferences among sets, could be modified, mutatis mutandis, so that the class of events would not be the class of *all* subsets of S, but rather a Borel field, that is, a σ-algebra, on S;

the set of *all* consequences would be a measurable space, that is, a set with a particular σ-algebra singled out; and an act would be *a measurable function* from the measurable space of events to the measurable space of consequences." [italics added] Note how Savage explicitly writes the word "all" for the events and consequences, but none of such for the acts. His intelligence here works against him in the sense that I do not believe that this ambiguity in language came by accident. The last part of §5.4, pp. 81-82, speculates on acts with unbounded utility and clearly shows that Savage is in the blue on what the domain of preference, i.e, the set of acts considered, is. His nonbehavioral definition of bounded acts on p. 79 in §5.4 (could easily have referred to upper/lower bound *consequences* instead, which under finite additivity is somewhat more restrictive and safer) is also unfortunate.

Fishburn (1970) deviates from Savage by clearly and unambiguously stating that the preference domain contains all maps from states to consequences, and then proving that utility has to be bounded. Fishburn is kind to Savage by stating that Savage missed this implication, rather than that Savage covered up his lack of understanding by being vague. Wakker (1993 MOR) showed how to handle unbounded utility in Savage's model.

I think that mainly Savage's P2 is responsible for the vast implications in statistics, being main in implying the likelihood principle, ruling out classical statistics. Savage's book does not contain this view. As he explained in the preface of his 1972 edition, he was not aware of the likelihood principle in 1954. His text on pp. 206 bottom and p. 207, §13.5, goes a bit in the direction. He does mention a special role of P2 there. But the first example, on Chernoff, only involves his P1, weak ordering. His second example, minimax loss, does indeed seem to involve violation of P2, but not clearly explained, and if so then in an almost trivial manner. Then he seems to return, on the banquet committee, to just P1. So, P2 does not give much mileage. %}

Savage, Leonard J. (1954) "*The Foundations of Statistics.*" Wiley, New York. (2nd edn. 1972, Dover Publications, New York.)

{% Points out that one's view of probability (frequentist or subjective or otherwise) will contribute to one's view on statistics, but does not pin it down as I have in mind. Discusses behavior theory versus inferential theory. Section 5, especially p. 581 3rd para, tries to argue that the classical approach is more subjective than the

Bayesian, but does so by taking as only objective component in the classical approach the admissibility criterion, which I do not agree with. P. 580 2nd para is very interesting. It shows that by betweenness, a weak version of von Neumann-Morgenstern independence w.r.t. probabilistic mixing, the tradeoffs between errors of type I and type II should be linear, leading to a critical likelihood ratio mentioned in the third para of that p. 580. This vNM independence is similar in spirit to the sure-thing principle (I mean here only Savage's P2), but nothing in the paper comes closer to P2. P. 582, 4th para, writes negative about the 1954 book in being too deeply in the frequentist tradition to do a good job. Savage (1954) was indeed confused about what the brilliant first half of his book would imply for statistics.

P. 583 2nd para is on the likelihood principle, but does not link it to the sure-thing principle. It points out that the likelihood function is a minimal sufficient statistic.

P. 585 2nd para has me surprised, in saying that randomization is useful to statistics. As a Bayesian, I think that an optimal decision never involves randomization. But, on the other hand, it is a useful mathematical devise that can give us useful insights. The value of a two-person zero-sum game may require randomization but still gives useful insights. %}

Savage, Leonard J. (1961) "The Foundations of Statistics Reconsidered." *In Proceedings of the Fourth Berkeley Symposium on Mathematics and Probability*, Berkeley, University of California Press.

{% P. 17: Likelihood follows from subjective probabilities + Form. Bayes. Seems that he says having learned about the Stopping Rule Principle from Barnard in 1952 and then considering it patently wrong, to now considering it patently right. So, in 1952 he had little awareness of the likelihood principle.

paternalism/Humean-view-of-preference: Adrian F.M. Smith seems to have written: "Consistency is not *necessarily* a virtue: one can be consistently obnoxious." %}

{% **updating: discussing conditional probability and/or updating**
P. 308 first full para and p. 309 first full para (pointed out to me by Bob Clemen and Bob Nau): "In what sense is this theory normative? It is intended that a reflective person who finds himself about to behave in conflict with the theory will reconsider. … To use the preference theory is to search for incoherence among potential decisions, of which you, the user of the theory, must then revise one or more. The theory itself does not say which way back to coherence is to be chosen, and presumably should not be expected to." %}

Savage, Leonard J. (1967) "Difficulties in the Theory of Personal Probability," *Philosophy of Science* 34, 305–310.

{% **proper scoring rules**: P. 785 discusses that proper scoring rules assume linear utility. Section 9.4 proves that the logarithm and its linear transformations are the only proper scoring rules for three or more nonnull events that are local (have payment under some event depend only on score assigned to that event, and not on how the scores for the other events). Most papers in the literature prove this only under differentiability assumptions, but Savage proves it in full generality.

BEGINNING OF EXPLANATION OF EQ. 9.27

It took me several hours before I understood the correctness of Savage's reasoning as follows (p. 794)

" $f_1(yw)q + f_2\big((1-y)w\big)(1-q) \;<\; f_1(qw)q + f_2\big((1-q)w\big)(1-q)$ (9.27)

if $y \neq q$. The left side of (9.27) is, therefore, in q, a strict linear function of support at y of g_w, where

$$g_w(y) \;=\; f_1(yw)y + f_2\big((1-y)w\big)(1-y) \qquad (9.28)\text{"}$$

mostly because of the use of the symbol y in Eq. 9.28. For me the following reasoning works: take

$$g_w(q) = f_1(qw)q + f_2((1-q)w)(1-q)$$

as a function with the variable argument q. Take any fixed value y in its domain, say $y = ¼$. Then the linear (affine) function $f_1(¼w)q + f_2(¾w)(1-q)$ of q is linear in q, it is equal to g_w at $q = 1/4$, and is strictly below g_w everywhere else because of Eq. 9.27. We can do this for every fixed value y in the domain of g_w other than

¼ and, hence, g_w is strictly convex. For me it was confusing that Savage seemed to denote by y the variable function argument in Eq. 9.28. Only later I understood that he means y to be a constant there, substituted for the variable argument q. But, at any rate, his reasoning is correct.

END OF EXPLANATION OF EQ. 9.27

random incentive system: P. 785 1st column suggests it, ascribing it to personal communication with W. Allen Wallis, and referring to Allais (1952) for it.

linear utility for small stakes: p. 786: "Within sufficiently narrow limits, any person's utilities can be expected to be practically linear." %}

{% **decreasing/increasing impatience**: Find the usual decreasing impatience for long periods, but increasing for short (less than a week). Time consistency is equated with dynamic consistency (where, for fixed calendar time of consumption, the calendar time of choice changes and then should not matter). It is also referred to as longitudinal test of time inconsistency. Cross-sectional test of time consistency is stationarity (calendar time of decision is always now, and calendar time of consumption changes). P. 471 2^{nd} column last para points out that equating the two involves the implicit assumption of time invariance (decisions go by stopwatch time; so, these authors do not confuse **DC = stationarity**). P. 473 2^{nd} column 2^{nd} para does it again. Yet some sentences are hard to read because they refer to changes in time without specifying if consumption time or decision time is changing.

Table 1 lists many studies in the literature, where only three really test longitudinal (p. 472 last para).

real incentives/hypothetical choice, for time preferences: study 1 has real incentives, with monetary outcomes. %}

{% 1^{st} commentary: **uncertainty amplifies risk**: they find this, although overestimation of probabilities may also play a role.

N = 254 subjects were told that they had inherited a painting (part A of exp.) or a sculpture (part B), each worth $2000. Were asked WTP for insurance against fire/theft. Only one of 254 subjects played for real, which is not much. Note that they insure a thing given to them, so, no real loss. Groups 1 & 2 were told that the painting would be considered strolen iff 24 rain days in July at Frankfurt airport (sculpture: 23 rain days in August). This will confuse subjects, because is it risk of theft or risk of 24 days of rain that the experimenter wants them to think of? Authors estimate probability 1/10000 (so, 1/5000 for the two events together), but do not tell subjects. Group 3 had it contingent on 12 rain days in July (probability 1/10). ´After that subjects were asked the same but now with those probabilities as objectively given. Note that a 1/5000 probability of losing $2000 is very small, and of little concern. That only one or two (if both objects) o 254 play for real further decreases the interest.

They use BDM (Becker-DeGroot-Marschak) where subjects were given sealed envelope beforehand with the random prize already specified. After stating WTP, subjects were asked for estimates of subjective probabilities. They were also asked “how worried” they were.

Subjects paid much more under ambiguous probability than under objective. One-third of subjects paid nothing (fewer under ambiguity). Subjects greatly underestimate small ambiguous probabilities 1/5000, and slightly underestimate 1/5 (contrast effects will contribute). WTP is hardly different for small and large probabilities! Can be explained by subjects thinking of theft rather than rain. The worry variable predicts WTP well. No surprise, because it can be proxy for WTP. (Tests around Table 7 do not help.) Subjects pay much more than EV.
2nd commentary:
losses from prior endowment mechanism & random incentive system between-subjects (paying only some subjects; p. 535)**.** Only some subjects play for real, get prior endowment and then pay back. But nicely and convincingly implemented: N = 263 students were told they own a valuable painting ($2000), given a picture, told that small risk of losing, and asked premium to insure. Only two randomly chosen played for real at the end. Did modified WTP (introduced by Schade & Kunreuther 2001 in their working paper), where the random prize is drawn at the beginning (but left unknown; no info such as probability distribution is given to the subjects about this). Marvelous way to give them reference point. Found that feelings of worry better predict premium than subjective probability

estimate, but little surprise it is because feeling of worry is quite the same as fear-of-loss, so willingness to pay. Many subjects pay nothing for insurance, others do remarkably much. They pay more under ambiguity than under risk. They are remarkably insensitive to changes in likelihood (even by a factor 1000), suggesting insensitivity. %}

{% An agent observes repeated trials from an exchangeable process (iid but with unknown probabilities). This paper looks at observations of properties never observed before. It uses Carnap's formulas of induction (i.e., Bayesian updating with beta priors) and variations. Properties never observed is important in biology for species never observed before, and in anonimity protection of data files for the probability of a unique (so, very identifiable) subject showing up. It is also related to reversed Baysianism of Karni & Vierø (2013). %}

Schipper, Burkhard C. (2024) "Predicting the Unpredictable under Subjective Expected Utility," working paper.

{% Proper scoring rules and matching probabilities have been used to measure beliefs (subjective probabilities). These two methods can be used for one-off events of whom we can only observe whether or not they happen, and sometimes even without that (Prelec 2004). But these methods are not very easy to understand for subjects. This paper considers cases where way more information is available: the events have objective probabilities already known to the experimenter. For instance, they concern the proportion of white balls in an urn, or, as in the experiment in this paper, the number of subjects in an experiment on the stag hunt game that chose to be selfish. The experimenter wants to measure the subjective probabilities of subjects who do not yet know the objective probabilities. Then other measurement methods, using different reward systems, become available. This paper considers what is called the frequency method. Subjects receive a reward if their guess is fully correct, and nothing otherwise. So, it is a kind of guessing game. It can be considered to be a special case of calibration.

Pro of the frequency method is that it is easier to understand for subjects than the above two methods. Besides the big con of restricted applicability, another con is that the method is not really incentive compatible: Assume Bayesianism beliefs with a 2nd order subjective probability distribution over the frequency to be estimated. Optimal in this method is to take the *modus* of the 2nd order distribution, whereas the subjective belief is the mean. In practice, these will often agree.) As for the restricted applicability, belief measurements are often used if the experimenter wants to learn from the subject (e.g., an expert). The frequency method cannot be used then.

The writing of the paper is sometimes misleading. Whereas the first two lines of the abstract properly write that the frequency method needs (way!) more info than other methods, many parts, including the whole discussion-conclusion §6, never mentions this restriction, suggesting that the frequency method is on a par with other methods regarding applicability. %}

Schlag, Karl & James Tremewan (2021) “Simple Belief Elicitation: An Experimental Evaluation,” *Journal of Risk and Uncertainty* 62, 137–155. https://doi.org/10.1007/s11166-021-09349-6

{% **survey on belief measurement**; p. 463 footnote 5 suggests that the logarithmic proper scoring rule is the only one that is proper for more than two events, with payment for any event depending only on that event (locality), although the footnote seems to consider only two events where it is not only the logarithmic function. The authors suggest that this result is hard to find in the literature. On the basis of this footnote I asked some people if they know about proofs in the literature. In the end, Jingni Yang found a general proof in Savage (1971 §9.4).

P. 465 Proposition 1: For every proper scoring rule different than quadratic there is a distribution where quadratic gives better incentives to tell truth. So, in a way, quadratic is not Pareto inferior.

P. 469 2nd para suggests that Offerman et al. (2009) could only handle probabilistic sophistication, but this is not so. Offerman et al. consider as Case 3 probabilistic sophistication, and then Case 4 as its generalization where probabilistic sophistication need no more hold, and they also handle that case. Weele (12Oct2015, email) explained to me that the text here is ambiguous. They had meant this text to refer back only to §2.4.3, which is about probabilistic sophistication, and did not mean to suggest that Offerman et al. cannot handle probabilistic sophistication.

The authors point out several times, e.g. p. 473 top, that we have no gold standard of true subjective beliefs usually.

§4.1 discusses how belief elicitation can distort decision making to be measured later. %}

{% An expert should provide an interval estimate of a variable. He should be off (true variable outside estimated interval) no more than 1-gamma times, which can encourage him to take the interval large. However, given the restriction, he gets rewarded for taking the interval as tight as possible. It is obvious that the expert will choose a threshold and incorporate all values with probability density exceeding the threshold. Question is how to make him choose the right threshold, giving probability gamma. A most likely interval rewarding formula is proposed (p. 458). The purpose is that, as long as the expert's subjective probability of an interval stated is smaller than gamma, it pays to enlarge, and when it is bigger than gamma, it pays to reduce. In the optimum, the first-order condition should imply a probability gamma. The result holds under EU where utility is concave (or linear). A question is why the criterion to have exactly subjective probability gamma (in the spirit of classical statistical hypothesis testing, a theory not respected by me I must say). Section 4 gives examples. %}

event/outcome driven ambiguity model: event driven

my handwritten notebook p. 401;

Argues against prior probabilities of statistics, against probability sophistication; does not say clearly that for risk one should do EU, although comment 4.2, p. 586, argues normatively against probability transformation of RDU. Says nowhere clearly if capacity reflects only belief and not attitude towards belief, although some places do suggest it a bit.

P. 576 nicely points out that in Schmeidler's view, completeness is the most restrictive axiom: "Out of the seven axioms listed here the completeness of the preferences seems to me the most restrictive and most imposing assumption of the theory." (**completeness criticisms**)

Pp. 586-587 points out that his model can accommodate the co-existence of gambling and insurance.

A small mathematical problem is that the paper assumes only an algebra of events, but needs a sigma-algebra. The reason is that it assumes closedness with respect to the mixing of acts. As Wakker (1993 MOR, Example 1.2) shows, with an algebra of events the sum (or mixture) of two measurable acts need not be measurable. %}

{% They take prospect theory where the reference outcome need not be constant, but can depend on the state of nature, as in Sugden (2003, JET). Then they consider preference reversals such as a P-prospect (0.97:$4) versus a $-prospect (0.31:$16). They do not consider straight certainty equivalent determination from ping-pong choices for instance, but only WTA: The subject is first endowed with the prospect, can focus on this as reference outcome (not constant, of course), and then evaluates giving up the $-prospect for a sure amount x as a (0.97: −$4+x, 0.03:x), and the P-prospect as (0.31:−$16+x, 0.69:x). They then show that under usual Tversky & Kahneman (1992) parametrizations of PT, preference reversals are accommodated. They, finally, add numerical calculations of which parameter combinations can accommodate preference reversals, and numerical analyses of which parameter combinations of PT generate preference reversals. %}

Schmidt, Ulrich & Horst Zank (2001) “A New Axiomatization of Rank-Dependent Expected Utility with Tradeoff Consistency for Equally Likely Outcomes,” *Journal of Mathematical Economics* 35, 483–491.

{% Derive PT with linear utility with kink at zero from cosigned comonotonic additivity (nicely called independence of common increments), generalizing Chateauneuf (1991) to PT. %}

Schmidt, Ulrich & Horst Zank (2001) “An Axiomatization of Linear Cumulative Prospect Theory with Applications to Portfolio Selection and Insurance Demand,” School of Economic Studies, The University of Manchester.

{% Define weak loss aversion as $y_{0.5}(-y) >' x_{0.5}(-x)$ ($>'$ denotes strict preference) whenever $x > y \geq 0$ (Kahneman & Tversky, 1979, p. 279), and strong loss aversion as $\alpha y + \alpha(-y) + (1-2\alpha)P >' \alpha x + \alpha(-x) + (1-2\alpha)P$ whenever $x > y \geq 0$, where α is a probability, x and y are degenerate prospects, the mixing is probabilistically, and the outcomes x and y have the same rank in both mixtures, and so do –x and –y. Under EU and OPT (’79 prospect theory) these conditions are equivalent to utility differences for losses exceeding those for gains. Under ’92 PT (CPT), an equality comes in with ratios of weighting functions.

SPT instead of OPT: they do this for general lotteries in Eq. 2.

Authors plead strongly for a definition of loss aversion entirely in terms of preferences, and not in terms of theory-dependent concepts such as utility.

P. 164 para –3: For probability weighting functions that are “too steep” at zero, the loss-aversion condition of the authors cannot be satisfied. The authors write that such weighting functions are unreasonable. %}

Schmidt, Ulrich & Horst Zank (2005) “What is Loss Aversion?,” *Journal of Risk and Uncertainty* 30, 157–167.

{% Characterize PT with linear utility for risk. They properly assign priority to a 2002 version of Schmidt & Zank (2009) that appeared later but was written earlier.

RDU with linear utility has been characterized by Chateauneuf (1991, JME), De Waegenaere & Wakker (2001), and Diecidue & Wakker (2002). This paper extends sign dependence to those results. %}

Schmidt, Ulrich & Horst Zank (2007) “Linear Cumulative Prospect Theory with Applications to Portfolio Selection and Insurance Demand,” *Decisions in Economics and Finance* 30, 1–18.

{% Study strong risk aversion under prospect theory. Holds iff:

(i) For gains, U concave and w+ convex;

(ii) For losses, U concave and w- concave (or convex if you do, like they do, top-bottom instead of the conventional bottom-up integration for losses);

(iii) The ratio of the left- and right-derivatives of utility at zero should exceed w+´(p)/w-´(p) (w+ weighting for gains, w- for losses) at each p in (0,1).

Here, (i) and (ii) are like Chew, Karni, & Safra (1987), but, very nice, they don’t use differentiability. This is desirable because there is no easy preference condition to give differentiability. (iii) is an entirely new thing. Utility can be linear for gains and losses, strictly convex at zero, if probability weightings are accordingly, in particular have appropriate jump(s) at 1. %}

Schmidt, Ulrich & Horst Zank (2008) “Risk Aversion in Cumulative Prospect Theory,” *Management Science* 54, 208–216.

{% Characterize PT with linear utility for uncertainty through a rank-sign weakening of additivity. Although this paper appeared later than Schmidt & Zank (2007), it preceded it in writing and Schmidt & Zank (2007) properly assign priority to this paper. RDU with linear utility has been characterized by Chateauneuf (1991, JME), De Waegenaere & Wakker (2001), and Diecidue & Wakker (2002). This paper extends sign dependence to those results. First consider only finite state space with nonnull states (at least three of them) and strictly increasing linear utility. Then do general state space with null-invariance (being nonnull for one rank-ordering and sign then for all) where they handle all bounded prospects using supnorm continuity. They use a theorem of Chew & Wakker (1993) to obtain their result.

In their integration for losses, they (unfortunately!) do top-down integration instead of the bottom-up integration that was used by Tversky & Kahneman (1992) and that is conventional. %}

Schmidt, Ulrich & Horst Zank (2009) "A Simple Model of Cumulative Prospect Theory," *Journal of Mathematical Economics* 45, 308–319.

{% **tradeoff method**: used theoretically.

Big issue in PT is what the reference point can be. Many want to derive it endogenously. This paper does so, by taking it as the inflection point of utility. The essential condition, constant diminishing sensitivity (p. 104) is nice: For every outcome, either there should be consistent concavity above (if it is a gain) or consistent convexity below (if it is a loss). It is formulated such that it also implies PT by a kind of implied tradeoff consistency (Theorem 1, p. 106). If there are outcomes of both kind, then their strict inequality conditions imply that there is one unique outcome that is of both kinds: this is the reference point.

They also present a more general condition (one-sided comonotonic tradeoff consistency, p. 107), which does not commit to concave or convex, but only requires that for each outcome either the utility standard sequences are consistent above this outcome (then it is a gain) or below (then it is a loss). They again state it in such a manner that it automatically implies PT, by capturing a kind of tradeoff consistency (Theorem 2, p. 108). Very nice! Would be nice to derive it from loss aversion, which the authors state as an important topic for future research. %}

Schmidt, Ulrich & Horst Zank (2012) "A Genuine Foundation of Prospect Theory," *Journal of Risk and Uncertainty* 42, 97–113.

{% **risky utility u = transform of strength of preference v**:
Consider decision under risk with simple lotteries over money. The authors consider a functional

$(p_1{:}x_1,\ldots,pn{:}x_n) \mapsto V(x_1) + p_2U(x_2-x_1) + \cdots + p_nU(x_n-x_1)$ (for x_1 the minimal outcome), and call it chance theory. Here V can be interpreted as a riskless utility function and U as a risky utility function. (**risky utility u = transform of strength of preference v**) Unlike utility of gambling models, chance utilitydoes not violate basic conditions such as monotonicity or transitivity. It can accommodate paradoxes such as Allais and Rabin.

If we increase x by a small $\varepsilon > 0$, so that it remains the minimal outcome then the functional gains

$V(x+\varepsilon)-V(x)$

but also loses

$P(E_2)\big(U(x_2-x_1+\varepsilon)-U(x_2-x_1)\big) + \cdots + P(E_2)\big(U(x_n-x_1+\varepsilon)-U(x_n-x_1)\big)$

Taking p_1 very small we see that, to satisfy monotonicity, $V'(x_1)$ should not be smaller than $U'(y)$ for any $y \geq 0$. V' exceeding U´ ever ywhere (U can only have positive arguments) means that lowest outcomes get overweighted. Proposition 1 shows that the functional satisfies weak risk aversion.

The authors provide a preference foundation and comparative results.

Because of the deviating treatment of $x_2,\ldots,x_n$, chance theory only overlaps EU in expected value.

In some places, the authors put up as motivation for the different treatment of the minimal outcome that one can be sure about that from the start whereas other uncertainties may get resolved later and there may be intermediate decisions to be taken, where one can already reckon on the minimal outcome but not yet on the other outcomes. But I think that this deviates too much from the basic decision model and I therefore prefer different motivations.

The functional, and its treatment of $x_2,\ldots,x_n$, is VERY reminiscent of the formula for prospect theory for many outcomes in the working paper Kahneman & Tversky (1975), which also gives a similar special place to the minimal outcome (for gains).

Kahneman and Tversky later replaced utility of difference by difference of utility in their published 1979 paper, thus extending to general not-real-valued outcomes. It is very natural to, similarly, replace chance theory by

$(p_1{:}x_1,\ldots,pn{:}x_n) \mapsto V(x_1) + p_2\big(U(x_2)-U(x_1)\big) + \cdots + p_n\big(U(x_n)-U(x_1)\big)$ (for x_1 minimal). %}

{% **criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**: **updating under ambiguity with sampling**; Consider Anscombe-Aumann framework. Under probabilistic sophistication, independence for risky choice becomes equivalent to monotonicity and SEU. An experiment shows that monotonicity is violated in a systematic direction by half the subjects, and this is strongly correlated with just violating independence in the regular Allais paradox. The experiment considers the common consequence version of Allais' paradox. With M denoting $\$10^6$, the conditional choice is between M on balls 1-11 versus 5M on balls 2-11 and 0M on ball 1.

- First they do the regular Allais paradox, where there are 89 other balls in the same urn (so, it has 100 balls in total), and in one choice situation the common consequence is 1M under these balls so that the certainty effect comes in, and in the other situation one receives 0M under these balls, so, no certainty effect.
- Then they do an uncertainty version. There are no more than the 11 balls in the urn. But now a horse race takes place, with 100 symmetric horses. In both situations the conditional choice is only if horse 1-11 wins the race. The conditional outcome on horses 12-100 is either 1M, so that the certainty effect comes in, or 0M, and then no certainty effect.

Under probabilistic sophistication (+ RCLA) the two choice situations should be identical. %}

Schneider, Florian H. & Martin Schonger (2019) "An Experimental Test of the Anscombe-Aumann Monotonicity Axiom," *Management Science* 65, 1667–1677. https://doi.org/10.1287/mnsc.2017.3010

{% The agent is a convex combination of a rational EU maximizing constant discounter and a prospect theory maximizing nonconstant discounter. The model can accommodate many anomalies. %}

Schneider, Mark (2018) “Dual Process Utility Theory: A Model of Decision under Risk and over Time,” working paper.

{% %}

Schneider, Mark & Jonathan W. Leland (2015) “Reference Dependence, Cooperation, and Coordination in Games,” *Judgement and Decision Making* 10, 123–129.

{% This paper considers violations of independence/sure-thing principle under different framings. In particular, a matrix frame that displays the common outcome in a salient manner, has fewer violations. The paper only cites some recent papers on this dependence on framing, but it has been known for decades. Wakker, Erev, & Weber (1994) mention it on top of p. 202, citing Keller (1985) and Erev, Bornstein, & Wallsten (1993) for it and, hence, using four different framings.

Here is another, old, argument: That subjects violate less in the matrix frame where the common outcome is clear, need not mean that their true preferences satisfy it, but it can also mean that subjects do it only as heuristic to simplify their task without this being their true preference. Unfortunately, I cannot give a reference now where this was stated, but it has been written long ago. I stated it for several years preceding 2019 in this annotated bibliography when commenting on the issue for p. 1267 of Bordalo, Gennaioli, & Shleifer (2012). I think that the point has also been discussed in the literature on regret theory (Starmer & Sugden 1998 find that the matrix representation better fits regret theory). Different, but similar in spirit, is the shaping hypothesis of Loomes, Starmer, & Sugden (2003). %}

Schneider, Mark, Jonathan W. Leland, & Nathaniel T. Wilcox (2018) “Ambiguity Framed,” *Journal of Risk and Uncertainty* 57, 133–151.

{% They study ambiguity in the Anscombe-Aumann framework. They propose a new ambiguity model that reminds me of Gul’s (1991) disappointment aversion model, although that is not cited. For an act, a separation is made between the bad states that have an outcome (is horse-race lottery) worse than the act itself (disappointment) and the good ones that have a better outcome (elation). Then the subjective probabilities (those are assumed in the model for the horses) of the bad states are overweighted by a factor 1+ρ, those of the good states are overweighted by a factor 1−ρ, and then there is renormalization; if my diagonal reading made me understand properly. Because objective probabilities are available, matching and calibration can be done. The main axiom, Axiom 6 (p. 28) requires existence of a ρ such that … and then recalibration with objective probabilities. The main point of the analysis is that unique subjective probabilities on the horses result, and this is interesting. It means that we have probabilistic sophistication within the horse race, and that it fits within the source method.

The model seems to satisfy Siniscalchi's Complementary independence (p. 28), which means that it cannot accommodate the empirically prevailing insensitivity or reflection. %}

{% Show that describing the outcome $0 as "losing nothing" or "gaining nothing" makes a difference. %}

Scholten, Marc, Daniel Read, & Neil Stewart (2019) "The Framing of Nothing and the Psychology of Choice," *Journal of Risk and Uncertainty* 59, 125–149.

{% The authors propose an intertemporal choice model with attribute-based rather than alternative-based evaluations, simpler and more comprehensive than a preceding model by Scholten & Read (2010) in this journal. Alternative-based evaluation means that each choice option is evaluated by aggregating over its attributes (independent of everything else), and a choice between two is determined by the one that received the higher evaluation. This is typical for transitivity, or unitary evaluation as Burks (1977) nicely called it. Attribute-based evaluation means that in a choice between two, first for each attribute comparisons are made, and then those are aggregated into an overall evaluation. This is typical of regret theory and may give violations of transitivity. The latter way of reasoning underlies the tradeoff method that I worked much on in young years. Tversky (1969) called the former approach horizontal and the latter vertical. The intro cites many papers using attribute-based evaluation for risk and time. The time bias is quite like the present bias, adapted to the new model. %}

Schotter, Andrew, & Isabel Trevino (2014) "Belief Elicitation in the Laboratory," *Annual Review of Economics* 6, 103–128.

{% Aumann & Serrano (2008) proposed a global index of riskiness of a prospect:

For a lottery and a level of wealth, the risk factor is the risk tolerance (reciprocal of the Pratt-Arrow index of risk aversion) for which the lottery, at that level of wealth, is equivalent to not gambling. It is real-valued for prospects with both positive and negative outcomes.

This paper does the same in a relative sense. It considers lotteries with positive outcomes, at both sides of 1. It considers the risk tolerance (reciprocal of now the relative index of risk aversion) for which the lottery is equivalent to having 1 for sure. It is real-valued for prospects with outcomes at both sides of 1. Outcomes are best interpreted as returns per unit invested.

The literature uses the term risk tolerance both for the reciprocal of absolute risk aversion used by Aumann & Serrano, and the reciprocal of relative risk aversion used in this paper. %}

Schreiber, Amnon (2014) "Economic Indices of Absolute and Relative Riskiness," *Economic Theory* 56, 309–331.

{% An applied study using Tversky & Kahneman's (1992) prospect theory to fit observed certainty equivalents. The use logpower (CRRA) utility and the one-parameter probability weighting family of T&K. Strangely enough, although T&K used choice lists and are cited three times more than Holt & Laury (2002), the authors still credit Holt & Laury for the use of choice lists. Well, this is the spirit of current times (2025). They do it regarding drought risks for Kenyan (agro-)pastoralists, deriving policy recommendations. %}

Schrieks, Teun, W.J. Wouter Botzen, Toon Haer, & Jeroen C.J.H. Aerts (2024) "Drought Risk Attitudes in Pastoral and Agro-Pastoral Communities in Kenya," *Journal of Behavioral and Experimental Economics* 108, 102143. https://doi.org/10.1016/j.socec.2023.102143

{% **ambiguous outcomes vs. ambiguous probabilities**: subjects play lotteries where with known probability they get "something," where the latter is an unknown outcome. Those stimuli are called lotto lotteries. So, there is uncertainty about the outcome. An example is taking a medicine with known probabilities of side effects but uncertain what the effects of those side effects will be. The author remodels it as I like: as two-stage uncertainty, where the second stage of uncertainty concerns the outcome and is ambiguous. Subjects are very averse to the second-stage ambiguity which is naturally explained as a contrast effect. Note that the model is what Machina jokingly called an Aumann-Anscombe model. The roulette events precede the horse events. The paper takes a two-stage evaluation with backward induction and α-maxmin (w.r.t. a set of subjective priors that if I understand right is determined and communicated to the subjects by the experimenter; I did not check carefully) to model ambiguity. It notices the similarities with belief functions and, to my joy, cites Jaffray (1989) for it. %}

Schröder, David (2025) "Lotto lotteries — Decision Making under Uncertainty when Payoffs Are Unknown," *Journal of Behavioral and Experimental Economics* 114, 102310. https://doi.org/10.1016/j.socec.2024.102310

{% Use RIS. Use choice list (as did so many preceding Holt & Laury 2002) to get certainty equivalents.

gender differences in risk attitudes: in insurance-framed decisions, women are as risk averse as men. In the abstract framing women are more risk averse for gains and more risk seeking for losses, suggesting more pronounced **inverse S.** Loss prospects were identical to gain prospects in final wealth, but were implemented by **losses from prior endowment mechanism**, so that it was really only framing.

reflection at individual level for risk: they do not report this;

risk averse for gains, risk seeking for losses: I did not find whether there is risk aversion for gains and risk seeking for losses. %}

{% P. 831: **utility = representational**:

"the unholy alliance between economics and Benthamite philosophy,"

it is directed against Benthamite utilitarianism.

Appendix to Ch. 7 describes history of utility, criticizing Benthamite utility again and again, in the context of utilitarianism. For example, in §3, "impression that marginal utility theory depended upon utilitarian or hedonist premisses—Bentham certainly thought so—and could be attacked successfully by attacking these. Jevons was the chief culprit: he even went so far as to call economic theory a 'calculus of pleasure and pain' "

§4 of the appendix ("Psychology and the Utility Theory"), however, gives a balanced account of the matter:

"it is preferable to derive a given set of propositions from externally or 'objectively' observable facts, if it can be done, than to derive the same set of propositions from premisses established by introspection. And, as we shall presently see, this can actually be done in the case of the utility theory of value, at least as long as we do not ask it to do more for us than to furnish the assumptions or 'restrictions' that we need within the equilibrium theory of values and prices."

Note here the crucial antecedent "at least as long as" Schumpeter writes elsewhere in the §4: "the efforts of psychologists to measure psychical quantities is not a matter of indifference to any economist who is not entirely lacking in scientific imagination."

§5, on cardinal utility, gives a fine historical account, would have been useful if I had read it before October 18, 1997. Top of p. 1061 there writes that it was Edgeworth who did away with additively separable utility of commodity bundles. §6 then goes into ordinal utility. §7 is on some consistency by Samuelson and §8 on wefare economics. Apparently, welfare economics is normative whereas positive economics is descriptive. %}

Schumpeter, Joseph (1954) "*History of Economic Analysis*." MacMillan, London.

{% **tradeoff method**: use this to measure utility of money; find that individuals who prefer to deliberate over decisions have more linear utility; N = 200 students, 15 outliers were discarded, arguing that they did not choose deliberately.

Use **random incentive system**; indifferences were elicited through pingpong choices.

random incentive system between-subjects (paying only some subjects); **real incentives/hypothetical choice**: One of every 17 subjects played one of their choices for real, however was paid only 1% of the real amounts, which can be taken as a distortion of the outcomes, in the first sample of 68 subjects. This was dropped in the second sample of 132 subjects, where it was only hypothetical choice. There were no differences in the results between the two samples. Half of their stimuli concerned losses and, although they don't comment on this point, I assume that the real incentives were only for gains.

The fitted power (α; median 0.91) for gains and (β; median 0.90) for losses. %}

{% **second-order probabilities to model ambiguity**; Many authors write that Segal was the first to abandon RCLA to model ambiguity, but this is not the case. My keyword gives preceding papers.

Segal’s model of ambiguity is two-stage. Uncertainty about 1st order probabilities (on the outcome-relevant events) is modeled through 2nd order probabilities. Backwards induction is used at each stage. All of this is as the smooth model (KMM 2005). The difference is that at each stage Segal uses a nonEU functional, whereas the smooth model uses EU at each stage. Further, Segal assumes the same nonEU risk functional at each stage (“time neutrality”), whereas the smooth model has a different EU functional at each stage. A pro of Segal’s model is that it is empirically more realistic. A con is that, at least to my knowledge, it does not distinguish between ambiguity and two-stage risk (+ backward induction …). This is also stated by Evren (2019, p. 298, 5th para): “Obviously, ambiguity attittudes are also non-separable from risk preferences in Segal’s (1987) theory.”

{% **dynamic consistency**; like Border & Segal (1994), it considers the special case of long-run events going to 0 where event E has probability p, its complement E^c has probability 1–p, p goes to 0, and all else remains the same. It assumes dynamic consistency only for the optimally-chosen strategy. That is, pref between that strategy and other available strategies should remain unaffected. In addition, it assumes that prefs between optimal strategy and nonavailable strategies should also be unaffected. All other prefs are, however, permitted to change freely after updating. (**updating under ambiguity**) Thus, only the indifference class of optimal choice is EU. Rest is free.

Then comes, on p. 214, the question of what those other prefs mean. They are not related to hypothetical choices as in decision analysis or consumer demand theory. They are related to “reconsidered choice” because of earlier mistakes in modeling. In counterfactual nodes the agent would have acted believing in the wrong tree. %}

Segal, Uzi (1997) “Dynamic Consistency and Reference Points,” *Journal of Economic Theory* 72, 208–219.

{% This paper considers the vNM axiomatization of expected utility. Given the common axioms of weak ordering and continuity in probability mixing, consider the independence axiom: $\forall$P,Q,C, $0<\lambda<1$: $P \succcurlyeq Q \Rightarrow \lambda P+(1-\lambda)C \succcurlyeq \lambda Q+(1-\lambda)C$. It can be weakened to $\forall$P,Q,C, $\exists 0<\lambda<1$: $P \succcurlyeq Q \Rightarrow \lambda P+(1-\lambda)C \succcurlyeq \lambda Q+(1-\lambda)C$.

Then still, with the other axioms available, it is strong enough to imply expected utility. A very nice reinforcement of a classical result!

criticizing the dangerous role of technical axioms such as continuity: the result illustrates it once more. By continuity the weak ∃ axiom is turned into the strong ∀ axiom.

The result is very similar to Observation 88 of Hardy, Littlewood, & Polya (1934), and the proofs are very similar, as indicated by the author.

Similar results are provided for betweenness and mixture symmetry. Discussions of observability of axioms are added.

I felt that there was dilution in this paper. It could better have focused on the above theorem than add the further results. %}

{% Theorem 1 characterizes a result for partial separability, the weakening of joint independence that only excludes reversals of strict preferences after replacement of common outcomes, a condition studied by Blackorby, Primont, & Russell, and some others. For three or more dimensions, monotonicity, symmetry, indifference monotonicity (kind of same degree of strict monotonicity all along indifference curves), and partial separability hold if and only if there exists a representation that kind of maximizes a kind of additively decomposable multiplicative form with one degenerate origin-point, and min everywhere below the origin-point, or a dual representation, with max. representation above an origin and additive decomposability below. Fig. 1 on p. 137 gives a good idea.

The authors equate linearity with the combination of invariance under adding a constant (like constant absolute risk aversion) and multiplying by a positive constant (like constant relative risk aversion), but linearity is stronger. RDU with linear utility satisfies constant absolute and relative risk aversion, but is not a linear functional. %}

{% **Christiane, Veronika & I**: they pay in probabilities unit.

linear utility for small stakes: if payment is not in money but in probability for a prize, then by any rational theory with RCLA and stochastic dominance, subjects should maximize expected probability. This point has often been observed under the assumption of subjective expected utility. It is a nice observation, which the paper starts with, that it in fact holds for every probabilistically sophisticated (meaning (additive) subjective probabilities are used and decisions are based on only those; the paper does not use this term) agent under the minimal assumptions of preferring the highest probability at a good outcome and RCLA.

However, extensive violations have been found empirically that are farther apart from expectation maximization than for real money. Payments vary between 0 and 500 pfennig, which is between \$0 and \$2.50, with one loss gamble for about −\$1 added. The common ratio effect, the “reference point effect” (I assume loss aversion), preference reversals, and violations of stochastic dominance persist and seem to be even stronger.

Backward induction seems to be natural in the paper’s setup.

{% **coherentism**
Argues that internal consistency conditions are unconvincing if not related to external criteria. While essentially true, I disagree with the presentation in this paper. Internal consistency is never all of it, indeed, but still it is worthwhile to study it. The more so as, for any external consistency requirement, one can require further external justification (to every answer one can ask again "why"), so, external consistency need not be principally more sound.

P. 498: the necessity of bringing in something outside choice behavior is the issue.

P. 500, fortunately, uses the terms contraction consistency and expansion consistency instead of Sen's earlier unfortunate terms property α or property γ.

Many many examples of all kinds of violations of IIA etc.

§3 gives a long list of examples of context-dependence, always arguing for the one side of the coin that that can happen and never for the other side of the coin that then not much theory can be developed or predictions be made.

I also disagree with the use of the social choice theory analysis of the author. He first argues that for a social choice relation there is less reason for consistency

than individual. Well, OK. Then he revisits Arrow's impossibility theorem without imposing internal consistency conditions (such as transitivity) on social preference. He does impose Pareto and some other conditions invoking individual preferences. He then says that the conditions invoking individual preferences are external consistency conditions for social preference. Under this heading he derives a few formal axiomatic variations on Arrow's result. I think that taking the individual prefs as external and not as part of the internal system is ad hoc and the "external consistency" of Pareto, for instance, is not more convincing than the internal consistency condition of transitivity of group preference in a fundamental way.

Gives nice example of violation of IIA: from {b,c} you take c, from {a,b,c} you take b. Reason: these are slices of cake and you were taught not to take the largest slice but only the second-largest. %}

Sen, Amartya K. (1993) "The Internal Consistency of Choice," *Econometrica* 61, 495–521.

{% Abstract last sentence shows enthusiasm that one often sees: "These differences have considerable relevance in studies of economic, social, and political behavior."

P. 765: Buridan's ass; paper gives further examples where basic principles of revealed pref. such as IIA are violated, and distinguishes many reasons for those violations. Term menu-independence is used as a nice alternative for Tversky's context-dependence. Elementary results on revealed pref are given; they don't seem to be new. Variation of the Luce & Raiffa restaurant example: {t,O} where t is take tea invitation from friend, O is going home. You're inclined to take t. Then comes {t,O,H} where friend also offers H (heroin) ...

{% Axiomatizes basically the same model as Klibanoff, Marinacci, & Mukerji (2005) (KMM), but assumes an extra stage with objective extraneous probabilities prior to the model. He thus also considers probability distributions over acts. In this respect he is as the original three-stage of Anscombe & Aumann (1963); they also assumed such a third prior stage. He assumes EU within the extra stage, as he does within all stages of his model (same as KMM), but he abandons RCLA so as to have deviations from EU and to have ambiguity and Ellsberg behavior (with multistage modeling). That is, he abandons the reversal-of-order axiom of Anscombe-Aumann. That reversal-of-order axiom justifies assuming the third prior stage away and moving it into the afterwards-stage. (Most papers using the Anscombe-Aumann framework since the 1980s take it, following Fishburn, in the latter sense, and have only objective-probabilities afterwards and not prior.) Seo can use the extra prior probabilities to calibrate, à la matching probabilities, the subjective probabilities over the states. In this way we can recover info about μ, although μ need not be unique. (This is a problem: the prior μ cannot be uniquely separated from the utility transformation function φ.) Seo thus does not need the unobservable second-order acts of KMM, but in return is less general. He has the same parameters and modeling of ambiguity as KMM.

As regards the calibration procedure: if receiving some roulette lottery (that is how I refer to probability distributions over deterministic prizes resulting after the horse-race/states) under event E is equivalent to receiving it over the whole state space with prior probability 1/3, then the second-order integrated subjective probability (μ) over E must also be 1/3.

Halevy & Ozenoren have a similar model with probabilistic sophistication instead of EU within each stage, where they put the calibration idea central. %}

{% P. 251 writes: "I suggest, therefore, that when he contemplates this inner range of outcomes each of which carries no potential surprise, the entrepreneur does in fact concentrate his attention exclusively on the best and the worst hypotheses in this range." However, it is only within a set of outcomes that are not at all surprising to occur. Too vague to be related to inverse S. %}

Shackle, George L.S. (1941) "A Means of Promoting Investment," *Economic Journal* 51, 249–260.

{% Introduces his idea of nonadditive probability ("potential surprise"). The derived decision model does not seem to be interesting (you should group, for a given act, all outcomes with same degree of surprise, and then consider of them only the highest????????).

Ch. II insists on differentiating between gains and losses; says that sign-dependence: people first assess gains-part, then losses-part, then aggregate.

Seems to argue that statistical information is not relevant to single-shot decisions: (**principle of complete ignorance**): P. 8 seems to ask as a meant-to-be rhetoric question: "Suppose the captains in a Test Match have agreed that instead of tossing a coin for a choice of innings they will decide the matter by this next throw of a die, and that if it shows an ace Australia shall bat first, if any other number, then England shall bat first. Can we now give any meaningful answer whatever to the question, "Who will bat first?" except "We do not know?" " Shackle is making elementary mistakes!

Arrow (1951 Econometrica p. 419) criticizes Shackle's theory for it being impossible to incorporate any sense of updating after repeated trials. It seems that Shackle was a student of Keynes. %}

Shackle, George L.S. (1949) "*Expectation in Economics.*" Cambridge University Press, Cambridge.

{% Shackle was early to argue for using nonadditive probabilities and sign dependence (gains different than losses), ideas central in prospect theory, and deserves some credit for that. But he seems to suggest theories or formulas that are incomprehensible to me and, I guess, everyone, and, therefore, he does not deserve much credit I think.

Nonadditivity is taken to express amount of information, somewhat like belief functions. Says beliefs must sum to 1 but potential surprise need not. Draws sharp distinction between indivisible experiment (unique event) and divisible (repeatable).

P. 71 seems to argue that probabilities are irrelevant for single events

P. 72 claims as self-evident ("The reader will at once, I think, concede") that, among a number of hypotheses with equal degree of surprise, only the one with the highest gain is of concern to the agent. That makes sense to me only if the hypotheses are choice options. Apart from this strange claim of max-only-concern, repeated several times, it always seems that hypotheses are uncertain events.

Shackle seems to favor a max-max approach to uncertainty, but discusses also an “integral” solution that he does not like. P. 72/73 argues that you cannot integrate over mutually exclusive hypotheses, which seems absurd to me. He describes an integral idea that was described by a Professor Svennilson, but only in Swedish, and was reported to Shackle by a Mr. Turvey. I thought for some time that maybe it referred to a rank-dependent form, but in Copenhagen in 1997, with the help of Jacob Gyntelberg who has Danish as his mother language and therefore can understand some Swedish, read in Svennilson’s work and came to conclude that he probably does not have it.

P. 73 ℓ. -14/-10 seems to derive decision weights as differences betweencumulative weights, bit similar to rank dependence. %}

{% **restricting representations to subsets**: Shows that characterizing SEU on finite structures is extremely difficult. Many people who, erroneously, think that this amounts to simply restricting Savage's axioms to the finite case can learn from this paper that it is way more complex.

I like the opening in Sections 1 & 2, with good criteria specified: The axiomatization should be on finite sets and for incomplete preferences there. This is what one should do to really understand a model. Such an axiomatization is not yet available for subjective expected utility, so, we do not really know what this model means.

When I reread this paper March 2011 I was disappointed to see that the author involves artificial compound prospects (he calls them compound tickets) involving repetitions and extendability of the preference relation to these, e.g. in the theorem on p. 1295, no 6.0. Extendability arguments can be used to assume any desired structural richness, and are of limited interest only. Once you have

compound prospects and sequences of outcomes, then easier axiomatizations become possible than provided in this paper. %}

{% The paper discusses, and axiomatizes, the following ambiguity model. Assume that W is a convex weighting function and a probability measure P in the core of

W* (i.e., P(E) ≥ W*(E) for each E). The author interprets W as objective info. Since it is convex, it can be interpreted as a lower probability of a set of priors, which can be taken as its core. The P chosen is subjective. The author assumes W and P given, exogenous.

One example of the model of this paper is if the decision maker defines the convex combination W* = αP + (1–α) W* and maximizes rank-dependent utility (= Choquet expected utility). We can interpret W* as resulting from taking the objective W in full, but discounting the extra subjective belief P–W by a factor α ≤ 1. It can accommodate the Ellsberg paradox. But it is not very new, just using the convex W*.

This paper generalizes by also considering nonlinear combinations of W and P (or P–W). Those can also accommodate Machina's counterexamples to rank-dependent utility. The paper axiomatizes its model. The requirement of having W and P as inputs is not easy to implement, and the nonlinear combination of W and P are also general. %}

{% **time preference** %}

Shelley, Marjorie K. (1993) “Outcome Signs, Question Frames and Discount Rates,” *Management Science* 39, 806–815.

{% Consider a probabilty space (Ω,Σ,P), where P is given by a regulator, or by nature. And, thus, can be used as primitive in axioms, as in decision under risk in the eonomic literature. However, this paper is in the literature on risk measures, where a quantitative risk measure ρ is the primitive, rather than a preference relation as often in economics. *Law-invariance* of the risk measure ρ means that $\rho(X) = \rho(Y)$ whenever the random variables X and Y generate the same probability distribution over $\mathbb{R}$. It is similar to how economists define decision under risk. This paper considers partial law invariance: $\mathcal{G}$-law-invariance means that there exists a sub-sigma algebra $\mathcal{G}$ such that law-invariance only holds for $\mathcal{G}$-measurable random variables. The idea is that P is reliable (or whatever term one uses) on $\mathcal{G}$ but not outside. Economists might say that there is ambiguity (unertainty about true probability) outside $\mathcal{G}$, but the field of risk measures will interpret it differently I guess. A proper term is yet to be invented here. The paper derives several mathematical results, such as, if I understand right, continuity conditions sufficient that quasi-convexity plus translation invariance implies that ρ is maxmin, but expectation on $\mathcal{G}$, and conditions that imply, for X and Y, that their conditional expectations given $\mathcal{G}$ have a pointwise dominance relation. If a risk measure ρ satisfies conditions such as (quasi)convexity, then its conditional expectation give $\mathcal{G}$ will inherit many of these properties. Taking conditional expectation in itself is expected-value based, treating the conditional uncertainty linearly, which does not fit nicely with this conditional uncertainty taken as ambiguous.

The paper considers sets of priors with $\mathcal{G}$ independent, meaning that the priors all agree on $\mathcal{G}$. ρ is a sup over a set of priors and is $\mathcal{G}$-law invariant, if and only if the set of priors satisfies some sort of law-invariance w.r.t. $\mathcal{G}$ %}

{% **updating under ambiguity**: the authors study dilation: receipt of info turns risk into ambiguity.

Assume that a fair coin is flipped giving H or T, 50-50. Also, a ball is randomly drawn from an unknown Ellsberg urn, containing R(e(eds.)d) and B(lack) balls in

unknown proportion, giving R or B as result. Assume the gamble is that one receives $1 if H and $0 if T:

	B	R
H	1	1
T	0	0

The gamble is risk, not ambiguity. But assume one gets informed whether {(HB), TR)} happened or {(HR, TB)}, so, which diagonal. After receipt of the info, there is ambiguity. (It could be increased by letting the draw of ball be done AFTER the toss of coins, but a different urn after H than after T.) For Bayesians, who are ambiguity neutral, the info has no value, and they will be indifferent to receiving it or not. But ambiguity averse people will dislike it and ambiguity seeking people will like it. Such info is called dilation, borrowing this term from statistics where it concerns the fact that extra observations can increase the variance of estimators.

This paper uses the above example in an experiment, but it interprets B as correctness of a signal, R as incorrectness, {(HB), TR)} as signal "H" and {(HR, TB)} as signal "T". The interpretation of signal makes it easier to remember for subjects but has the drawback of arousing nonneutral emotions. Results: ambiguity-seeking subjects evaluate the info positively and after like the gamble more, but ambiguity-averse subjects neither like not dislike these things.

The theoretical claims do depend on attitude to dynamic decisions. Under McClennen's resolute choice, i.e., Machina's (1989) dynamic consistency, one simply adheres to one's preferences when born and is indifferent to info if worthless, i.e., the value of free info is never negative. The authors discuss this briefly on p. 16 middle.

At the end of the paper, the authors point out that their findings are negative for most current ambiguity models.

Kops & Pasichnichenko (2023) suggest that the formulation of unreliable signal generates aversion. %}

{% Seems to give arguments against efficient market hypothesis. %}

Shleifer, Andrei (2000) "*Claredon Lectures: Inefficient Markets.*" Oxford University Press, Oxford.

{% Lists many biases.

P. 1080: "The broad field of behavioral economics—perhaps the most important conceptual innovation in economics over the last thirty years—might not have existed without Kahneman and Tversky's fundamental work."

P. 1081: "My feeling is that the most profound influence of Kahneman and Tversky's work on economics has been in finance, on what has now become the field of behavioral finance"

P. 1081: "large and costly errors people make in important choices. Let me illustrate. First, individuals pay large multiples of actuarially fair value to buy insurance against small losses, as well as to reduce their deductibles (Sydnor 2010)." (**small risks overinsured**)

P. 1081: "Second, the standard economic view that persuasion is conveyance of information seems to run into a rather basic problem that advertising is typically emotional, associative, and misleading—yet nonetheless effective (Bertrand et al. 2010; DellaVigna and Gentzkow 2010; Mullainathan, Schwartzstein, and Shleifer 2008)."

"The second objection holds that market forces eliminate the influence of psychological factors on prices and allocations. One version of this argument, made forcefully by Friedman (1953) in the context of financial markets, holds that arbitrage brings prices, and therefore resource allocation, to efficient levels. Subsequent research has shown, however, that Friedman's argument— while elegant—is theoretically (and practically) incorrect. Real-world arbitrage is costly and risky, and hence limited (see, e.g., Grossman and Miller 1988, DeLong et al. 1990, Shleifer & Vishny 1997). Dozens of empirical studies confirm that, even in markets with relatively inexpensive arbitrage, identical, or nearly identical, securities trade at different prices. With costlier arbitrage, pricing is even less efficient."

P. 1086 writes that reference dependence is the most radical assumption of prospect theory. On the reference point of Kahneman & Tversky versus Köszegi & Rabin: "The reference point is thus left as a rather unspecified part of Kahneman and Tversky's theory, their measure of "context" in which decisions are made. Köszegi and Rabin (2006) suggest that reference points should be rational expectations of future consumption, a proposal that brings in calculated thought." This is exactly the point where Köszegi and Rabin (2006) deviate from earlier thoughts. %}

Sikorski, Roman (1969) "*Boolean Algebras*;" 3rd edn. Springer, Berlin.

{% The authors did crowdsourcing analysis. It means that one same dataset is given to different teams that separately (or in communication) analyze it statistically. They did it with 29 teams, investigating the hypothesis that players in football with a dark skin get more red cards. 20 teams find the result significantly, and 9 teams not. The basic idea may be interesting. Problem is that the result found is unsurprising and uninformative. If one study finds something significant, and another study does not, then this is not a contradictory finding because finding H_0 does not mean much and may be just coincidence (unless a good power analysis if added). Whereas for simple t-tests and the like (with simple monotone distributions) there is a clearly best test, for many more complex distributions there is no clearly best statistical test, and different tests have different pros and cons. Comes to it that always subjective choices have to be made in the data analyses, such as what to consider missing.

Of the version that I saw (undated, around October 2015) the opening sentence suggests that these authors restrict the scientific process and creativity to empirical/experimental studies: "In the scientific process, creativity is mostly associated with the generation of testable hypotheses and the development of suitable research designs." %}

{% This paper assumes the Anscombe-Aumann framework, where maxmin EU was axiomatized by Gilboa & Schmeidler (1989). What this paper adds is a necessary and sufficient condition for a prior to be contained in the set of multiple priors. Such a prior is characterized by the existence of a convex subset of acts such that on this convex subset EU is satisfied w.r.t. the prior, and such that there is no other probability measure with respect to which this holds. In the main result, axiom 6 (no local hedging in the sense that for each sequence of acts converging to an act there is a subsequence of acts that, losely speaking, provide no hedge against each other) characterizes the existence of a finite coverage of acts such that within each coverage, EU holds.

While this paper characterizes whether or not a single probability measure is contained in the set of priors, it does not provide a verifiable characterization of the set of priors. For the latter one would have to check for every single probability measure whether or not it is contained, which is an infinite task. The author formulates this point in Ghirardato & Marinacci (2012 p. 2832) as: "that plausible priors are identified individually, rather than as element of a set." %}

{% S is state space, f is act from S to outcomes. It is Anscombe-Aumann framework with outcomes being probability distributions over prizes, which mathematically amounts to utility being linear in outcomes. P denotes the subjective probability measure on state space S used in EU and elsewhere.

$$V(f) = EU_P(f) + A\Big(\big(E_P\big(\zeta_i(s)\cdot u(f(s))\big)\big)_{0\le i\le n}\Big)$$

where ζ_i is a random variable, density of a signed measure if you want, with P-expectation 0, and the dot following ζ denotes inner product. Because ζ has P expectation 0, the inner product gives the P covariance between ζ_i and $u\big(f(s)\big)$. Can simplify some by taking ζ and P together as just one signed measure with total measure 0. (Keeping absolute continuity w.r.t. P in the back of one's mind, primarily to avoid violations of monotonicity.) The ζ depend on the states and not only on their probabilities implying that we do not have probabilistic sophistication. A deviation from probabilistic sophistication is needed to accommodate Ellsberg. $A(x) = A(-x)$ for all $x \in \mathbb{R}^n$. So, A is a generalized Absolute value function. The idea is that each ζ_i captures an informational interaction (ambiguity) between events. And that A is mostly negative and punishes for variance over ambiguous events. So, in Ellsberg 3-color with red know color and black and yellow the unknown colors, P assigns 1/3 to all colors, $\zeta(R) = 0$, $\zeta(B) = 1$, $\zeta(Y) = -1$, and A punishes for nonzero covariance with ζ.

Big descriptive problem of the model is that $A(x) = A(-x)$ excludes inverse S because, with outcomes in utils, for an unlikely event E the prospect 1_E0 is undervalued as much as $1_{E^c}0$ is $\big($turn 1_E0 into -1_E0 and then use weak certainty independence to add 1 util to all outcomes, which does not affect A$\big)$, whereas inverse S implies that the former is overvalued but the latter is undervalued. This makes the model descriptively problematic (in addition to the problems of the Anscombe-Aumann framework).

The ζs are not unique but become so if sharpness is imposed: then they are required to be orthonormal (linearly independence + orthogonality) and to assign value 0 to any crisp act (crisp means informally entailing no ambiguity or hedge against it, formalized by being replacable in any mixture by its certainty equivalent).

The model can be related to anchoring and adjustment à la Einhorn & Hogarth (properly cited by the author on p. 802). The model chosen here with interaction captured through inner product with complementarity between positive and negative part of ζs primarily captures n "binary" complementarities in a natural way. If the urn contains k exchangeable ambiguous colors with k > 2, then I don't see an easy way to model this. Maybe many ζ's must be defined (for each color one?) and A must capture the k-interactions? Not clear.

The axioms characterizing the model are some usual ones: weak ordering (A1), monotonicity (A2), continuity in outcomes (A3), nondegeneracy (A4), weak certainty independence (A5: only mixing with sure prospects to give independence under translations but not under rescalings), monotone continuity (A6) to give countable additivity of P, a probably redundant Complementary translation axiom (A8; only needed to handle two-sided bounded utility), and the crucial axiom of Complementary independence (A7), which I reformulate:

Assume that f and f* are complete hedges (their sum is constant as is their 50-50 mixture; the author calls it complementary), and so are g and g*. Assume that f ~ f* and g ~ g*. Then for all mixture weights α,

$\alpha f + (1-\alpha)g \sim \alpha f^* + (1-\alpha)g^*$.

Key in this model is pairs of acts that are perfect hedges (complementary) for each other, meaning that they sum to a constant act. Particularly useful are such pairs if they are indifferent (obtainable by adding constant utility to the worst of a pair of perfect hedges). Then their sum gives a constant act equal to the value of the two acts if EU were to hold; i.e., if A were 0. How much this constant act exceeds the certainty equivalent of the acts is how big −A is. Thus, we can measure the EU functional and also A. Being able to measure EU means that we can also measure P. Complementary independence will ensure, I expect, that the P measured this way is additive.

The model holds together with CEU (Choquet expected utility) if and only if there is a probability measure P such that, with W the weighting function, W underweights each event as much as its complement: $W(E) - P(E) = W(E^c) - P(E^c)$ for all events E. This property contradicts inverse S.

More ambiguity averse results are derived implying same subjective probability P and utility u, characterized by one A function always dominating the other.

biseparable utility violated: The model is not biseparable utility, although it does intersect with the latter (see above intersection with CEU). The main reason is that the function A can be too general and nonlinear. For example, take S =

$\{s_1,s_2\}$, payment in vNM utility (for instance prizes are [0,100], u is the identity on prizes, and for known probabilities we have EV). $p_1 = P(s_1) = p_2 = P(s_2) = 0.5$, and only one $\zeta_0 = \zeta$, defined by $\zeta(s_1) = 1/3 = -\zeta(s_2)$. $A(\alpha) = -|\alpha|$ if $|\alpha| \leq 37/3$, and $A(\alpha) = -|\alpha-37/3|/2 - 37/3$ if $|\alpha| > 37/3$. It means that, as long as outcomes within an act differ by no more than 37, then we have RDU with linear utility and $\pi(s_j)^b$ (the decision weight of state s_j when having the best outcome) = 1/3 and $\pi(s_j)^w$ (the decision weight of state s_j when having the worst outcome) = 2/3. In other words, $W(s_1) = W(s_2) = 1/3$. If the difference in outcomes exceeds 37, then whatever the best outcome has more than the worst + 37, is weighted only half as much. Then (using stimuli of Wakker 2010, §4.1) we have, with (x_1,x_2) denoting the act that yields vNM utility x_1 under s_1 and x_2 under s_2,

(38,1) ~ (24,8) and

(24,1) ~ (10,8)

implying, in Wakker's (2010, Eq. 10.5.2) notation, $38 \ominus 24 \sim^t_c 24 \ominus 10$.

However,

(39,0) ~ (24,7) and

(24,0) ~ (10,7)

imply, $39 \ominus 24 \sim^t_c 24 \ominus 10$. We have a violation of rank-tradeoff consistency (Wakker 2010 Def. 10.5.5), and RDU is violated by Wakker (2010, Theorem 10.5.6). %}

{% p. 1 writes, on the combination of no-arbitrage with risk aversion: "The problem of valuation of a nontraded contingent claim has always been of central importance in mathematical finance ... Given a nonreplicable security, the market mechanism is not sufficient to determine an interval I of "threshold" prices such that any agent should buy at a price smaller than every p ∈ I, sell at a price greater than every p ∈ I, and *do nothing at any price* p ∈ I. Indeed, since the buying or selling at any *arbitrage-free price* could lead both to a loss or to a gain, the attitude of the agent toward risk must be taken into consideration to decide what he should do at any such price. Intuitively, the interval of threshold prices should depend on the investor and his initial wealth, and it should be contained in the interval of arbitrage-free prices. The classical approach in mathematical finance is to assume that the preferences of the agent are determined by the maximal expected utility u(x, q) that he can obtain by investing in the market an initial capital x if holding an endowment consisting of q illiquid contingent claims. Pricing rules derived from u(x, q) are called utility-based" [italics from original] %}

{% **criticisms of Savage's basic framework**: Takes acts and events as primitive, consequences are act-event pairs. In beginning of paper, value of consequence can depend on counterfactual consequence and context, leading to a general model (Theorem 1) that can accommodate regret, disappointment, and most other things. §4 considers additive aggregation that in itself does not yet seem restrictive but in presence of "separability" (which does not relate solely to global prefs so might better be called something like forgone-branch independence (often called consequentialism)) it becomes restrictive. It results from making the structure preferentially isomorphic to Debreu (1960). The appendix extends to infinitely many events. Because the model is in fact **state-dependent utility**, the probability measure, which is indeed used, is pointed out to identify only null events (Example 1, (a), in the appendix, p. 362)

The technique is as follows. A general model is assumed for DUU. A substructure is assumed, however, that satisfies the SEU assumptions (say; in fact, the paper does it for state-dependent SEU). Say the substructure concerns all acts with monetary outcomes and here SEU is satisfied. Let us call this substructure the canonical structure. Next, for a general act where all interactions whatsoever between outcomes are permitted, we make a corresponding canonical act that is such that for each state of nature it yields the monetary amount that is equally good for that state of nature as the outcome resulting there for the general act. In this manner, the SEU representation from the canonical structure is extended to all acts, while permitting for all interactions thinkable. %}

Skiadas, Costis (1998) "Recursive Utility and Preferences for Information," *Economic Theory* 12, 293–312.

{% Has a nice variation of the Anscombe-Aumann framework with a finite roulette-event space and a finite horse-event space, and uncertainty joint. The resulting product structure of the state space can nicely be used. One can better discuss the order of resolution of uncertainty (done in final para of main text, p. 73). Assumes quasi-convexity/uncertainty aversion. Weak certainty independence now more clearly amounts to constant relative risk aversion. The paper examines the role of weak certainty independence in detail. The sure-thing principle together with weak certainty independence imply SEU with log-power utility. This is proved in Appendix B.1, but it had been known before (Blackorby & Donaldson 1982, *International Economic Review;* Corollary 1.1; Wakker 1989, Theorem VII.7.5). The main Theorem 5 (p. 65) embeds this in a maxmin EU framework.

Theorem 11 has an SEU representation with power utility both for horses and for roulette, but they are only linked through an ordinal monotonicity and CE substitution, so they can have different powers, leading to source-dependent SEU (**event/outcome driven ambiguity model: outcome driven**). Can refer to this as Skiadas' source-dependence CRRA model. The author assumes the usual (but restrictive!) monotonicity of Anscombe-Aumann, called R-monotonicity here, meaning that we condition on horses. This result can, therefore be taken as recursive expected utility in the Anscombe-Aumann framework, which is the smooth ambiguity model but with the two stages exogenous.

criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity: P. 63 penultimate para, ℓ. 6 writes, appropriately on monotonicity in the Anscombe-Aumann framework, called R-monotonicity here: "This is not an innocuous assumption" %}

Skiadas, Costis (2013) "Scale-Invariant Uncertainty-Averse Preferences and Source-Dependent Constant Relative Risk Aversion," *Theoretical Economics* 8, 59–93. https://doi.org/10.3982/TE1004C

{% The paper is a variation of Epstein-Zin by having several sources of uncertainty and then "local" EU, within each source, with a source-dependent utility function. It is like Chew et al.'s (2008) source-dependent EU. (**source-dependent utility**) (**event/outcome driven ambiguity model: outcome driven**) Time separability is assumed. This is like Abdellaoui et al.'s (2011 American Economic Review) source method, with local within-source but no global between-source probabilistic sophistication. The author assumes SEU within each source and captures source preference (my term) through source-dependent utility, as in the smooth model.

I regret that, if there is source dependence of preference, the author calls it different risk attitude. If a first source has more concave utility than a second (so, lower certainty equivalents), the author says that the first source has more risk aversion. This same unfortunate terminology was used by Chew et al. (2008) and Kilka & Weber (2001). It may be easier to sell to noninitiated audiences at first acquaintance, but this terminology cannot survive. Risk attitude should only concern known OBJECTIVE probabilities. The difference between the unknown and the known Ellsberg urns is due to ambiguity attitude, and not due to changed risk attitude.

In the axiomatization, SEU within each source comes from separability giving state-dependent SEU, and then constant relative risk aversion which is known to then imply SEU (Wakker 1989-book Theorem VII.7.5), and give CRRA (logpower) utility. %}

{% This book follows Keynes (1937) (more than Keynes (1936) general theory, which is what Paul Krugman seems to prefer). Most of economics assumes that uncertainty can be reduced to risk, so that we can calculate expectations, correlations, and so on with certainty, and can use Lucas' rational expectations. The efficient market hypothesis is based on it. A spokesman of Goldman Sachs' (chief financial officer David Viniar ?), seems to have declared August 17 2007, at the beginning of the financial crisis, that events were occurring that according to the best models around should happen once in 10^{140} times. It shows that uncertainty isn't like risk, a point raised forcefully before by Keynes (1921) (better than Knight 1921), and reiterated by Keynes (1937). The author even argues that macroeconomics should be dedicated to the study of uncertainties that cannot be reduced to risks. %}

{% **conservation of influence**: Deviates from Watson's behaviorism, who took living beings as no more than mechanistacally reacting to stimuli, and added to that "operant gedrag" where the living being has influence. That is, Skinner added agent's influence! %}

Skinner, Burrhus F. (1971) "*Beyond Freedom and Dignity.*" Knopf, New York.

{% Seems to be last text he wrote, knowing he would die. It is a very opiniated text, arguing against the cognitive approach and favoring behaviorism. So, he wants to keep things simple at the level of directly observable phenomena and predictions directly in terms of them and their (cor)relations. Wants no abstractions such as cognitive concepts. I did not understand several parts, conjecturing that they are not clearly written. In several parts he puts up straw men. His expectations of neurology are naïve, and of a physicism-ubiquity-fallacy type. Thus, p. 293 end of para −3: "In a behavioural account the whole organism responds, and it responds to the world around it — for reasons which neurology, not cognitive science, will eventually discover." P. 295: "What is happening inside is a question to be answered by neurology, with its appropriate instruments and methods." P. 300: "Cognitive science is often only premature neurology." (**ubiquity fallacy**)

P. 294 has a nice text: "Mrs. E. Craster (d. 1874) suggested that when the toad asked the centipede: 'Pray, which leg goes after which?' the centipede worked her mind to such a pitch/She lay distracted in the ditch/Considering how to run."

P. 295: "A similar mistake is made when cognitive psychologists call operant behaviour purposive or goal-oriented. Features suggesting direction toward a goal are the products of consequences experienced in the past." (**conservation of influence**) and p. 300: "I accuse cognitive scientists of reviving a theory in which feelings and states of mind observed through introspection are taken as the causes of behaviour rather than as collateral effects of the causes." %}

Skinner, Burrhus F. (1985) "Cognitive Science and Behavourism," *British Journal of Psychology* 76, 291–301.

{% **probability intervals**: pp. 192-193 mentions the difference between multiple priors and interval probabilities. Unfortunately, it takes combinations of Dempster-Shafer belief/plausibility functions, and of convex-concave capacities, as an example of interval probabilities. This is not formally incorrect, but can be confusing because, if the concave capacity is to be taken as the dual of the convex one (similarly as a plausibility function is the dual of the belief function), then the convex capacity alone captures all the info, and this capcity can in turn be related uniquely to a set of priors. So, this is a case where the interval probabilities can be uniquely related to multiple priors, and the two models are not fundamentally different. Essential differences do arise if we relax some assumptions, such as allowing for nonconvex-nonconcave capacities. Full generality is achieved if we further allow the lower capacity not to be the dual of the upper capacity. %}

{% **coherentism**: They argue/show that preferences can be predicted from neurodata. P. 2 writes: "Furthermore, since there may also be stable relationships between real choices and a much broader class of nonchoice variables, there is no a priori reason to limit a prediction exercise to elicited preferences." They use the nice term nonchoice variables. This general point was also central in Abdellaoui, Barrios, & Wakker (2007). %}

Smith, Alec, B. Douglas Bernheim, Colin F. Camerer, & Antonio Rangel (2014) "Neural Activity Reveals Preferences without Choices," *American Economic Journal: Microeconomics* 6, 1–36.

{% Has the concept of utility, between Bernoulli (1738) and Bentham (1789).

Put forward the famous water-diamond paradox; i.e., the paradoxical difference between value in use and value in exchange. Water exceeds diamond as regards the former but not the latter.

equate risk aversion with concave utility under nonEU: Smith does not do this but clearly distinguishes.: Book I, Ch. X, §1 on risky choices between "lotteries" is interesting. Bréban & Lapidus (2019) nicely argue that Smith assumes diminishing marginal utility (1759-1790) "*The Theory of Moral Sentiments*" [1976 edn., p. 44 seems to be clear on it) but risk seeking, which is a good motivation for RDU. Smith clearly ascribes the risk seeking to overestimation of chance of good fortune. "The chance of gains is by every man more or less overvalued, and the chance of loss is by most men undervalued."

inverse S (although it does not specify small probability as relevant to inverse S) P. 210 seems to write: "That the chance of gain is naturally over-valued we may learn from the universal success of lotteries … The vain hope of gaining some of the great prizes is the sole cause of this demand. The soberest people scarce look upon it as a folly to pay a small sum for the chance of gaining ten or twenty thousand pounds."

Smith nicely distinguishes probability overestimation from overestimating own abilities, and seems to write: "The over-weening conceit which the greater part of men have of their own abilities, is an antient evil remarked by the philosophers and moralists of all ages. Their absurd presumption in their own good fortune, has been less taken notice of. It is, however, if possible, still more universal. There is no man living who, when in tolerable health and spirits, has not some share of it. The chance of gain is by every man more or less over-valued, and the chance of loss is by most men under-valued, and by scarce any man, who is in tolerable health and spirits, valued more than it is worth." (pp. 124-5)

On other-regarding preferences, seems to write: "How selfish soever man may be supposed, there are evidently some principles in his nature, which interest him in the fortune of others, and render their happiness necessary to him, though he derives nothing from it except the pleasure of seeing it." %}

Smith, Adam (1776) "*An Inquiry into the Nature and Causes of the Wealth of Nations*" [1976 edn. by Roy H. Campbell & Andrew S. Skinner], Clarendon Press, Oxford.

{% **probability intervals**; **Dutch book**; §13, p. 13, introduced lottery-prizes as quantitative outcomes alternative to money, to avoid utility curvature. The story is funny: a very small diamond is put in beeswax, you get y gram, it will be melted, and you find or do not find the diamond. %}

{% **Conservation of influence**: flexibility is future influence.

They use a consultancy with an oil/gas company to compare standard option pricing techniques (where often a discount rate higher than the risk-free market discount rate is used to reflect extra risks borne) and decision analysis techniques, and show how to integrate them.

P. 15 endnote 6: discusses as-if risk-neutral evaluation by market in presence of risk aversion.

The paper illustrates several points for applied decision analysis:

(1) The major issue in practice is to get the right model.

(2a) One should pay attention to future decision options ("flexibility;" (P. 1 1st column ℓ. –4 and throughout).

(2b) The finance techniques of pricing the future choice flexibility of options can be useful to evaluate future decisions.

(3) One has to trade off completeness of a model and tractability. (P. 3 2nd column 2nd para, that Figure 2 is much too large. 3rd para about 52,500 end points in simplified tree. P. 4 2nd para, discussing for instance getting amount of computer programming).

(4) When to use market expectation and when own subjective (p. 9 2nd para penultimate para). P. 9 ℓ. –3: option valuation for market risks and DA for private risks.

(5) Instead of lognormal distributions assumed in finance, here mean-reverting distributions were better (p. 6 2nd para). This reduces the impact of incorporating flexibility (p. 7 1st column ℓ. –3). %}

Smith, James E. & Robert F. Winkler (2006) "The Optimizer's Curse: Skepticism and Postdecision Surprise in Decision Analysis," *Management Science* 52, 311–322.

{% Made brain scans of subjects (N = 9, all medical students) while doing Ellsberg paradox etc. These subjects had electrodes in themselves and got radio-active liquids injected every two minutes ...

risk averse for gains, risk seeking for losses: This they find, the subjects are risk averse for gains and risk seeking for losses when probabilities are known. Figure 2 shows more risk aversion for gains than risk seeking for losses.

ambiguity seeking for losses: They do find less ambiguity avoidance for losses than for gains, but subjects are still ambiguity averse also for losses. The reason may be, first, the contrast effect, the choice is directly between known and unknown probability. There is a second reason: Subjects cannot choose their color in the unknown urn, so they may be suspicious (**suspicion under ambiguity**). This also occurred in Lan, Cherng-Horng, Peter Ayton, & Nigel Harvey (2010).

reflection at individual level for ambiguity %**}**

{% %}

Smith, Richard D. (1996) “Is Regret Theory an Alternative Basis for Estimating the Value of Health care Interventions?,” *Health Policy* 37, 105–115.

{% P. 324 & 325: Considers EU to be normative. But does not want to qualify deliberate violations to be mistakes.

event/outcome driven ambiguity model: outcome driven: The title already indicates this. Further, p. 325 writes: “But I do not care for the probabilistic interpretation of the violations. To me probabilities are probabilities in the sense of nonnegativity, additivity and the property of the unit measure over the whole event space. I grant the right of a man to have systematic and deliberate preferences for rewards based on dice game contingencies over the same rewards based on Dow-Jones stock price contingencies. But if he insists also that he is less than certain that the Dow-Jones average will either rise or not rise by five points or more tomorrow, then so far as I am concerned he is now making a “mistake.” He does not understand what is (or should be) meant by probability. He is entitled to his tastes, but not to any new definitions of probability.”

P. 325, on Ellsberg-like situations: “…, there may be real or imagined elements of skill which increase or reduce the subjective value of the outcomes “lose” or “win.” ” So, he thinks that in, say, Ellsberg two-color paradox, the utility of an outcome can be lower if it results from a color from the unknown urn than from the known urn. I find this a very very weird idea. In the same way as Smith writes on p. 325 ℓ. 6: “probabilities are probabilities” I will say “a dollar is a dollar” where “is” is in the sense of giving the same utility. You can do the same with a dollar if you have it after a black ball from a known urn as after a black ball from an unknown urn. Then he brings in, on p. 325 2/3, the competence effect, with social effects of being blamed brought in.

second-order probabilities to model ambiguity: p. 329 closing para, suggests that ambiguity is the same as 2^{nd} order probability.

{% **real incentives/hypothetical choice**

Kachelmeier & Shehata say: the “dominance postulate” has induced incentives in the economics literature (clarified in Smith & Walker, 1993). %}

Smith, Vernon L. (1976) "Experimental Economics: Induced Value Theory," *American Economic Review, Papers and Proceedings* 66, 274–279.

{% Much cited, and sometimes given a sort of bible status. But I find it a weird paper. It formulates conditions for microeconomic experiments:

saliency: rewards should be linked to actions of subjects;

Payoff dominance: reward structure dominates (subjective) costs of participation (e.g., calculation costs).

The paper is best understood from a historical perspective. Smith wanted to convince mainstream orthodox classical theoretical economists that experiments are to be taken seriously. So, he wanted everything to look solid and strict. This is why he had an obsession for calling experimental economics "science" rather than research. And this is why this paper puts up formal observations and theorems. And precepts. I do not find them useful. In many situations, a precept is trivially satisfied and then no need to think about it. In other situations, the precept is violated, but then it just is no good. For instance, Precept 1, nonsatiation, requires monotonicity of utility in payoff. But if we study a payoff that is not monotonic, such as amount of wine drunk per day (utility first increasing, then decreasing), then it is just not satisfied. No reason to forbid studying such. Or privacy, where subjects are supposed not to know the payoffs of others. Well, in game theory we usually want all payoffs to be common knowledge. Or we want to study reactions to repeated payoffs given to others. %}

Smith, Vernon L. (1982) "Microeconomic Systems as an Experimental Science," *American Economic Review* 72, 923–955.
https://www.jstor.org/stable/1812014

{% P. 159, footnote 8, argues for a behavioral preference assumption (constant relative risk aversion) that market data are not well suited to refute it because they are too complex:

> I have been asked: "How do you react to criticisms which say that from market data we can reject the assumption of constant relative risk aversion? We can look at how individuals change their portfolio with wealth, and it does not conform even to a much looser specification of the utility function? Why test a theory which has been rejected by

> market data?" Here are my reactions. (1) We can't reject the theory from this kind of market data. The data tells us how portfolios change with some measure of "wealth," confounded with changes in time, income, expectations, information, unmeasured probability assessments, and so on *ad infinitum*. We can't learn what we want to know from this sort of exercise independently of some rigorous tests, although market evidence and experimental evidence can illuminate each other. (2) … (3) [(2) and (3) describe two empirical findings that do support constant relative risk aversion] (4) Constant relative risk aversion need not be valid over the entire interval of positive income to yield predictive accuracy over the relevant range of observations. Probably no functional form will be satisfactory everywhere.

P. 164 argues that the vNM axioms do not speak to what the outcomes are, apparently taking EU as branch of abstract mathematics rather than as an empirical science:

"The axioms of the theory do not tell us what the prizes are." %}

{% **inverse S:** confirmed

decreasing/increasing impatience: find both, with decreasing not prevailing though

As the title says, this paper studies the interaction between risk and time. It cites much preceding literature, and adds many refinements. It confirms the general finding that adding time reduces many risk-attitude effects and vice versa. They find no time dependence of utility, but strong time dependence of probability weighting. In general, they find that models that allow for time-risk interaction fit better (with AIC) than models that have no such interaction. %}

{% Show that subjects prefer simple prospects more than complex ones. Complexity here is a broad term, where number of timepoints plays a role.

Their first experiment is single-period, and may speak to event splitting. The authors have one preference switch that they claim supports complexity aversion. However, the result is only marginally significant, with 17 switches (of 97 subjects) supporting their hypothesis but 7 going opposite, then have p = 0.065. (Footnote 14 writes: The hypotheses that the probability of switching from choosing A in problem I (I =b 1,2) to choosing B in problem j (j = 3,40 is equal to the probability of switching from B to A is similarly rejected at p ≤ 0.05.) They claim that "generalized prospect theory" with overweighting of small probabilities cannot explain it, but never define generalized prospect theory, and I guess it is separable OPT. The lotteries are quite different and there can be many explanations. I guess that CPT can accommodate the results. %}

{% Individual stocks and underdiversified portfolios have positive skewness.

Consider investment products and analyze mispricing using the source method (not using this term, but calling it the exchangeability method). Measure, in lab, certainty equivalents of 20 simple individually tailored deposits. Use source method, to first measure additive subjective probabilities, and then apply transformations (§5). They use Prelec's (1998) one-parameter family for probability weighting (what I'd call source function). I regret that no two parameters. *§5.5: source method does best in AIC measure, better than alternative models, including α maxmin!* **PT falsified**: well, source method (which uses prospect theory) in fact does best, but with unconventional parameters. Subjects are optimistic in overweighting gain tail events but, and this is deviating, they are also optimistic for loss tail events in the sense of underweighting them. This also happens when they do regular risky choices.

The authors, interestingly, repeat the experiment but now with known probabilities. Comparisons capture ambiguity attitudes. The certainty equivalents have a trend of being higher for risk, suggesting ambiguity aversion, but do not reach significance. The strange optimism of underweighting tail loss events, found under ambiguity, disappears.

Loss aversion is there, but is lower for risk, and lower than in other studies. %}

{% The authors take data from six other empirical studies on decision from description (DFD) and decision from experience (DFE). They do data fitting with a mean-variance-skewness model (MVS), and with prospect theory (PT), the latter with power utility and the Goldstein-Einhorn probability weighting family. The authors point out that PT can also capture preference for skewness. For simple prospect, with 1/2 outcomes, they find for both DFD and DFE that a mix of PT and MVS does best. For complex prospects (2-3 outcomes) in DFD 100% PT is best, and in DFE 100% MVS is best. In DFD, the authors take the observed empirical frequencies as probabilities. They do not discuss that this involves ambiguity.

Note that Hertwig always uses the term “statistical probability” for probability that is not objectively known, and always cites Knight (1921) for this, whereas Knight contributed less to this than Keynes in quantity, and much less in quality. %}

https://doi.org/10.1016/j.cognition.2018.10.023

{% This paper examines decisions under risk and uncertainty. Decision under risk is done the usual way, what is also called decision from description. Uncertainty is implemented with what is called decision from experience (DFE). It should be noted that the subjects then know that the gambles have objective probabilities (even that those are multiples of 0.05), only those are unknown to the subjects. It is not clear to me whether subjects also know that their samples are IID samples. The authors consider choices between simple lotteries, witih no more than two outcomes per lottery, and what they call complex choices, where the two lotteries to be chosen from together involve more than four outcomes. They properly (e.g., sentence pp. 1188-1189) point out that complexity can involve other things, where I add that many outcomes also triggers other emotions such as spit-event effects.

For uncertainty they use what I call the source method, i.e., they assume what I call a-neutral probabilities (have to be additive!) over events and then apply probability weighting functions to these. The authors call it the two-stage model of Tversky and co-authors but this is not correct. They are instead using Abdellaoui et al.'s (2011) source method. Both models consider a decomposition w(P). However, in the source method ambiguity is captured through w, which can be source dependent, and P is additive capturing nothing of ambiguity. In the two-stage model, to the contrary, P can be nonadditive capturing ambiguity, and w (surely as Tversky intended) is the risky-probability weighting function, not capturing ambiguity. This difference is crucial. This paper captures uncertainty attitude through w and not through P, as in the source method and not the two-stage model.

P. 1198 properly explains that most of the popular ambiguity models in the economic literature are too general, involving for instance sets of priors or 2nd order distributions over 1st order probability distributions. Big question for the source method: where get a-neutral probabilities from? For DFE, the authors consider three candidates: (1) the true objective probabilities (unknown to subjects); (2) subjective introspective assessments of beliefs; (3) relative frequencies observed in the sampling that the subjects did. (2) has been used in what Tversky and co-authors called the two-stage model, apart from (non)additivity as discussed above. They find that (3) works best. (P. 1202 2nd para) P. 1197 1st para points out that taking a-neutral probabilities as subjective parameters may be too general and give identifiability problems.

It is remarkable that these psychological authors distinguish between statistical significance and *economic* significance.

The decision theories that the authors consider are expected utility (EU), new 1992 prospect theory (CPT), separable prospect theory (N-CPT), a three-moment model which is a linear combination of expected value, variance, and skewness, and Blavatskyy's (2018) generalization of the latter in terms of utility rather than money. Mean-variance is popular in finance but never worked well in decision theory, for one reason because it violates stochastic dominance.

P. 1191 end of 2nd para, to my joy, suggests expected value as normative.

P. 1196 2nd para has a strange text: "If the prospect with a desirable (undesirable) rare outcome is chosen more (less) often in description than in experience, this indicates a description-experience gap. *This corresponds to an "as-if" overweighting of rare events in description and an "as-if" underweighting of rare events in experience with respect to the objective probabilities.*" [italics added] The italicized part is out of the blue. I think that this was overselling by the field of DFE.

For parametric fitting, the authors use the commonly used power utility and, for probability weighting, the Goldstein-Einhorn family. (They also consider a cubic family but that does not perform well.)

As mentioned above, p. 1198 properly points out that most models of ambiguity in the economic literature are (too) general: "Theoretical models of decision-making under uncertainty (often referred to as ambiguity in the economics literature) are typically extremely complex, for instance, requiring multiple priors over first-order beliefs (e.g., Ghirardato et al., 2004; Gilboa & Schmeidler, 1989) or second-order beliefs over priors (e.g., Klibanoff et al., 2005). These would be computationally expensive in complex decisions from experience as a large set of beliefs would have to be updated dynamically and simultaneously with sampling. Furthermore, to experimentally compare these models is particularly challenging as the multiple priors and/or second-order beliefs need to be inferred or elicited and a learning process stipulated—even the elicitation of first-order beliefs is already relatively daunting. Therefore, we are not optimistic that, in a sampling paradigm of complex lotteries, multiple priors and second-order beliefs can be reliably and soundly elicited or are strongly identifiable if estimated as latent variables. For this reason, we focus on a model that does not raise such complex measurement issues, the two-stage model of decisionmaking under uncertainty (Fox & Hadar, 2006; Fox & Tversky, 1998; Tversky & Fox, 1995). According to this model, decision makers first form subjective beliefs from the experienced evidence before transforming them through a rank-dependent nonlinear PWF that is typically subadditive, as is the case in CPT."

P. 1199 2nd para is misled by Bernheim & Sprenger (2020) to erroneously claim that rank dependence had not been tested extensively.

P. 1199 describes separable prospect theory (N-CPT). It defends against my criticism of it in Footnote 13 but I disagree: they write that a counterexample put up by me can be avoided by allowing the functions in N-CPT to depend on the number of outcomes. However, this generalization is not a minor modification but a drastic generalization making the whole theory to general and worthless, as pointed out in the literature several times in history, e.g. by Kahneman & Tversky (1979). Probably the authors were again misled by Bernheim & Sprenger (2020), who also tried to push this idea in ways that I think are very wrong. They also have some remarks on normative-descriptive that are irrelevant because Wakker's criticism is descriptive. True that they test independence of number of outcomes empirically, but testing independence of A from B is a far cry from having an interesting theory on depence of A on B.

P. 1199 top of second column discusses reference dependence supporting some claims in the literature on utility of income that I disagree with. However, because this experiment has no variable reference point, this discussion is irrelevant for this paper.

The authors find that allowing for different parameters in simple choices than in complex choices does not help much (p. 1204 - 1205). I interpret this as negative evidence for dependence on number of outcomes.

The authors sometimes mention that ranking outcomes, as required for rank dependence, takes much calculation power. (p. 1299 1st column 2nd para & p. 1208 2nd column 1st para), thanking Bruhin for this in footnote 12.

Psychologists, including the authors, are inclined to go for context dependence, and the main conclusion of this paper is that there is not one theory that works well in all contexts. Economists like me rather go for context independence. My reading of the results is that CPT is best. In most contexts considered it is best or second-best. Further, EU and N-CPT (p. 16) perform poorly. Good to see that separable prospect theory, with I think is not viable anyhow, also performs poorly empirically. One reason why I prefer CPT is that besides EU there is no serious decision-theory contender. Contrary to the authors'

Footnote 13, N-CPT can be disqualified beforehand, and the moment theories don't work well for decision theory for one reason because of their violations of stochastic dominance. %}

{% A short evaluation, documented below: This paper finds more risk aversion in probability equivalents (PEs) than in certainty equivalents (CEs). This is not new, has been known since the 1980s, and has been extensively documented since. Positive is that the experiment is done with great care here. Further positive is that the paper points out, interestingly, that this discrepancy can be accommodated by the Köszegi-Rabin (2006) model. The latter one-sentence contribution is, frankly, all that I learn from this paper. So, it is very very thin. There are many weak points, revealing theoretical weakness. The citation of

preceding literature is very incomplete. There have been many alternative good explanations of the discrepancy, not cited. The claim that prospect theory would assume just one fixed reference point is a blunder. A crucial novelty of prospect theory is reference dependence, which has meaning only if one considers several reference points. Prospect theory can well accommodate the discrepancy and is not violated here. The discrepancy found violates every reference-independent transitive theory. This can be said in one sentence, and does not need pages of analyses for each theory separately, putting one of them (Gul's disappoinbtment aversion), arbitrarily chosen, central. The writing is repetitive. Below, I document the claims in detail.

DETAILS:

The experiment in this paper has been done particularly carefully, with between- and within-subject comparisons, many controls, and of course real incentives, as is common by the high experimental standards of experimental economics. The finding can be accommodated by the Köszegi-Rabin model if we make the plausible assumption that in the PE question the certain outcome is chosen as reference point and in the CE question the lottery. Under reference dependence, the reference outcome is favored relative to others (whose cons are overweighted and pros are underweighted) and, hence, choosing the lottery as reference point, as in CE questions, brings more preference for the lottery and more risk seeking. The observation similarly holds for any theory that allows the (noncertain) lottery to be a reference point, such as the PT^3 theory cited for this by the author.

I have two MAIN difficulties with this paper:

(1) P. 1463 last para claims that prospect theory would assume the same reference point for CE as for PE and, hence, would be violated by the discrepancy between PE and CE: "A similar argument can be made for cumulative prospect theory, which establishes loss-averse utility relative to some fixed referent and relaxes the independence axiom's implied linearity in probability … Under such a utility formulation, certainty and probability equivalents again yield identical risk attitudes as the reference point is fixed at some known value.". This is absolutely not true. Bleichrodt, Pinto, & Wakker (2001 *Management Science*; received the Decision Analysis Society Publication award of 2003) gives detailed experimental and numerical analyses showing that prospect theory can explain the discrepancies between PE and CE *because it*

assumes different reference points here. It shows that this works for the commonly found parameters for PT.

This para cites Kahneman & Tversky (1979) to show that variability of reference points is a crucial component of prospect theory. In their Problems 11 & 12, K&T carefully choose a framing that generates different reference points in their subjects' perception, whereas in terms of final wealth the two problems are identical. The difference found must have been caused by the different reference points. It is only from that that the authors conclude: "the carriers of value or utility are changes of wealth, *rather than final asset positions*" (p. 273) [italics added here]. The novelty is in the second part of the sentence, explicitly breaking the relationship with final wealth. A more detailed discussion of changes of reference points is in Kahneman & Tversky (1979 pp. 286 ff.).

(2) The first 35 pages do not cite the extensive preceding literature on the CE-PE discrepancy. Makes superficial readers such as busy editors and narrow-read within-clan referees believe that it is all completely new. Then the paper cites some initial papers that reported the CE-PE discrepancy before in the early 1980s, but only does so at the back, p. 1494 2nd para. **Prospect theory not cited**: I am glad that the author, unlike experimental economists such as Holt & Laury (2002), took note of papers written by others than experimental economists, but it would have been more proper had this work been cited up front. Also, there is much more literature on this, with satisfactory alternative explanations for the discepancy already long available. If I may start with papers written by my students, besides the paper cited under (1) above, there is Bleichrodt (2002 Health Economics) who offers a careful explanation of the discrepancy using prospect theory, and van Osch, van den Hout, & Stiggelbout (2006) who let subjects do speak-aloud to investigate what reference points they used. For other literature, my bibliography here, sometimes using the term standard gamble (SG) instead of PE, has some keywords: **PE doesn't do well**, **PE higher than CE**, **PE higher than others**, **CE bias towards EV**, giving some 40 references on the topic. The author calls the topic a "long-standing issue" in the literature and writes: "The present results and use of the KR model may help to resolve this longstanding issue." This is incorrect because it ignores the explanations provided before. Similarly, p. 1462 writes "the KR preference model, under the assumption of an alterned referent, outperforms leading alternative explanations in terms of predictive power." Again, the author is simply

ignoring the explanations provided before.

Some further details that I found problematic:

p. 1460 writes: "Given the potential confounds of prior experimental methods, it is important to move away from hypothetical choice, physical endowments, and ownership-related language. Hence, I opt not to follow the prior endowment effect style literature and choose a design without an explicit form of endowment." This is misleading. There is nothing wrong with inducing referencce point by prior endowment, for instance. (The preceding citation of Plott & Zeiler is too gratuit.)

P. 1462 writes: "Fourth, the KR preference model, under the assumption of an altered referent, outperforms leading alternative explanations in terms of predictive power." This overstatement is solely based on the author ignoring most preceding explanations.

p. 1472: Although I did not study in detail, I did not understand something in Table 1 on p. 1471. In this experiment, it is crucial whether subjects are risk neutral or not. Choice lists are usually most refined in the area of maximal interest. However, choice lists here are least refined around risk neutrality. See, for instance., the last column. There is also a tendency for subjects to just always switch in the middle of the choice list, the middle-switching tendency. It seems that the midpoints are different for different stimuli. Could middle-switching explain the findings of this paper? I did not inspect in detail. %}

{% **PE doesn't do well**: in the TTO and PE (if I remember well, he calls it SG) measurements, subjects do not sufficiently adjust responses if the best outcome perfect health is replaced by a lower outcome not-perfect health. That is, subjects give too much the same p answer in PE and too much give up the same proportion in TTO. Closer inspection of the data (p. 62 top) shows that about 25% of subjects does not trade off at all, which seems to suggest appropriate normative adaptation which is then zero, but in fact reflects total insensitivity. Among the other 75%, 3/5 (so, 45% of the total) does not change the answer at all if the best outcome perfect health is replaced by a worse outcome.

P. 55 3rd para of first column suggests insufficient numerical sensitivity of

subjects, judging a variation in risk of 0%-8% as equally important as a variation in risk of 0%-4%. %}

{% **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**: this paper gives beautiful support for the hypothesis that risky utility = riskless utility.

Measure utility, of health outcomes (# days migraine), through direct strength-of-preference and through CE (certainty equivalent). Correction for probability transf. reconciles partly but not completely, CE utility remains more concave. They propose that this is caused by framing + loss aversion. They then strongly frame outcomes as losses so that loss aversion plays no more role. In the latter case, indeed, the discrepancy between risky and riskless utility disappears.

They let subjects write down probabilities and outcomes in a figure to verify that the subjects took notice of probabilities/outcomes. Do few subjects (8 + 6), but very thorough treatment, several session, hours, repeated measurements, of each subject, videos to show the subjects effects of migraine etc.

inverse S: they find that probability weighting is inverse S.

P. 19 bottom of version of October 1998: "Thus, it appears that a prescriptive choice needs to be made as to which framing effect is desired …"

Seems to find, as do Hershey & Schoemaker (1982), that in standard gamble choices people focus on the sure outcome as their reference point. %}

{% **real incentives/hypothetical choice**: uses random incentive system;

PT falsified: when OPT (1979-prospect theory) predicted particular violations of transitivity and monotonicity (if no editing), the theory was widely criticized for it. This paper, however, tests such violations of transitivity (or monotonicity) and

finds them confirmed. It, thus, gives empirical support to OPT.

Details:

Prospect A = $14_{0.20}0$; Prospect B = $8_{0.30}0$; Prospect C = (0.15:8, 0.15:7.75, 0.70:0). By monotonicity, B ≻ C, but by subadditivity of probability weighting under OPT (which does not amount to event splitting here because lotteries are always collapsed) we can have C ≻ B. OPT predicts C ≻ A ≻ B (including C ≻ B) because the evaluating function implies these prefs. It, however, predicts B ≻ C because of monotonicity and editing, and thus intransitivity results.

Testing number of cycles C ≻ A ≻ B ≻ C versus number of reversed cycles C ≺ A ≺ B ≺ C would not be very satisfactory because simple error theories could predict fewer errors in B ≻ C because of salience of monotonicity, and thus predominance of former cycles, without genuine intransitivity underlying it. This paper, therefore, tests only frequency of A ≻ C versus A ≻ B, and finds the former dominating. This is enough, under any plausible error theory, to ensure that either monotonicity or transitivity must be violated. Data find few violations of monotonicity and, hence, transitivity must be violated. These data were found for many stimuli A,B,C similar to the above ones. %}

{% Well-organized and accessible discussion of the normative/descriptive debate about the Allais paradox, with nice references and citations, focusing on Friedman & Savage (1948) arguments. Starmer argues that normative appeal need not imply descriptive plausibility. P. 297 bottom: his paper takes EU axioms as normatively appealing, only for the sake of argument.

Pp. 281-282 give the formula SUMw(p_j)U(x_j) as "This is essentially the type of value function assumed in prospect theory of Kahneman and Tversky (1979)". For two-nonzero-outcome prospects K&T79 used a different formula, and there have been many misunderstandings about it. The above formula has sometimes been called separable prospect theory.

P. 287 has Raiffa argument that prescriptive theory would have nothing to offer if no descriptive violations.

On two points I disagree with the author.

1. We may be DESCRIPTIVELY interested in the behavior and preferences of people only at a level of thinking where, what we have chosen to designate as elementary mistakes, are avoided. (Starmer calls our choosing a precommitment to a descriptive viewpoint.) We may think that preferences and value system are per definition transitive so that, if we observe a violation, it is a mistake and not preference or value. This point is propagated by many experimental economists. Then normative considerations do enter a purely DESCRIPTIVE enterprise. Savage did Allais paradox upon first acquaintance but not after thinking. If we want to know descriptively what Savage would do from some time in history on, then it is: not violating EU in the Allais paradox!

2. I think that normative status of something does make it empirically plausible. Only in very exceptional situations such as the Allais paradox are what I consider mistakes likely to arise and a majority may deviate from what is normative. This is a very exceptional situation that does not invalidate the descriptive plausibility implied by a normative status. Starmer seems to impicitly focus his attention to those very exceptional situations. %}

Starmer, Chris (2005) "Normative Notions in Descriptive Dialogues," *Journal of Economic Methodology* 12, 277–289.

{% **real incentives/hypothetical choice**: **random incentive system**, explained on p. 93; this is same experiment as their 1989 JRU paper, so see there for further explanation.

PT falsified: They find a necessary condition of PT and RDU violated. The necessary condition, explained on pp. 86-90, was found by accident (explained on p. 95 bottom), but actually is really clever.

Define the cumulative prospect theory functional (so, rank- and sign-dependent utility) for decision under risk, in the appendix. Preceded Tversky & Kahneman (1992) and Luce & Fishburn (1991). Well, they don't take a general probability transformation for losses but the dual of the one for gains (as reflection would have it), but still it is clear that the rank- and sign-dependent idea is there. This paper was, in turn, preceded by Šipoš (Sipos) (1979) who also defines the symmetrical integral. %}

Starmer, Chris & Robert Sugden (1989) "Violations of the Independence Axiom in Common Ratio Problems: An Experimental Test of Some Competing Hypotheses," *Annals of Operations Research* 19, 79–102.

{% **coalescing; part-whole bias**

real incentives/hypothetical choice: **random incentive system**, explained on p. 166-167; also for losses (though there subjects had a prior choice of whether or not they wanted to have the random incentive system actualized, with the loss gambles surrounded by more gain-gambles; virtually all subjects preferred to really play.) They received prior endowment (**losses from prior endowment mechanism**) but not enough to compensate all potential losses.

They don't report raw data, and not even all of the stimuli they used. They show that with juxta-position manipulation they can confirm predictions of regret theory.

inconsistency in repeated risky choice: about 26% %}

{% **backward induction/normal form, descriptive**; Shows, in reaction to Holt (1986, American Economic Review), that the isolation effect works for the **random incentive system**. Shows that **RCLA** is violated more than compound independence. Thus, gives evidence in favor of backward induction; also positive evidence for isolation effect.

They consider a standard test of the common consequence effect. That is, a choice between (0.2:10, 0.75:7, 0.05:0) versus (1:7) and a choice between (0.2:10, 0.8:0) versus (0.25:7), 0.75;0). Several subjects got only one choice. Others got both, knowing it was fifty-fifty which one would be implemented for real (RIS). Under single choice the authors found, between-subject of course, significant violation of expected utility, with the common Allais paradox (AP) pattern more frequent than its reverse. Under RIS they found the same (so, isolation). Complete RCLA would predict as many AP patterns as their reverses. So, they significantly reject complete RCLA to the favor of isolation. Other violations of isolation are not ruled out of course, the more so as confirmation of isolation is only a H_0 not-rejected. %}

Starmer, Chris & Robert Sugden (1991) "Does the Random-Lottery Incentive System Elicit True Preferences? An Experimental Investigation," *American Economic Review* 81, 971–978.

{% **coalescing;** Found that a prospect generally becomes more attactive when an event that yields a positive outcome is unpacked into two components. They thus undermine the regret-theory explanation of violations of monotonicity, and cast doubt upon regret theory. %}

Starmer, Chris & Robert Sugden (1993) "Testing for Juxtaposition and Event-Splitting Effects," *Journal of Risk and Uncertainty* 6, 235–254. https://doi.org/10.1007/BF01072613

{% Paper investigates various explanations for the preference cylces, originally explained by regret theory. Somewhat surprisingly, it finds that event splitting (**coalescing**) does not do much, and does not explain things. It is not clear what the degree of event splitting is (maybe unless one studies the data in detail). They

find more agreement with regret theory for matrix-presentations than for other presentations, and argue that framing is doing much. %}

{% This paper points out that in lottery choices, as in fact in all choices, there is a winner's curse going on. Not only will the lottery be good, but also the error probably was favorable. So, one should lower one's evaluation of one's preferred choice somewhat. Note that this can only reduce the lead of the most-preferred option over the others, and never reverse the ranking, and in this sense it is choice-irrelevant.

For every first bias/error, one can imagine situations where other errors occur and such that the first bias/error reduces the others. Then the first bias/error happens to be useful there. This paper shows that, thus, under particular errors in observations, the overestimation of small probabilities can mitigate the consequences of those errors. One reasoning is that for the most preferred prospect the probability of a good outcome is probably high so that overweighting the small probability lowers the evaluation (p. 1603 2nd para). The result of course depends much on the errors assumed. (Here, as in the formal model, the authors implicitly assume the same support of outcomes so that a good lottery cannot result from having better outcomes but only from having better probabilities.) If an agent knows about an error in observation, may also mitigate the error there rather than overweight small probabilities. The authors often link their result to evolution (e.g. p. 1604 mid).

The two observations above were provided before in the same journal by van den Steen (2004), not cited here, which seems though to be a thorough work. Benoît & Dubra (2011 Econometrica) also describe situations where probability distortion can be rational.

P. 1608 middle: The small corrections considered here only matter for decisions that are perceived close to indifferent. (But then the change of choice does not matter much.) From this the authors come to a most remarkable conclusion (P. 1620 end of Section V): "Put differently, debiasing may be beneficial in certain circumstances, but only in those that, from an evolutionary perspective, rarely result in a tie." Wow! Every biologist ever working on evolution (and still alive) should be informed about this insight, as should be every still-living person who ever

worked on debiasing. Note how evolution is used here as when putting sugar in every dish because, supposedly, sugar makes everything taste better.

P. 1617: the choice problem considered is that from a set of options a fixed fraction κ is chosen. %}

{% **ratio-difference principle**: seem to have it. %}

Stevens, Stanley S. & Hallowell Davis (1938) "*Hearing: Its Psychology and Physiology*." Wiley, New York.

{% Prothetic continua are scales that are perceived in a concave manner, e.g. duration, loudness, etc. Their perceptions are usually power functions, less curved than the logarithm (so, power between 0 and 1). Metathetic continua can in principle be perceived in a linear manner, e.g. visual position.

P. 388: "Despite pride of ownership, at least one of the authors is prepared to admit that this function is probably too steep to be representative."

Pp. 389-390 has two nice paras on validity being difficult and subjective that I reproduce below:

"The question of validity.—An equation such as the one proposed above may be expected to hold under some set of "standard conditions," e.g., lifting weights of standard, uniform size under a standard method of lifting. It will not necessarily hold for the lifting of weights that differ in size, or weights presented in different ways. As in all scientific endeavor we have to start with some set of "standard conditions," determine the empirical rules, and then explore the problem of the invariance of the rules under transformations of the conditions. Contrary to what some authors seem to imply, the failure of invariance to hold does not invalidate the rules or the equations that hold for the standard conditions. Our aspiration, of course, is to formulate rules of wide invariance, for that is the chief aim of the scientific enterprise. The demonstration that the outcome of an experiment depends on "conditions" is a way of showing that invariance is limited, but this fact has no necessary bearing on the problem of validity.

The validity of a subjective scale, or of any other scale, is always a matter of opinion. Valid is what makes sense to the scientific community in terms of the problems before it, and, unfortunately, when we push the problem back to where we have to make fundamental choices, there are no external criteria to guide the ultimate value judgments that have to be made.

Reliability is a tempting criterion, but sometimes we find that agreement among experimental results is due to the operation of factors that force agreement, as when all Os give identical ratings to the three weights shown by the squares in Fig. 4D. Predictive power is another tempting criterion, but it occasionally happens that prediction succeeds for wrong reasons, as when Fechner's law predicts the outcome of some types of category judgments. What we consider to be valid measures of things is subject to constant revision because we are always up against the uncertain task of deciding, without firm external criteria, that the given measures do or do not assess the things we are interested in."

P. 390 2nd para describes history how Stevens run into nonlinear subjective perceptions.

P. 397: the oldest subjective category scale available is judgments of brightness of stars by astronomers. %}

{% This is a highly impressive work that I enjoyed immensely and spent much time on. I have one major criticism. Stigler is often overly negative on others. It seems that he does not try to understand what others did, but rather seeks to ascribe mistakes to others, to show that he understands things better.

Here are some examples of points where Stigler did not seem to be accurate.

(1) In §I (first citation of Bentham) he cites Bentham and thinks that it is about interpersonal comparison. I think it isn't. When Bentham speaks about two individuals it is only his way of expressing dependence on !one! individual. I

think that Bentham is discussing consequentialism there, properly pointing out that one cannot incorporate “everything relevant” because then the model becomes intractable. (Note: Becker goes in the opposite direction.)

(2) In §V (p. 94) he cites Fisher on ordinal nature of utility and criticizes Pareto for being inconsistent in using cardinal utility elsewhere. However, in the cited part of Fisher, Fisher does not say utility is ordinal. He says: Utility is ordinal !!if!! we only seek ... Similarly for Pareto, his commitment will depend on context and antecedent assumptions. It seems that Bruni & Guala (2001) point out this mistake of Stigler.

(3) On p. 77, footnote 82, he suggests that §VII will demonstrate that Slutsky had seen something on quasi-concavity versus concavity of additively decomposable utility. However, I think §VII does not give that. (I didn’t check very carefully.)

(4) §VIII C argues that people do not gamble and that this should have been used to ... For this purpose, the claim of no gambling is armchair.

coherentism

Outline:

- §I on Bentham and others who posited utility.

- Then the Ricardians who did not adopt Bentham’s utility.

- Then §II on people who stated diminishing marginal utility but did not do anything with it.

- Gossen was nice, first to derive optimality condition (marginal utility divided by price should be same for all commodities).

- §III on marginal-revolution people (Jevons, Menger, Walras) who used utility and did things with it and to measure it in ways not-too-convincing.

- §IV on shape of utility, additive decomposability, concavity, competing and completing commodities, here also the earlier Bernoulli is mentioned. Also **just noticeable difference**.

- §V on (non)measurability, Fisher and Pareto, and Slutsky who banned psychology from economics

- §VI on complementarity (saying it’s hard to reconcile with ordinalism)

- §VII more on utility versus demand; Part A does abandonment of utility.

- §VIII, the final one, does general comments on parsimony versus generality and empirical reality.

Beginning of §II refers to several people who assume: m**arginal utility is diminishing**

utility families parametric: §IV.C: "The precise shape of the utility function received little attention in the main tradition of utility theory."

Mentions many people who, on the one hand, say interpersonal utility comparisons are impossible, but on the other hand do need and use them in their analysis.

§IV describes much of assumption of additively decomposable utility function among economists in the preceding section.

§V, ascribes to p. 11 ff of Fisher (1982) a reasoning that is not present in Fisher's work in this form. Stigler's reasoning reflects the idea of **tradeoff method** measurement in the additively decomposable MAU context, and of a standard sequence, but Fisher's original text does not:

> "Select arbitrarily a quantity of any commodity, say, 100 loaves of bread. Let the marginal utility of this quantity of commodity be the unit of utility (or util). Grant the ability of the individual to order the utilities of specified amounts of two goods, i.e. to indicate a preference (if one exists) or indifference between the two quantities. Then it is possible to construct the utility schedule of (say) milk. Start with no milk and find the increment of milk (δm_1) equivalent to the hundredth loaf of bread, i.e. the minimum amount of milk the individual would accept in exchange for the hundredth loaf of bread. Find a second increment (δm_2), given the possession of δm_1, equivalent to the hundreth loaf, etc. We obtain thus a schedule (or function) such as that given"

The procedure described gives a sequence 0, δm_1, δm_2, δm_3, δm_4, ... of amounts of milk that are equally-spaced in utility units, a "standard sequence," based on indifferences $(100,0) \sim (99,\delta m_1)$, ..., $(100,\delta m_i) \sim (99,\delta m_{i+1})$, ... etc.
Fisher (1892) only shows that marginal utilities can be compared under additive representation (even, more restrictively, independence of marginal utility of a commodity from the levels of other commodities) by assuming that in optimum chosen the marginal utility of money for each commodity is the same (so, Gossen's 2nd law), but he does not construct a standard sequence. And Fisher never considers direct tradeoffs between bread and milk.

Blaug (1962), §9.2 ascribes to Fisher (1927) what Stigler ascribes to Fisher (1892). I spent many hours checking out the two Fisher works, and the idea is not there. Blaug (Feb. 12, 2002, personal communication) explained that he had taken the reference from Stigler (1950) without checking the original.

§VII, on Marshall, discusses assumptions of linear utility for money.

P. 381 seems to ascribe to Pareto, incorrectly, that strengths of preferences cannot be measured (Ellingsen 1994 footnote 18). %}

{% P. xiv, about the risk/uncertainty distinction assigned to Knight: "Fortunately this is an extreme caricature of his work, because modern analysis no longer views the two classes [risk and uncertainty] as different in kind." It is not clear whether Stigler means here that risk is a special, extreme, case of uncertainty (the interpretation that I like) or that he means that people should satisfy the Savage axioms and then wants to interpret subjective probabilities as objective probabilities (**SEU = risk**). The latter is an, I think unfortunate, interpretation of the term risk that deviates from the traditional and still most common terminology. People who use the deviating terminology may write things such as "Savage showed that we need not distinguish between risk and uncertainty." In the common terminology, risk refers to objective probability, and Savage's SEU model with additive subjective probabilities is uncertainty and not risk. I prefer the traditional common terminology because I prefer that whether something is decision under risk or under uncertainty does not depend on the decision attitude of the agent. %}

Stigler, George J. (1971) "Introduction." *In* Frank H. Knight, *Risk, Uncertainty, and Profit*. Chicago University Press, Chicago.

{% Can be cited for strict ordinalist view of economics.

U(x) depends on past consumption y and, hence, that should be added in the formula. Many people add past consumption as an index to U and then have the utility function $U_y(x)$ depending on past consumption. This paper adds past consumption as an index to x, U(x,y) and then has nonchanging U: voilà! I don't think that the paper, often considered a classic, really has more to say than this.

"Market good" is the tangible object you consume, "commodity bundle" is the consequentialist thing that simply comprises "everything relevant" such as your secret admiration of your wife etc.

P. 76: "tastes (do) neither change capriciously nor differ importantly between people ... one does not argue over tastes for the same reason that one does not argue over the Rocky mountains - both are there, will be there next year, too, and are the same to all men." P. 89: "Indeed, given additional space, we would argue that the assumption of **time preference** impedes the explanation of life cycle variations in the allocation of resources, the secular growth in real incomes, and other phenomena."

P. 78, **discounting normative**: Uses formula with discounting, but footnote 4 says that "A consistent application of the assumption of stable preferences implies that the discount rate is zero; that is, the absence of time preference" It seems that they do not distinguish between ageing effect and discounting: D**C = stationarity**. When they say somewhere that discounting means that your taste for 1984 consumption changes as you move closer, they are confusing a number of things. (For example, tradeoff between 1984 and 1980 remains constant, also between 1984 and 1981, but "present" is not well defined if you assume it moving.) %}

{% real incentives: **random incentive system**. Average outcome in experiment was £2130, but when paying subjects it was divided by 1000 (brr!) (p. 113 top).

error theory for risky choice: central;

inverse S: Almost not found, Prelec's one-parameter family fits best with parameter 0.94, which is very close to linear and has almost no inverse S. (Utility $x^{0.19}$ is very concave.)

Data are nonrepresentative because it is always a choice between two two-outcome prospects where one of the two has one outcome equal to 0 (p. 112 3rd para). Birnbaum, Slovic, and others have shown that the 0 outcome generates many special biases.

Is impressive data fitting using PT. The data-fitting uses Akaike's method to discount for the number of parameters used.

P. 104 bottom: error theories always have choice probability depend only on preference value, and not on other aspects such as monotonic configurations.

90 prospect choices were elicited from N = 96 subjects, combining several parametric families for utility, probability weighting, and error theory.

P. 112 middle has discussion of interactions between parameters in parametric fitting ("multicollinearity"), and P. 121 ff. (Subsection 5.3) has results on it.

BEST FIT: power utility $U(x) = x^r$ for r = 0.19, Prelec's one-parameter family

$$w(p) = exp\left(-\,(-ln(p))^{r}\right) \text{ for } r = 0.94 \text{ (very close to linear),}$$

and a logit error function using Luce’s (1959) probabilistic choice theory. $(V(f)^{\varepsilon}/(V(f)^{\varepsilon}+V(g)^{\varepsilon})$ for ε = ? (I did not find it).

P. 102, and p. 123 top: the mean-variance model behaves very poorly in fitting data.

P. 101 last para claims that to fit one parameter, the others must be assumed. This need not be so for specially constructed data sets. For instance, when using data from the tradeoff method for parametric fitting, the parameter of utility can be fit irrespective of what weighting-function parameter is taken. Arguments in favor of nonparametric fitting will be given on p. 125.

The author uses the term “nonparametric” to refer solely to the approach where the utility of each outcome considered and the probability weight of each probability considered is taken as a separate parameter, without the stimuli targeted much to optimally give the parameters (p. 107 6th para). Then it will not perform well because it has too many parameters (each charged by Akaike’s formula) that, accordingly, mostly pick up noise.

The author is a psychologist and theoretical parts sometimes deviate from economic conventions. The author uses the term normative to indicate that a preference foundation (“axiomatization”) has been given, irrespective of whether this foundation is supposed to have a normative status.

equate risk aversion with concave utility under nonEU: as do most economists, in absence of EU as working hypothesis he confuses risk attitude with utility curvature, writing for instance on p. 106 that linear utility reflect risk neutrality.

P. 106: The HARA family in Table 2 is not correct. The formula for Luce’s theory in Table 4b $(V(f)^{\varepsilon}/(V(f)^{\varepsilon}+V(g)^{\varepsilon})$ is the probability of prospect f being preferred to g), the one found to perform best, is unacceptable for zero or negative values of V, and will already misbehave for positive V values close to 0.

P. 108, top: The author incorrectly suggests that power probability transformation could not satisfy quasi-concavity and quasi-convexity. Wakker (1994) and Wakker & Yang (2021 IME) prove that quasi-concavity holds if and only if w is convex, and quasi-convex if and only if w is concave, which shows that these things go together well with power utility. The 2nd displayed formula on p. 108 has probabilities not summing to 1.

P. 111 middle has a strange claim that indifference data cannot be used to investigate choice functions (i.e., error theories). Glenn Harrison also has sometimes written so (e.g., Harrison & Rutström 2009 p. 139 end of §2). Indifference data is way more informative than choice data. It is only that these authors use statistical techniques that only work for binary choice.

P. 114: $e^{-64.2}$ = 0.49??? %}

{% Nice introduction to nonstandard analysis, recommended to me on April 6, 1989 by Jan Jansen. %}

Stroyan, Keith D. & Wilhelm A.J. Luxemburg (1976) "*Introduction to the Theory of Infinitesimals.*" Academic Press, New York.

{% This paper takes the variational model of Maccheroni, Marinacci, & Rustichini (2005) as point of departure. It thus uses the Anscombe-Aumann framework. It

adds Savage's sure-thing principle to the pure horse-race acts. This gives exactly enough extra separability to reduce the variational model to a version of the robust Hansen & Sargent model, where the relation is if and only if. A pretty result!

§3.3 relates the model to recursive expected utility (called SOEU), for which I think that Kreps & Porteus (1978) is the primary reference. I guess that in general Savage's s.th.pr. in itself only gives a state-dependent generalization of recursive expected utility, but that the additional axioms, primarily certainty independence which is similar to constant absolute risk aversion, then reduce it to really recursive EU. This is similar to the one-stage models where constant absolute risk aversion, if added to state-dependent expected utility, not only implies linear-exponential utility but also, as an extra bonus so to say, implies state independence (Wakker 1989 book, Theorem VII.7.6).

On several occasions (e.g. Section 4) the paper uses Tversky's source idea. It mostly cites Chew & Sagi (2008), Ergin & Gul (2009), and Nau, but not Tversky, for this idea, although it is Tversky's idea.

P. 62 top points out that KMM's axiomatization of smooth ambiguity aversion is not behavioral and gives an alternative condition (quasi-concavity type) that is.

biseparable utility: satisfied if we focus on purely subjective acts, in which case we even have SEU (p. 57 footnote 10). %}

{% For variational preferences, probabilistic sophistication ⇔ EU if there exists an event for which independence holds. Extends Marinacci (2002). %}

Strzalecki, Tomasz (2011) "Probabilistic Sophistication and Variational Preferences," *Journal of Economic Theory* 146, 2117–2125.

{% Studies recursive decision under uncertainty. The author takes a convex set of outcomes X with an affine u on it. So, this can be Anscombe-Aumann, if X is let of lotteries, but the author does not commit to it. He refers to Anscombe-Aumann as one possible interpretation in §7.3. So, it can also be monetary outcomes with linear utility which, for moderate outcomes, is fine and is preferable to

Anscombe-Aumann. §7.2 does suggest that probabilistic mixtures are treated fundamentally differently than uncertainty mixtures, which may suggest Anscombe-Aumann type work, but I did not study enough to be sure. He does define ambiguity aversion in the Schmeidler (1989) mixture way, which can only be interpreted that way (rather than as pessimism) if one commits to the Anscombe-Aumann framework.

The author considers several kinds of ambiguity models that are popular today: Maxmin EU (Gilboa & Schmeidler 1989), recursive EU (Neilson), smooth (KMM; which he does not equate with recursive), variational (Maccheroni, Marinacci, & Rustichini 2006), multiplier preferences (Hansen & Sargent 2001), Strzalecki 2011), confidence as he calls it (Chateauneuf and Faro (2009). Footnote 10 suggests that RDU is a subclass of maxmin EU, referring to their overlap under convex weighting function, but I disagree, because convex weighting function is not the main subclass of interest in RDU.

The main finding is that only maxmin EU can be neutral to the timing of the resolution of uncertainty, through the independent product class of Sarin & Wakker (1998) and Epstein & Schneider (2003). In all other cases, ambiguity attitude interferes with timing attitude. %}

Sugden, Robert (1989) Book Review of: Peter C. Fishburn (1988) "Nonlinear Preference and Utility Theory," Johns Hopkins University Press, Baltimore, MD; *Economic Journal* 99, 1191–1192.

{% **Nash equilibrium discussion**;

P. 752: "within economics ... received theory of rational choice: expected utility theory."

game theory can/cannot be viewed as decision under uncertainty: Sugden's paper says that it has been generally accepted that Savage's SEU, with strategies as states, is appropriate for game theory. I think that this may be so in Aumann's papers but doubt if it is elsewhere. Sugden himself points out difficulties in that assumption, e.g. at the end of §V and also end of §VII. Seems to point out that opponent strategies cannot be modeled as extraneous states of nature because a player, when thinking about his own strategy, thus also affects his probabilities over opponents' strategies. §XI, p. 782 bottom, states the point in a crystal-clear manner.

P. 754, footnote 4: how indifference is a problem of revealed preference

P. 755 **free will/determinism**: on Kant who says humans are part of physical world and have physical explanations. But when we reason we cannot do other than conceive ourselves as autonomous ... Kant wants categorical imperatives, which are normative (more in ethical sense) principles to agree upon by reason with no concern of desires or Hume's passions.

paternalism/Humean-view-of-preference: p. 757: I regret that Sugden puts Savage forward as representative of the consistency view of rationality (also called coherentism). The consistency view says that rationality should require no more than consistency, i.e., consistency is sufficient for rationality. Savage, unlike his more narrow-minded colleague de Finetti, never committed to that, but only has consistency as necessary for rationality.

P. 758: that the interpretation of preference as binary choice, and nothing else, is in Sugden's opinion standard in economics.

P. 760: I disagree with the reasoning. It takes reason as fixed, and then says that it is an empirical question whether our passions, desires/beliefs, are such that reason can always maximize them. I take reason not as fixed. Whatever the passions, reasons/desires, are, reason must be such as to optimize them.

P. 760/761 says he finds it hard to formulate rationality of Savage's theory; I wonder if it is in the sense that Savage's conditions can at most be necessary for rrationality, never sufficient. This is well understood!

completeness criticisms: §IV pp. 760-761 gives criticism of completeness axiom as sort of indecisiveness, the argument I find unconvincing. Then discusses regret and transitivity. Assigns normative status to intransitivities resulting from regret.

"Savage's theory, of course, tells us nothing about how we should form probability judgements about states of nature; that is not its function."

P. 763 top claims that regret is just yet another passion in Hume's sense, but I disagree. Regret can be a silly, "nonfundamental," emotion.

The discussion on rationality in game theory centers around the paradoxes if infinite hierarchies of beliefs and common knowledge, but also brings in the view I like, that there is a meta-dependence generated by rationality (if a rational players decides on something it automatically implies that his rational opponent decides the same, bringing a meta-dependency). See also conclusion p. 783 top.

Sugden, Robert (2000) "The Motivating Power of Expectations." *In* Julian Nida-Rümelin & Wolfgang Spohn (eds.) *Rationality, Rules and Structure,* 103–129, Kluwer, Dordrecht.

{% Reference-dependent subjective expected utility evaluates, at reference point h, an act f by

the expectation of v(f(s),h(s)).

Imposing Savage's axioms for each separate h gives expectation of v(f(s),h) as representation with probability P depending on h. Having more-likely-than independent of h gives P independent of h. Separability of (f(s),h(s)) implies that v(f(s),h) depends only on h through h(s), so that the above representation results. It constitutes a desirable and appealing extension of classical models.

Theorem 2 considers the case v(f(s),h(s) = φ(u(f(s) − u(g(s)). This is obtained by ordering the separable pairs ((f(s),g(s)) and imposing preference-difference axioms on this ordering. Sugden's axioms S1-S4 amount to the axioms of Debreu (1960, Theorem 2), Köbberling (2003, "Preference Foundations for Difference Representations"), and Shapley (1975). In particular, Sugden's S4 is the crossover axiom.

u is called a satisfaction function and is interpreted as a riskless component, and φ is a gain/loss evaluation function. Risk attitude is composed of these two. It seems to me that φ affects more of risk attitude than only gains versus losses. For example, if we restrict attention to the subdomain of one fixed reference point and only gains, then the model φ(u(x)-u(0)) coincides with the value-utility model that was popular in decision analysis in the 1980s and 1990s (Dyer & Sarin 1982, etc.), where u is taken as riskless value function and φ adds risk attitude (and loss aversion plays no role). More concave φ generates more risk aversion in this domain where loss aversion plays no role.

If we consider variable reference points and reference-independence, then φ must be linear (so, "absent") and u governs all of risk attitude. Pp. 178 and 180 write that u(x) may reflect satisfaction from x. The interpretation can, for reference independence, be maintained only if vNM utility is taken as a riskless u, an interpretation that I am sympathetic to (**risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**) although the common terminology in the field today deviates and it is too late now to change.

Schmidt (2003) also considers reference dependence, but only for constant (riskless) acts.

P. 173, para 2, incorrectly claims that prospect theory would have utility independent from the reference point. Footnote 2 weakens the mistake, but does not correct it. Kahneman & Tversky (1979, pp. 277-278) gives the right nuances.

P. 173, para 3, incorrectly claims that prospect theory has no states of nature. The ’92 version of prospect theory does have states of nature.

P. 175 1st para, f > g|h is interpreted as: if the agent is in h and can choose between f, g, and h, then he rather takes f than g. This interpretation is unrealistic if h is most preferred. Would be better not to leave the option of staying at h, or not to have his completeness axiom R1 and instead restrict the analysis to the acts preferred to h (requiring considerably more difficult proofs).

Savage (1954) used the term sure-thing principle in an informal sense, comprising his P2, P3, and P7. In its modern use, it refers only to Savage’s P2. Sugden’s verbal text on p. 177 relates it, however, to Savage’s P1 and P2.

Presenting so many valuable and sophisticated results in such a short space is an impressive achievement. The proofs then have to be concise, and many details must be skipped. Indeed, the latter happens in this paper, and many of the more complex technical steps in the proofs are claimed without justification. This makes it hard for the readers to verify correctness of the results. At some places, there are inaccuracies. Theorem 1 claims necessity of the preference axioms, but the richness axiom of state-space continuity, R.8, can never be implied by the representation. (Counterexample: SEU with two states of nature, equally likely, real outcomes, and expected value, so that also Sugden’s uniqueness requirements are fulfilled.) The last sentence of the proof of Theorem 1, p. 188, suggests an assumption of atomlessness that is, however, neither claimed nor defined in the main text. Atomlessness is complex under finite (contrary to countable) additivity as here. I conjecture that a convex-rangedness condition as in Gilboa (1987) and Savage (1954) (that I prefer to call solvability) can work, but this remains to be proved.

P. 178: in Def. 10, the domain of φ varies as u varies (discussed at the bottom of p. 188).

P. 179, Consequence-space continuity, S2, is hard to read because most of the "for all" quantifiers are in the wrong place. In Definition 13, it is not clear what "distinct" means for acts. I guess that acts that differ only on a null event are not distinct. No proof of Theorem 3 is given so that the confusion cannot be clarified. %}

Sugden's set of opportunities is like my potential influence. Section 9.1 discusses Aristotle's telos (goal). Hasppiness (*eudaimonia*) comes from serving the goals. %}

Sugden, Robert (2017) "*The Community of Advantage: A Behavioural Defence of the Liberal Tradition of Economics.*" In preparation.

{% If I am among the most paternalistic workers in decision theory, Sugden, Bob henceforth, is amongs the least, and is the most anarchistic (my term) decision theorist I can think of. Famous is his and Loomes' regret theory that goes as far as just giving up transitivity. Every few years Bob and I have enjoyable email exchanges on it, although the many years haven't brought any convergence.

This paper shows how Bleichrodt, Pinto., & Wakker (2001), BPW hencceforth, can be reinterpreted subtly and then reconciled with Bob's views (though not endorsed; see end of §1) by avoiding any allusion to anything like true preference. Instead, it does what Bob calls regularization. There is a policy maker (PM) having to take policy decisions that affect persons, and seeking only to do best for the persons. The PM takes expected utility (EU) as normative for her decisions without any assumption that this would be best for the persons or about what true preferences for the persons are. This is the idea of regularization. First of all, it is not my opinion because I think EU is normative also for the persons, and I like to use the concepts of true preference and bias/error. But, second, even without that, I see little interest in assuming EU normative for the PM but not for the persons. If the PM does not consider the persons' deviations from EU irrational or bad, how can she defend changing them? I could be more sympathetic to a pragmatic interpretation, where the PM would say that nonEU is just (too) difficult to implement.

Further comments.

I disagree with the last sentence of the 2nd para on p. 772: "I conclude that the supposed normativity of the EU axioms does not justify the claim that behaviour that contravenes those axioms is evidence of error or bias." As I see it, if two choices are inconsistent with EU, then this proves that THERE EXISTS a bias. Only, EU does not say which or where. My preceding sentence makes me agree with all text preparing for the criticized sentence. But I disagree with that sentence. Bob's p. 781 end of 1st para, claiming misleading, follows from this, and I disagree with the

qualification of misleading there too.

P. 776: I do not equate normative utility with experienced utility, but this does not affect any other point here.

Regarding the point starting the second half of p. 776, Bob is right. Diminishing sensitivity of utility is a reference-dependent bias that BPW ignore. To prepare my defense, I have been fully aware of this point since my youth. Kahn & Sarin (1988) discussed it nicely. We only did not write about it because it is too far from the current state of the art in the field. I think that intrinsic utility should be concave throughout. The convex-concave shape found empirically is due to yet another bias, which may be general numerical (mis)perception. We did not mention it because no theory exists yet. Our phrase referring to the current state of the art may justify. Our phrase that Bob cites on pp. 777-778 was deliberately written to avoid this issue. I discussed the issue with Köbberling for Köbberling & Wakker (2003) and we decided to stay out of it. There is an empirical paper on it, Köbberling, Schwieren, & Wakker (2007), but this paper never received much attention.

P. 781 end of 1st para: I disagree with the "misleading" qualification about showing systematic biases, as explained before. %}

{% Text of plenary lecture for statistical society.

criticizing the dangerous role of technical axioms such as continuity: §2 discusses the status of axioms, with what I would call intuitive versus technical axioms. The latter are about richness with existence quantifiers, such as Savage's (1954) P6. There are some interesting claims, but much is half-baked with nuances lacking. The para on p. 162-163 argues that, when a patient has to decide on a risky treatment with subjective probabilities involved, comparisons with objective probabilities (as in the Anscombe-Aumann framework) will not be useful. I think it depends too much, and sometimes it will be useful. But I agree with him that often it will just not be of use. As I argued on several occasions, for 999 out of 1000 diseases, decision theory is of no use at all. But for 1 out of 1000 diseases it is, and that is a good thing.

P. 164 points out that the Archimedean axiom is not first-order.

P. 167 3rd para, that axioms be about the appropriate degree of crudeness, comes out of the blue and is apparently an attempt to sell his axioms yet to come. The axioms consider the case of n equally likely events with crisp probability 1/n for calibration, which are used to provide upper and lower bounds for the probabilities of the other events in the obvious way. As regards the axiomatization, this is not very interesting.

§4 compares to geometry and quantum mechanics. An argument that can be advanced against upper and lower probability models (as against multiple priors) is that not only about probabilities, but also about anything else such as length, we can have uncertainties, so, if we should work with upper and lower probabilities should we then not just as well work with upper and lower lengths instead of deterministic lengths? Suppes argues that subjective probabilities are to be treated differently than physical length, and that subjective probabilities should rather be treated as physical scales in quantum mechanics, where often locations and so on are not deterministic but probabilistic. More precisely, they are intrinsically probabilistic. The physical laws of quantum mechanics require that sometimes location is probabilistic and not deterministic, and the laws would be invalid otherwise. So, it is not just probabilistic in the sense of not well known or having inaccurate measurement instruments, but it is intrinsically probabilistic. Heisenberg's uncertainty principle describes this. Suppes points out that the source of uncertainty—that any measurement will distort location/etc—also holds for subjective probability, where each measurement will distort it. Unlike most social scientists, Suppes does not start writing silly and exaggerated comparisons with quantum mechanics but keeps control and credibility, writing on top of p. 172: "I do not mean to suggest that the exact theoretical ideas of quantum mechanics carry over in any way to the measurement of belief, but I think the general conceptual situation does." I personally do not believe that the analogy holds. I think that the measurement of beliefs through certainty equivalents and so on does not meet the fundamental impossibility of quantum mechanics to reach high degrees of precision, but this is a matter of taste. Suppes is in fact favoring the constructive view of preference here!!! Nice. Interestingly Suppes compares not only with quantum physics, the standard example of a probabilistic theory, but also with memory from psychology, also well known for being affected by measurement and being constructive (probabilistic?).

P. 174, final para of paper, compares the indeterminacy of subjective probability with the impossibility to do perfect meteorological measurements. The latter cannot be done because of complexity, which is a different point than for the indeterminacy in quantum mechanics. Suppes ends, poetically, with: "Our beliefs, it seems to me, are rather like the leaves on a tree. They tremble and move under even a minor current of information. Surely we shall never predict in detail all of their subtle and evanescent changes.” %}

{% **strength-of-preference representation**: representation uses absolute differences though.

All attempts to make strength of preference observable from actual decisions that I know are a special case of the following:

We consider two-attribute (x_1,x_2) and assume additive representation $V_1(x_1) + V_2(x_2)$. Under minimal continuity assumptions, V_1 and V_2, and their sum, are

interval scales, and their ordering of differences is meaningful. We can then for instance observe:

$(a_1,G_2) \sim (b_1,g_2)$ and

$(c_1,G_2) \sim (d_1,g_2)$

to conclude that the strength of preference of a_1 over b_1 is as big as that of c_1 over d_1, with V_1 differences correspondingly. That is, improving [a_1 into b_1] offsets the same gauge [improving g_2 into G_2] as improving [c_1 into d_1]. The additive representation means that there is no interaction between first and second coordinate, and this is necessary for things to work.

The authors consider on p. 260 the special case where the second coordinate x_2 refers to money, $g_2 = 0$, and G_2 is a positive side payment. The authors next consider the special case of a housewife who chooses between combinations of applyances. Say, starting from (a_1,a_2), that (b_1,a_2) is a better improvement than (a_1,b_2). Can we conclude that [from a_1 to b_1] is a better improvement than [from a_2 to b_2]? One again needs absence of interaction between the 1st and 2nd coordinate goods to derive strength of preference. If interactions then the improvement [from (a_1,a_2) to (b_1,a_2)] can be different than the improvement [from a_1 to b_1] (which we interpret as the improvement [from $(a_1,0)$ to $(b_1,0)$]). The improvement [from (a_1,a_2) to (a_1,b_2)] can be different than the improvement [from a_2 to b_2] (which we interpret as the improvement [from $(0,a_2)$ to $(0,b_2)$]). We could try to give more status to the improvement [from (a_1,a_2) to (b_1,a_2)] by assuming that $(0,a_2)$ instead of $(0,0)$ is the initial endowment, and we could give more status to the improvement [from (a_1,a_2) to (b_1,a_2)] by assuming that $(a_1,0)$ instead of $(0,0)$ is the initial endowment, but the two cannot be combined into one consistent initial endowment.

On p. 259 they consider the special case where (x_1,x_2) concerns a gamble yielding x_1 under one event and x_2 under its complement. Absence of interaction between the two coordinates holds under expected utility and is needed here.

On difficulty to disentangle different parameters, they write: "The interaction between probability and utility makes it difficult to make unequivocal measurements of either one or the other. The recent Mosteller and Nogee experiments (1951) may be interpreted as measuring utility if objective probabilities are assumed or as measuring subjective probabilities if utility is assumed linear in money." (p. 259)

P. 259 2nd para points out that measurements of utility under risk are distorted by interaction with probability weighting (they use the term subjective probability to indicate probability weighting), using this as argument to use introspective-based strengths of preferences.

questionnaire versus choice utility: p. 261 penultimate para of §1:

"It is also our opinion that many areas of economic and modern statistical theory do not warrant a behavioristic analysis of utility. In these domains, there seems little reason to be ashamed of direct appeals to introspection. For example, in welfare economics there are sound arguments for adopting a subjective view which would justify the determination of utility differences by introspective methods."

{% **PT falsified; probability weighting depends on outcomes**: they investigate this. They confirm that affect-rich outcomes give more pronounced insensitivity (inverse S). On one point my interpretation is different than the authors'. I think that probability neglect is an extreme form of insensitivity, and not something different as the authors think, expressed in their title ("versus"), and what they have as a central theme throughout their paper. Figure 7.1.1, p. 205, of Wakker

(2010) shows the point, with to the left perfect sensitivity, in the middle partial sensitivity, and to the right extreme insensitivity which means probability neglect. Thus, what the authors take as evidence against inverse S, in my opinion is strong support.

They also find higher elevation of probability weighting for affect-rich outcomes. It was not clear to me from the text and the formulas if higher elevation was coupled with more or with less risk aversion. Also, with only one nonzero outcome, elevation may be determined only up to one joint power for utility and probability weighting. This need not affect inverse S but it does affect elevation. Adding assumptions about (the power of utility makes the power of probability weighting also indentifiable. %}

{% N = 661 children aged 10-18.

real incentives/hypothetical choice, for time preferences: Use real incentives for time preferences, as for all preferences. In a school they pay on a prearranged future time.

They use choice lists to observe indifferences.

They estimate risk aversion from one observed CE (certainty equivalent) of a fifty-fifty prospect, referring to the known Ellsberg urn. For ambiguity aversion, they observed the CE for the unknown two-color Ellsberg urn, and took the normalized difference between the risky and ambiguous CEs (certainty equivalents) as index of ambiguity aversion.

gender differences in risk attitudes: women more risk averse than men. (P. 517.) Gender is only demographic that correlates with risk aversion. For example, age does not (**relation age-risk attitude**). No demographic variable correlates with ambiguity aversion (**gender differences in ambiguity attitudes**).

Time preference: They fix a near and remote timepoint, fix the payment at the near timepoint, and determine the remote payment to generate indifference. Did so 4 times, where two have early time right now and two have early time later (upfront delay). Find mostly constant impatience, but once decreasing impatience.

correlation risk & ambiguity attitude: There is a negative relation, but it is not written in the paper. Is pointed out in survey chapter by Trautmann & van de Kuilen (2015).

P. 510 cites seven studies that relate risk/time preferences to actual behavior. This paper does it for 661 children age 10-18. More impatient children smoke more, drink more, have higher BMI (body-mass index), save less, violate more school codes, and have lower maths grades. Risk and ambiguity aversion do not correlate with much. Risk averse subjects have lower BMI, ambiguity averse smoke less. P. 511 cites literature that children are more risk averse and more impatient than adults. More risk aversion then more patience.

P. 527 mentions that intertemporal attitude correlates better with other things than risk/ambiguity attitudes, in agreement with what has been found more often I think. A little bit this may also be because they used four questions to measure intertemporal attitudes, and only one to measure risk attitude and only one to measure ambiguity attitude. %}

{% On history of conflicts between experimental economists and behavioral economists. How behavioral economists and experimental economists, Vernon Smith, Plott, Kahneman, and others, discussed and how some hostilities came. On **Prospect theory not cited**: it explains why many experimental economists ignore prospect theory. Sidney Siegel initiated, independently of and simultaneously with Smith, the principles of experimental economics, emphasizing real incentives and no deception. Unfortunately, Siegel suddenly died at young age.

The author's writings on deception are shaky. P. 279 writes: "In general, deception in experiments occurs when the actual purpose of an experiment differs from the purpose announced to the test subjects." This is not the definition of deception commonly accepted. It is usually taken as giving false, untrue, information to subjects. For one thing, this is broader than just about the purpose of the experiment. For another, it allows for incomplete info. Often, subjects are not given complete info on an experiment and the purposes of the experimenter, e.g., "proving that theory X is superior to theory Y," or "showing that subjects overestimate probabilities." P. 290 ℓ. 4 erroneously writes: "the former group [behavioral] advocated allowing deception and hypothetical choices in economic experiments; the latter [experimental economists] avoided such experiments." Behavioral decision theorists do not just allow for deception. I don't remember that Kahneman & Tversky ever wrote about it, but I also do not remember any case where they used deception. Although I do not remember ever discussing deception with Tversky, I would be very surprised if he would not have thought that it should be avoided.

Another strange claim is on p. 288: "the emerging behavioral economics became less and less reliant on experimentation and was equally embracing other empirical as well as modeling approaches." I do not understand in which sense behavioral economics would care less about experiments. The author may think that psychology-type experiments are not to be called experiments? %}

{% **small risks overinsured**;

Point out that according to traditional EU analyses, the commonly found insurance decisions regarding deductibles for home insurance would imply absurd degrees of risk aversion. The author has real data on these insurance decisions.

P. 178 puts some criticisms of Rabin (2000) right: "part of the importance of this insight rests on the assumption that people are significantly averse to moderate risks, a point which some have questioned (Richard Watt 2002; Ignacio Palacios-Huerta, Robert Serrano, and Oscar Volij 2006) There is extensive evidence that people do display risk aversion over small stakes in laboratory settings … Outside of laboratory settings, … "

P. 183 penultimate para: By taking $1000 deductible instead of $250 or $500 deductible, people could on average have saved $100 per year! The price people pay extra for having $500 deductible instead of $1000 is five times its average value! P. 187 bottom: $4.8 billion per year can the saved by all house-owners in the US by taking $1000 deductble. One individual can on average gain $6,300 until age 65.

P. 184 mentions consumer inertia, of people keeping insurance even though price has become much worse. Hence, better to estimate only for new customers (p. 189 end 3rd para).

P. 192 ff: for measuring relative risk aversion, proper level of initial wealth is discussed in detail.

P. 193 penultimate para: People have to overestimate probability of loss by factor 5 (18.3 instead of 3.7) to come to single-digit relative risk aversion index. P. 195-196: Common degrees of probability weighting thus neither can explain it well. Traditional loss aversion plays no role because insurance is all about losses.

P. 196: if we take premium paid as reference point (which is psychologically plausible), then loss aversion can explain it. The Köszegi-Rabin (2006) model also leads to this. %}

{% **nonconstant discount = nonlinear time perception**: this point was stated nicely in the working paper version but, unfortunately, as the author explained to me in personal communication, a referee had him take it out in the published version.

decreasing/increasing impatience: finds counter-evidence against the commonly assumed decreasing impatience and/or present effect.

First part of paper tests stationarity qualitatively as often done before, which can be called utility free because it needs not know utility. Second part first uses decision under risk and the standard gamble method to measure utility, assuming expected utility, and then measures discounting in utility rather than in money. The author suggests that this part does not measure utility at all (p. 460, §2.2, 2nd sentence), but measuring the standard gamble probabilities is equivalent to measuring utility. All of this conditional on assuming expected utility, which the author does. Similar things have been done by Andersen et al. (2008, Econometrica) and partly by Chapman (1996). The author calls his method utility-free because it works, given his assumptions, whatever utility is. The idea to pay in probability and then under EU have linear utility has been used before (Allen 1987; Anscombe & Aumann 1963; Berg et al. 1986 QJE; Roth & Malouf 1979; Cedric Smith 1961). Its drawbacks are that EU is extensively violated, with Selten, Sadrieh, & Abbink (1999) finding that the deviations from EU are bigger than those from linear utility, and that cardinal utility under risk need not be the same as cardinal intertemporal utility, as established after the ordinal revolution

(Baumol 1959).

Given the assumptions made, the author can in fact measure a model D(t,x)u(x), with discounting D(t,x) outcome dependent, as he points out on p. 457.

The experiment finds quite some future bias.

{% **real incentives**: Average payment was $11, roughly 7-day labor wage for casual unskilled labor. Random incentive system with one choice played for real.

Use prospect theory, power utility and 1-parameter Prelec weighting function, and loss aversion, with same parameters for gains and losses. So, then the unit of payment assumed does not matter for the definition of loss aversion.

Choice stimuli: No sure prospects. Find indifference by choice list: $40_{0.30}10 \sim x_{0.10}5$; $40_{0.90}30 \sim x_{0.70}5$. The third choice list was more complex, with losses involved for both options. So, basically, three indifferences are used to fit three parameters. They use the first two indifferences to elicit utility power and probability weighting, and the third, given the first two, to elicit loss aversion. Find power 0.61 and weighting-function parameter 0.74.

real incentives/hypothetical choice, for time preferences: They implemented using again random incentive system. Future payments for subjects were left to one of the subjects, a specially chosen “trusted agent,” who was asked to deliver the money on the days promised. I find it hard to believe that this would work well. Actually, I think that it would be immoral for the trusted agent NOT to deliver the money immediately. He is then causing money (interest and opportunities) to be lost for the people in his village just because some American told him so, with no use for the research (already over) or anything else, other than tribute to an abstract ethical principle of “never break a promise also if completely useless and to someone you will never see again.”

The stimuli for intertemporal choice concerned immediate rewards versus rewards delayed by 3 days up to 3 months.

For discounting they use a 3-parameter discount function, combining generalized hyperbolic discounting with also presence-effect à la quasi-hyperbolic. I regret that the two parameters besides exponent overlap in generating decreasing impatience, but they cannot fit increasing impatience which will surely be found for part of the subjects. It is like fitting risky data allowing only for risk aversion for every individual. The families by Bleichrodt, Rohde, & Wakker (2009, GEB) can handle increasing impatience.

Subjects invited had participated in a demographic study 3 years before, so that things could be correlated.

Richer villages are less loss averse and more patient. Richer households are more patient but no risk attitude effects. %}

{% They use an American life panel that contains many measurements of time preference and risk attitude from many studies. Big limitation: They measure risk attitude only by fitting EU with CARA or CRRA utility. So, they only have an estimation of risk aversion and not of insensitivity and all the violations of EU are bugging this study.

They see how those are related to other variables and real-life decisions. They find that one choice-list type (actually, adaptive titration) works well and predicts much, quite suggesting that time preference is quite driven by one factor. For risk attitudes it does not work so easily, and risk attitude consists of several components it seems. Not measuring decision risk attitude, but direct introspection, predicts real-life behavior much better, something also found and emphasized by Dohmen et al. (2011). As I wrote on some occasions, this is not very surprising or interesting because, first, it is like twice asking the same and, second, the introspective measure, unlike attitude questions, is not related to normative concepts useful for cost-effectiveness studies and so on. %}

Thaler, Richard H. (2015) "*Misbehaving: The Making of Behavioral Economics.*" W. W. Norton & Company, New York.

{% A general discussion arguing for the importance of behavioral economics. Unfortunately, the author desires too much to show that other researchers are

dumb and wrong, with the implicit implication that he himself is more clever. And, unfortunately, he does not try to properly position views other than his own, but he tries to make them look ridiculous using puns (p. 1579: "explainawaytions"), which does not advance communication and exchange of ideas, even if primitive readers (the type that enjoys watching violent movies) may enjoy it. It is good in writing and for clarity to skip some nuances, but this paper does it too much. P. 1579 beginning of §II: "In the process of making economics more mathematically rigorous after World War II, the economics profession appears to have lost its good intuition about human behavior." P. 1579 footnote 1 is characteristic of the sense of humor of the author.

In the beginning of the paper, and in several other places (p. 1578 middle: "Indeed, Ashraf, Camerer, and Loewenstein (2005) convincingly document that Adam Smith, often considered the founder of economics as a discipline, was a bona fide behavioral economist."), the author tries to argue that the behavioral approach means simply returning to the preordinal period. I will explain that I disagree. First I note that, unfortunately, the author never uses the term ordinal or refers to the ordinal revolution, but this is the crucial dividing line. P. 1580 seems to confuse the ordinal and the marginal revolution, apparently putting the marginal revolution in the 1940s. The marginal revolution was in the 1870s. He sometimes refers to "after World War II." Now to why I disagree. It is for the same reason that I disagree with the idea expressed in "Back to Bentham" (elsewhere). The ordinal revolution added much good, giving a clear and firm basis to economics. The behavioral revolution (using this term, also sometimes used in this paper) does not mean throwing these ideas away. It means extending these ideas, keeping the formal concepts but extending the empirical domain (a) by incorporating irrational phenomena studied before in psychology; (b) relaxing the restriction to revealed-preference data. Those extensions should be linked to the firm basis thanks to the ordinal revolution. Fortunately, in one place the author puts this right, being p. 1592 1st para: "A second general point is that we should not expect some new grand behavioral theory to emerge to replace the neoclassical paradigm. We already have a grand theory and it does a really good job of characterizing how optimal choices and equilibrium concepts work. Behavioral theories will be more like engineering, a set of practical enhancements that lead to better predictions about behavior. So far, most of these behavioral enhancements focus on two broad topics: preferences and beliefs."

Unfortunately, in the conclusion p. 1597 the author returns to the unnuanced statement: "Rather, behavioral economics should be considered simply a return to the kind of open-minded, intuitively motivated discipline that was invented by Adam Smith and augmented by increasingly powerful statistical tools and datasets."

P. 1581, ℓ. −4 presents EU as normative: "Prospect theory was intended to be a descriptive alternative to von Neumann and Morgenstern's (1947) expected utility theory, which is rightly considered by most economists to characterize how a rational agent should make risky choices."

P. 1582 ℓ. −3 lists Thaler's 1980 paper together with the work of Kahneman & Tversky.

P. 1583 2nd para shows how the desire to show others wrong (end of 3rd para: "So critics can't have it both ways. Either the real world is mostly high stakes or it offers myriad opportunities to learn—not both.")
blinds the author: his point that decisions with large stakes usually cannot be repeated much is irrelevant and in no way weakens the argument that both large stakes and repetition/learning increase rationality.

real incentives/hypothetical choice: p. 1585 end of 2nd para: "In the nearly 40 years since Grether and Plott's seminal paper, I do not know of any findings of "cognitive errors" that were discovered and replicated with hypothetical questions but then vanished as soon as significant stakes were introduced." Many studies, also some with me as co-author, find more noise with hypothetical choice (and less risk aversion). This usually means that any pattern is weakened and, hence, also violations of preference conditions. Still, it is clear that real incentives, other things equal, gives higher quality of data.

P 1585, §C, can be briefly summarized as:
"market mechanisms will often but not always reduce irrationalities."
The play with words of "invisible handwave" p. 1585 3rd para is typical of this paper's style.

P. 1591 bottom: Theory and empirics ALWAYS go hand in hand, so, things are way more universal than in the following citation: "Some might worry about basing theories on empirical observation, but this methodology has a rich tradition in science. The Copernican revolution, which placed the sun at the center of our solar system rather than the earth, was based on data regarding the movement of the planets, not on some first principles."

P. 1592 footnote 9: utility of income has more to do with reference dependence than with mental accounting.

P. 1597 last para: "If economics does develop along these lines the term "behavioral economics"will eventually disappear from our lexicon." The ambitious idea is that everyone will be doing behavioral, so, no more need to use the adjective. %}

Thaler, Richard H. (2016) "Behavioral Economics: Past, Present, and Future," *American Economic Review* 106, 1577–1600.

{% The authors got some firms to implement a program, called SMarT, to automatically make their employees save each month, in a percentage that they could influence. It led to considerably more savings.

People save too little (p. 166 2nd para: As can be inferred from their answers if asked. A lternative explanation of their answer can be social desirability.). Four biases are advanced to be underlying this (summarized and listed briefly on p. 170 2nd para ("In summary … these households.")):

1. Bounded rationality. People cannot calculate what is optimal for them.
2. Lack of self-control (time inconsistency/hyperbolic discounting).
3. (Much like 2): procrastination.
4. Loss aversion (the authors also involve money illusion).

This lead to the following aspects of the SMarT program (§III pp. 170-1st para of 171):

Because of 1, SMarT does not ask the clients but determines itself to what level it tries to make clients increase payment, and then stop there. Because of 2 and 3, clients are asked to commit to payment way before the first payment comes. Because of 4, let payment be raised only after salary rises. Further loss aversion and the implied inertia (which will be generated much by incompleteness of preference rather than loss aversion) should serve to imply that clients do not opt out of the program once being in. Relying on this, clients at each stage had the possibility to opt out if they wanted.

paternalism/Humean-view-of-preference: All actions stay within the boundaries of libertarian paternalism, of not doing anything people do not want by their gut feelings.

P. 167 last para: D**C = stationarity**;

P. 169 penultimate para: Loss aversion underlies inertia which, in turn, underlies why people don't save enough. P. 185: "One reason why the SMarT plan works so well is that inertia is so powerful."

P. 170 end of 1st para: The authors suggest that a 7 percent wage cut under no inflation should be as fair as a 5% salary raise under 12% inflation. This is not correct because 12% inflation means that the economy is doing badly, making it more “fair” to get worse off by oneself.

paternalism/Humean-view-of-preference: Conclusions on p. 185 ff. discuss it. Refer to Thaler & Sunstein (2003) on libertarian paternalism. P. 186: “we plead guilty to the charge of trying to be paternalistic. ... we have used behavioral principles to design a plan to increase savings rates and tested the ideas in the real world.” %}

Thaler, Richard H. & Shlomo Benartzi (2004) “Save More tomorrow: Using Behavioral Economics to Increase Employee Saving,” *Journal of Political Economy* 112, S164–187.

{% Subsections 5.1 and 5.2: house money effect: A prior gain increases the willingness to accept gambles, as long as they do not risk loosing the entire recent winnings. So, it is a kind of decreasing ARA (absolute risk aversion). (In a casino you are then gambling with the money you already won, so, with the “house money.”) A prior loss decreases the willingness to gamble (so, again decreasing ARA), except if it can generate breaking even (or turn losses to gains). Subsection 6.1 discusses some alternative explanations.

They give evidence against the isolation effect; i.e., prior gains etc. can matter. It’s a kind of income effect.

real incentives/hypothetical choice: p. 652 beginning of Subsection 4.1: “However, an experiment in which subjects can lose money creates some ethical dilemmas.”

P. 653: subjects who lose money can pay by hours of clerical work, if they want.

utility concave near ruin: seems that they have a quasi-hedonic editing rule that suggests this. %}

{% This paper discusses CPT debiasing. CPT debiasing means that one takes expected utility, denoted EUT in this paper, as the right normative theory. To find the utility function to be used in EUT, one uses 1992 prospect theory, denoted CPT in this paper, as the best descriptive theory, to measure basic utility (utility but with loss aversion taken out), and then uses that as the utility function to be used in EUT. It means that probability weighting and loss aversion of CPT are taken as irrational. Somewhat circularly, a kink in utility at the reference point that is "genuine" is incorporated into basic utility. Genuine kinks can be distinguished from irrational ones (loss averion) because they, unlike the irrational ones, do not move with the reference point but stay at a fixed final-wealth level. The most explicit paper on CPT debiasing is Bleichrodt, Pinto, & Wakker (2001). The paper by Thoma carefully and slowly lays down the various arguments, citing much related literature.

The author disagrees with CPT debiasing for two reasons. Both assume, correctly, that CPT debiasing wants the utility function to cardinally capture goodness, i.e., to be the neo-classical cardinal utility of economics. The first reason for disagreement argues that the utility function resulting from CPT (so, its basic utility) may just be any ordinal transformation of neo-classical utility, and there is no reason that the two should be the same. The second reason for disagreement argues that the utility function to be used in EUT may just be any ordinal transformation of neo-classical utility, and there is no reason that the two

should be the same. The latter is in the spirit of the Dyer & Sarin (1982) distinction between value and utility, cited by the author. The rumerous "there is no reason that not" argument is stated on p. 212+8 2nd para ℓℓ. 2-3 and p. 216 ℓ. -3.

My first counter is that there neither is a reason that these functions should be different. Further, pragmatic after years of work in a hospital, allowing any ordinal transformation is too general and unspecific to be very useful. The author does add specificity. She argues that one should take the EUT model that is closest (in some sense) to the observed CPT model. That is, one should deviate as little as possible. I disagree. One should make one's *best* guess of the biases, and that does not need to be the *closest* guess. If I know a person is weighting probabilities simply because of misunderstanding them then I should not try to stay as close as possible but just fully correct.

I disagree with p. 212 §4 first line: "CPT debiasing can only be means paternalist if the basic utility function identified in CPT models in fact provides us with a reliable and complete measure of all the agent's relevant ends." It is not about reliable and complete. It is about *most* reliable and *most* complete that is possible. Which may be very unreliable and incomplete. Again, after having done applied work in a hospital, one often only has dirty data but one HAS TO decide.

The author defines means paternalism as paternalism where one accepts the final ends of an agent and only seeks to improve the agent's means to get them.

P. 205 ℓ. -3: "But the would-be means paternalist has no way of telling which way of resolving the inconsistency is more authentically the agent's own."

P. 211 ℓ. -4: "The mere observation of behavioral inconsistency points to no particular way of resolving that inconsistency that would honor the agent's ends, and do so better than the agent's own choices."

Section 4 has a long discussion on requiring (utility of) outcomes to be complete and also incorporate global properties of the lottery.

P. 214 suggests that a "genuine" kink in basic utility and a kink due to loss aversion are hard to separate. I counter: It is easy by comparing different reference points to see if the kink is genuine and travels with final-wealth level, or travels with the reference point.

P. 219 penultimate para: for justifying risk neutrality in terms of utility units

one can use no-arbitrage conditions or, better, additivity preference conditions, as in Wakker (2010 Ch. 1). %}

{% Detailed discussion of many aspects of axiomatizations for game theory and resource allocation. The paper is mostly oriented towards applications in other economic theories, so, with theoretical requirements such as continuity, and less towards empirical or practical prescriptive applications, in which continuity plays no role. There are some comments on operationalism in §10.1, and p. 372 point 4 of §12.2 has a nice discussion.

§4.1.1 argues that axioms should be independent. Related to this is the principle that axioms should be as weak as possible. This need not hold in descriptive studies that want axioms to be as strong as possible so as to test theories as much as possible.

criticizing the dangerous role of technical axioms such as continuity: §4.1.3 p. 338 penultimate para discusses the point that continuity can add empirical content to other axioms, but is completely optimistic and positive about it without seeing dangers. For instance, Pfanzagl (1968 §6.6) discusses this point but is more negative on there being dangers, and I agree. See also §9.1 of Krantz et al. (1971).

I like §4.3, that axioms should be conceptually compatible. As I see it, in Arrow's voting paradox IIA and group-preference-transitivity are conceptually incompatible, the former requiring that a choice between two alternatives have no info about a third, and the latter requiring that all choices between pairs of alternatives be made in same states of info.

§4.4 is strong on it not being bad to have many axioms, a point that I don't really understand.

A point that I missed in the discussion is that axiomatizations can give empirical meaning to theoretical constructs, and justify the use of the latter, for instance in the way that de Finetti justified subjective probabilities. %}

Tinbergen, Jan (1991) “On the Measurement of Welfare,” *Journal of Econometrics* 50, 7–13.

Abstract. The author believes in the measurability of welfare (also called satisfaction or utility). Measurements have been made in the United States (D.W. Jorgenson and collaborators), France (Maurice Allais), and the Netherlands (Bernard M.S. Van Praag and collaborators). The Israeli sociologists S. Levy and

L. Guttman have shown that numerous noneconomic variables are among the determinants of welfare. The determinants are numerous; the author proposes a list of about fifty. Various mathematical functions have been proposed, of which the logarithm of the determinants shows the highest correlation with welfare, as measured.

{% **conservation of influence**: known for putting forward four "why" questions for actions, which are cornerstone of modern ethology:

1st is immediately preceding history: Bird sings because its nerves … etc. So, causal, as a physical phenomenon.

2nd concerns longer past. Bird sings because learned from father. So, this is development at individual level.

3rd concerns even longer past. Bird sings because genes make it do so. Is evolutionary (but still basically causal as were the preceding two).

4th concerns purpose: Bird (say male) sings to attract female. Is functional, about purpose. Good singing improves survival. Fourth question requires consideration of: What would have happened had the bird not sung? Tinbergen did experiments in this spirit. Birds clean nest from remainders of shells. Tinbergen put up artificial nests with remainders of shells, to find out that craws etc. then came to steal. %}

{% **random incentive system between-subjects** (paying only some subjects): One of 100 subjects is paid one choice. Given that system is adaptive, it means that in principle it may not be incentive compatible. But for subjects it is totally impossible to recognize that it is adaptive, let be to see how to exploit it. So, theoretically it is not incentive compatible, but practically it is.

Use an adaptive system, well known in marketing, for measuring risk and time attitudes, which are measured through choice lists and indifferences derived from those. Adaptive means that for each subject, for each new question, it is calculated from the preceding questions what the most informative new question will be according to some minimization of some correlation-matrix's determinant or so, and that is asked as next question to the subject. The authors find that people with big debts on their houses discount more than others, but are not different in risk attitude.

They also do a traditional nonadaptive measurement in which they find no significant relation, but here they measured only two indifferences for time and two for risk (where it is not clear to me how they could calculate loss aversion from only two indifferences) so, they simply have less data and less power. %}

{% Distinguishes between lack of self-control due to present bias and self-control costs. The latter even like restricting future choices if they know they will resist temptation (to save the costs). Part of the experimental test involves the measurement of beliefs about future actions. This is difficult because rewarding the belief usually interacts with the actual choice made. The solution proposed on p. 868 is not to ask beliefs about own actions, but beliefs about actions of other subjects who in some respects (other past choices) were similar. After all, it is natural to expect that those others will choose similarly as one-self so that one's own anticipated choice may be the best predictor. %}

Toussaert, Séverine (2018) "Eliciting Temptation and Self-Control through Menu Choices: A Lab Experiment," *Econometrica* 86, 859–889.

{% There are circularities in the definitions, and I think that this paper is basically unsound. A first problem is that sets $\mathcal{A}_0$, $\mathcal{A}_1$, $\mathcal{A}_2$ are not well defined: "can be compared" can be interpreted in several ways, none leading to correct results. A second problem is that she only considers one-side-unbounded utility, not two-sided. The latter is the most problematic case because integrals may not just be ∞ or $-\infty$, but may be really undefined ("$\infty - \infty$"). A third problem is that extending preferences by independence and monotonicity may lead to intransitivities. I wrote two letters about this to the author end 1980s but she was too busy to reply. %}

{% **probability elicitation**. Compare five belief elicitation methods: Through introspection, CE measurement, PE measurement, proper scoring rule assuming risk neutrality, and proper scoring fule with correction for risk attitude. Belief is about behavior of others in ultimatum game. It can serve as a: s**urvey on belief measurement**. They consider 4 criteria: two versions of internal validity: (1) additivity; (2) prediction of own behavior; and, further (3) external validity

(closeness to objective probability), (4) complexity.

They analyze CE measurement and proper scoring rules with and without correction for risk attitudes. Find that that correction improves, but may be not by very much, so on the one hand they say that increasing complexity does not help but on the other that risk-attitude correction does. A drawback of this analysis, at least from the descriptive perspective, is that the first internal validity criterion, additivity, ignores ambiguity attitude (they only write this in footnote 16, p. 2133, where the same point is implicit in footnote 5).

They do the measurement with and without explicitly saying to subjects that this is about belief measurement, and find that it makes no difference. They cite Offerman et al. (2009) for the same result. (Offerman et al. thought that only the treatment with explicit mention was natural, but had to add the control treatment because a referee and editor required it.)

Results are summerized in §6. §6.1: nonadditivity is strong in all measurements, least so in introspective. §6.2: truth serums improve prediction of own behavior, but it is not very good. §6.3: the methods are all similarly close to true probabilities. %}

Trautmann, Stefan T. & Gijs van de Kuilen (2015) "Belief Elicitation: A Horse Race among Truth Serums," *Economic Journal* 125, 2116–2135.

{% **survey on nonEU**: valuable survey on empirical studies of ambiguity.

ambiguity seeking for unlikely: p. 103 ff. documents and reviews this.

ambiguity seeking for losses: they document this.

They write in several places that ambiguity attitudes depend on the likelihood of events (p. 89 ℓ.9: "This literature has shown that attitudes towards ambiguity depend on the likelihood of the uncertain events."; also p. 104 penultimate para). I would state this differently, and say that ambiguity aversion depends on likelihood. The latter is true: Ambiguity aversion increases with likelihood. The former need not be: There is a-insensitivity everywhere, for all the events the same. It MEANS ambiguity seeking for unlikely and ambiguity aversion for likely.

P. 89 ℓ. −3: "Interestingly, the empirical literature has so far provided relatively little evidence linking individual attitudes toward ambiguity to behavior outside the laboratory in these, theoretically, ambiguity-sensitive decisions."

P. 94 middle (on 2nd order probabilities for generating ambiguity): "if the theory regards unknown probabilities it might be inappropriate to operationalize them with known-risk compound lotteries."

natural sources of ambiguity: P. 94 argues for its importance. Pp. 94-96, on it, list three ways to control for unknown beliefs: (1) bets on events and their complements (which in fact is detecting source preference); (2) the source method; (3) first measure subjective beliefs (I assume introspectively) and then compare with bets with same objective probabilities. They give no references, but here are some: Hogarth & Kunreuther (1995) Heath & Tversky (1991), Zeckhauser (2006).

P. 97 ℓ. 10 ff: "Thus, the three-color problem elicits much lower ambiguity aversion than the two-color problem."

P. 102 middle: "Given that many experiments use designs where risky and ambiguous bets are directly compared, while outside the laboratory there are often few truly unambiguous options, it is not clear how far quantitative laboratory measurements are representative of the preferences in potentially noncomparative real-world settings."

P. 102 $\ell\ell$. −2/−1: "Interestingly, ambiguity aversion does not seem more justifiable than ambiguity seeking nor vice versa." Here justifiability refers to group discussions.

P. 107 3rd para: it is correct that ambiguity aversion is a special case of source preference. The authors cite a paper where source preference relations measured for different (pairs of) sources were unrelated, which of course can happen. Then however they are confused to suggest that ambiguity aversion and source preference would be different concepts.

P. 107 end of penultimate para: "However, there is surprisingly little evidence yet in support of the assumed link from Ellsberg-urn ambiguity attitude to behavior outside the laboratory, and thus on the external validity of the ambiguity attitude concept."

P. 108 penultimate para: One Dimmock et al. paper finds significant relation with a-insensitivity and not with ambiguity aversion, and the other finds it the other way around. These findings are not contrary because finding a null of no relation does not mean much.

P. 109 2nd para: a careful consideration of these gain-loss differences seems warranted in applications in insurance of health, where losses play an important role.

P. 109 1st para of conclusion: "Given the relevance of these domains in the field, the universal focus of theoretical work on ambiguity aversion seems misplaced."

P. 109 1st para of conclusion: "Are the psychological mechanisms leading to ambiguity aversion in one domain and ambiguity seeking in another domain the same?" My answer: Yes! The fourfold pattern of ambiguity all results from insensitivity.

P. 110 endnote 4: "It is noteworthy that the comparative-ignorance effect does not typically lead to decreased valuations for the ambiguous act, but to increased valuations of the risky act. Loosely speaking, the presence of ambiguity seems to make known-probability risk look nicer. This can have implications for the elicited risk attitudes when measured jointly with ambiguity attitudes (see the section, Correlation between risk and ambiguity attitudes)." %}

{% A strategy f is dominant if, conditional on every event, it gives a best outcome. That is, for each state of nature s and each strategy g, $f(s) \succcurlyeq g(s)$. f is *obviously dominant* if for each pair of states s,t, and each strategy g, $f(s) \succcurlyeq g(t)$ (Li 2017, American Economic Review). So, the inf. under f should be preferred to the sup under g. Assume that E is to be assessed, and $A_1 \succ \cdots \succ A_n$ are used for calibration. That is, we want to find the k such that $A_k \succcurlyeq E \succ A_{k+1}$. In the ascending mechanism, first randomly a stopping time $1 \leq s \leq n$ is chosen, unknown to the subject. If in a round j, the subject can choose to stop (then getting A_j and the process finishes) or continue. If continue, then, if it turns out to be the stopping time s, the process stops and the subject receives E. Otherwise, the subject proceeds to the next round (j+1). A dominant strategy is to continue until k, and then stop. Thus, this process reveals the subject's value. It is not obviously dominant because the subject may follow some silly strategy but just be lucky that the process stops very soon. There is also a descending mechanism that seems to be obviously dominant, but I did not understand it.

The author describes his result for the special case where the choice objects are events to gamble on for a fixed prize, so that this can serve for eliciting beliefs. The author names the mechanisms after Karni (2009 Econometrica). %}
Tsakas, Elias (2019) "Obvious Belief Elicitation," *Games and Economic Behavior* 118, 374–381.

{% **proper scoring rules**: if the belief of a subject is elicited, this can give an incentive to the subject to acquire extra info. This paper assumes that getting such info costs something. One way to avoid it happening, is making the stakes of the elicitation sufficiently small. %}
Tsakas, Elias (2020) "Robust Scoring Rules," *Theoretical Economics* 15, 955–987. https://doi.org/10.3982/TE3557

{% A new way to identify probabilities under statedependt utility, a topic on which Karni worked much. Let E_2 be the complementary event to event E_1, and let SEU hold for them with state-dependent utility. Assume we have another event S_2 that is the complement to event S_1, which I all signals (the author calls them proxies). Assume, as an example, that $P(S_1) = P(S_2) = 0.5$, and these signal events do not affect utility. Then we can, in standard ways, elicit $P(S_i|E_j)$ for all i,j. For example, assume $P(S_1|E_1) = 0.4$, $P(S_2|E_1) = 0.6$, $P(S_1|E_2) = 0.2$, $P(S_2|E_2) = 0.8$. Then, because $\big(P(S_2|E_1) - P(S_1|E_1)\big) : \big(P(S_1|E_2) - P(S_2|E_2)\big) = 1 : 3$, $P(E_1) : P(E_2) = 3 : 1$. So, $P(E_1) = 3/4$. Thus, we can always elicit $P(E_1)$ and $P(E_2)$ unless the degenerate case of $P(S_i|E_j) = 0.5$ for all i,j. That is, unless the case where the signals are stochastically independent of the underlying events. %}

{% **SEU = SEU**

real incentives: the **random incentive system**

P. 177 ℓ. 9–10 suggests that measuring utility when nonlinear probability may be difficult. **tradeoff method** of Wakker & Deneffe (1996) show it's not so difficult! Tversky writes: "To bypass the serious difficulty involved in simultaneous measurement of utility and subjective probability for each participant, researchers have derived and tested some empirical consequences of the SEU model."

… **risky utility u = transform of strength of preference v**: Utility for money is measured in a riskless context and found to be linear, as follows. For pairs (c_i,c_a) of cigarettes and candies, $W(c_i,c_a)$ is buy- or selling price for (c_i,c_a), $W(c_i,c_a) = f(c_i) + g(c_a)$ works well in data, so, it is concluded that $W(c_i,c_a)$ can be interpreted as riskless utility for money and further that therefore riskless utility of money is linear. Then also risky utility for money is measured, unfortunately in a somewhat confused manner. It is not always clear if the model is SEU à la Savage or SEU à la Edwards (separable prospect theory) (and **utility of gambling** is involved), and whether or not probability weighting at 1 is defined and is or is not 1. All these cases are discussed. It also seems that the !logarithm of! von Neumann Morgenstern utility is taken as risky utility. It is concluded from data that risky utility is different from riskless.

I like the general conclusion:

"The usefulness of utility theory for the psychology of choice, however, depends not only on the accuracy of its predictions but also on its potential value as a general framework for the study of individual choice behavior." %}

Nicely explains that in Allais paradox the central issue can be how to define outcomes; what Broome (1991) calls "individuation"

P. 163: "The axioms of utility theory (e.g., transitivity, substitutability) are accepted by most students of the field as adequate principles of rational behavior under uncertainty."

P. 164 has a marvelous text on U in EU versus risk aversion: "In utility theory [EU], risk aversion is explained by the concavity of the utility function for money. Once the monetary scale is properly transformed — no risk aversion remains. (In this respect it is somewhat misleading to refer to the measurement of the utility for money as 'the measurement or attitudes towards risk'. One's utility function reflects one's attitude towards money, not towards risk. Risk aversion is an epiphenomenon in utility theory.)"

P. 172: "When Savage argues (*convincingly, I believe*) against Allais, he is arguing in effect for the monetary interpretation of the consequences as much as he argues for the independence axiom. Savage advises us, in effect, to disregard the element of regret and behave as if the effective consequences are limited to monetary payoffs. In so doing, he is telling us how to feel and not how to choose. *Personally, I find the argument compelling*, but it is completely independent of utility theory [EU]." [Italics added] I 100% agree with Tversky. Tversky here unambiguously writes that EU is normative. %}

{% T 1996.1

P. 186: "if gambles are represented as random variables, then any two realizations of the same random variables must be mapped into the same object."

P. 188 bottom has a version of pseudocertainty effect that avoids any dynamic aspect. Very nice! Page restates that this sheds new light on the normative status of the Allais paradox. P. 189, end of §4, points out that this is additional defense for the irrationality of the Allais paradox: "It is noteworthy that generalized utility models can account for the violation of substitution in the comparison of problems 5 and 6, but not for the violations of desciption invariance in problems 6 and 7."

In many places Amos does not discuss his views of normative, but how most people perceive of normativeness. That is, he takes it as an empirical issue, as he did in Slovic & Tversky (1974). %}

{% **PT: data on probability weighting**; **natural sources of ambiguity**

inverse S: found for both risk and uncertainty

real incentives: **random incentive system** only for second out of three studies.

Basketball fans rather bet on basketball events, even while ambiguous, than on chance with known probabilities.

decreasing ARA/increasing RRA: use power utility;

inverse S; **ambiguity seeking for unlikely**: is found here (stated in sentence on pp. 281-282); they have gain outcomes only.

P. 271: "risk can be viewed as a special case of uncertainty where probability is defined through a standard chance device so that the probabilities of outcomes are known." Important: This shows that risk (I add: Ambiguity neutrality) refers to a neutral emotionless implementation of risk. The same statement is in Fox, Rogers, & Tversky (1996).

Pp. 271-272, on subcertainty: "$W(A) \le W(S) - W(S{-}A)$. This property, called subcertainty (Kahneman & Tversky, 1979) can also be interpreted as evidence that upper SA has more impact than lower SA; in other words, the certainty effect is more pronounced than the possibility effect."

P. 273 middle of 2nd column emphasizes that their certainty equivalents were derived from choice lists (and not from direct matching).

P. 274 last para points out that with only single nonzero outcomes, utility and probability weighting are not identifiable, and that one has to use prospects with two or more nonzero outcomes.

P. 276, 2nd column, ℓ. –3/–2, does a little discussion of measuring power in power utility and uses 1/3 probability gamble for \$100 gain because w(1/3) is approximately 1/3 on average.

P. 276: insensitivity is larger for unknown probabilities than for known probabilities, also for basketball events and basketball fans who have source preference for basketball over risk.

P. 279 considers the two-stage model that transformed introspective judgments of probability and finds it (taking those judgments transformed by the risk-probability-weighting-function) confirmed.

P. 279: "our main finding that decision weights are more subadditive for uncertainty than for chance." (**uncertainty amplifies risk**)

P. 280: **source preference directly tested.** They do it via certainty equivalents and transitivity.

Remarkable is the final text of the paper (p. 282): "To the extent that the experience of hope and fear is treated as a consequence of an action, subadditivity may have some normative basis. If lottery tickets are purchased primarily for entertaining a fantasy, and and protective action is undertaken largely to achieve peace of mind, then it is not unreasonable to value the first lottery ticket more than the second, and to value the elimination of a hazard more than a comparable reduction in its likelihood." It suggests that Amos can consider deviations of expected utility to be rational, contrary to all his other writings that I am aware of and contrary to my personal communication with him. I "discovered" this text, the first of that kind, only on 6 Sept. 2024. %}

{% I only came to read this paper for the first time in January 2001 (having thought before that it would just be a didactical restatement of their earlier work). What a marvelous paper! It is extremely well written, with every line reflecting deep thought. It is the most impressive paper I ever read. (The first half of the book Savage (1954) is the only work yet more impressive.) I regret that I was not aware of it when Tversky was alive and I would meet him and talk with him.

real incentives/hypothetical choice: all monetary experiments are done both with and without real incentives, these never giving different results.

paternalism/Humean-view-of-preference: The paper presents the various framing effects as deviations from rationality to be avoided if possible. Abstract ("Summary"):

"is a significant concern for the theory of rationality."

P. 453 opening para: "The definition of rationality has been much debated, but there is general agreement that rational choices should satisfy some elementary requirements of consistency and coherence. In this article we describe decision problems in which people systematically violate the requirements of consistency and coherence" This says that this paper considers many observed choices to be violations of rationality. It does not specify here whether rationality means EU.

P. 453 2nd column $\ell\ell$. 3-4: "Because of imperfections of human perception and decision,"

P. 453 last sentence: "When faced with a choice, a rational decision-maker will prefer the prospect that offers the highest expected utility." (This says 100% clearly that EU is rational.) Also p. 456, 1st para: "The certainty effect reveals attitudes toward risk that are inconsistent with the axioms of rational choice"

P. 454, on probability weighting: "but the function is not well behaved near the endpoints."

P. 456 first para: "The certainty effect reveals attitudes toward risk that are *inconsistent with* the axioms of *rational choice*" [italics added]

They clearly state that the certainty effect, one of the pillars of prospect theory, is irrational.

p. 456, first para of 2nd column: After having identified an inconsistency of choice they say that one choice must be wrong but that it is hard to determine which. P. 457, 3rd column, 2nd para: "Such a discovery will normally lead the decision-maker to reconsider the original preferences, even when there is no simple way to resolve the inconsistency." P. 458, 1st column., end of 3rd para, however writes, on consistency: "This approach enjoins the decision-maker to resolve inconsistencies but offers no guidance on how to do so. It implicitly assumes that the decision-maker who carefully answers the question "What do I really want?" will eventually achieve coherent preferences. However, the susceptibility of preferences to variations of framing raises doubt about the feasibility and adequacy of the coherence criterion."

P. 453 introduces the famous Asian disease problem. (now in 2024 I find this term politically incorrect) I never liked it much. The message "200 people will be saved" does not make clear what will happen to the other 400 people, whether they will die or not.

P. 453 3rd column penultimate para: "a framing effect with contradictory attitudes towards risks involving gains and losses." This is a common theme throughout the paper. The gain- and loss framing give different results. So, which is wrong, the gain or the loss framing? Answer: neither. The real problem is that preferences deviate from EV too much. (Under EV, a gain- or loss frame would give the same result.) Note that the authors call the attitudes for gains and losses not "different," but "contradictory." This word conveys the message, reflecting the deep writing of the authors. P. 454 2nd column last para states that for linear utility and probability weighting, framing would not matter. P. 457 top of 3rd para states that it is always framing together with nonlinearity.

P. 454: The major qualitative properties of decision weights can be extended to cases in which the probabilities of outcomes are subjectively assessed rather than explicitly given. In these situations, however, decision weights may also be affected by other characteristics of an event, such as ambiguity or vagueness (9)." Here endnote 9 refers to Ellsberg (1961) and Fellner (1961). This sentence describes part of the source method, although it probably is the two-stage model where the probabilities to be transformed are subjective nonadditive, whereas in the source method they are additive.

risk averse for gains, risk seeking for losses: p. 453 3rd columns describes the fourfold pattern.

P. 454 1st column 3rd para: "The displeasure associated with losing a sum of money is generally greater than the pleasure associated with winning the same amount". The authors here ascribe loss aversion to experienced utility and do not mention weighting. P. 456 last para of middle column also ascribes it to the value function.

P. 454 1st column 2nd para and endnote (5): note that the authors point out that for pure-gain or pure-loss prospects a different formula *should* be applied, so that they really do not take the separate-weighting formula of separable prospect theory.

P. 454, 2nd column, $\ell\ell$. 4-5 (on probability weighting function): "but the function is not well behaved near the endpoints."

P. 454 2nd column end of 1st para: "The major qualitative properties of decision weights can be extended to cases in which the probabilities of outcomes are subjectively assessed rather than explicitly given. In these situations, however, decision weights may also be affected by other characteristics of an event, such as ambiguity or vagueness." This describes the source method if subjective probabilities are assumed additive-which is not clear here.

P. 454 2nd column middle para: "The simultaneous measurement of values and decision weights involves serious experimental and statistical difficulties." Well, the **tradeoff method** gives utilities fairly easily!

reference dependence test: p. 454, 3rd column (Problem 3): The "Framing of acts" example is particularly interesting. For one thing, it demonstrates isolation beyond any doubt. I consider it to be the most impressive paradox of all of decision theory. Note that they replicated the phenomenon with real incentives (p. 458 Footnote 11): **real incentives/hypothetical choice & losses from prior endowment mechanism.**

. **real incentives/hypothetical choice**: **random incentive system between-subjects** (paying only some subjects): paid one of every 10 subjects in incentivized version of Problems 3 and 4, finding similar results as with hypothetical choices, given on p. 458 footnote 11.

Problems 5-6 test forgone-event independence (consequentialism) and find it well satisfied (22% and 26% choices for the risky option, respectively). The other dynamic decision principles together are strongly violated (58% R choice in Problem 7). P. 455 2nd column first para gives in fact the condition that Hammond (1988) called consequentialism; i.e., same assignments of outcomes to states of the world should be judged equivalently, no matter what the particular dynamic structure is that generates the assignment.

real incentives/hypothetical choice: **random incentive system between-subjects P.** 458 footnote 15 (paying only some subjects): paid one of every 10 subjects for Problems 5-7. They found similar results, and conclude that the elimination of real payment reduces risk aversion but does not change the pattern.

There is also a discussion of probabilistic insurance.

RCLA: p. 456 1st para of 1st column treats RCLA as a framing phenomenon.

P. 456 3rd column 2nd para ff. discusses lability of reference outcomes. This text continuing on the next page, probably Kahneman wrote this. The sentence "Rather, the transaction as a whole is evaluated as positive, negative, or neutral, depending on .." (p. 456 penultimate para) suggests that reference points are not chosen attribute-wise but overall, referring to the indifference class of the prospect.

P. 457 2nd para: People can take minimal accounts (1st para on that page) but also more comprehensive accounts (2nd para on that page). This is like narrow or broad bracketing.

P. 457 Problem 10: **ratio bias** plays a role here.

P. 458 1st column 2nd para recognizes that the inconsistencies can be considered rational in view of bounded rationality. It then suggests that prospect theory and framing give better models than "ad hoc" appeals to the notion of cost of thinking. (**calculation costs incorporated**)

coherentism: p. 458, 1st column, third para, describes the strict representational view of preference well: "In order to avoid the difficult problem of justifying values, the modern theory of rational choice has adopted the coherence of specific preferences as the sole criterion of rationality." I enjoyed how first T&K present, in a factual manner, the, I think overly restrictive, coherence-interpretation of rationality. Then, without being negative, typical of the marvelous Kahneman style ("In order to avoid the difficult problem of justifying values") they push it aside for better interpretations. In a few sentences four or five philosophical issues, taking others pages to formulate, are taken care of.

P. 458, 1st column, last para, describes the "predictive criterion of rationality".

utility = representational: somewhat before, referring to March (1978): "the common conception of rationality also requires that preferences or utilities for particular outcomes should be predictive of the experiences of satisfaction or displeasure associated with their occurrence."

P. 458, 2nd column, 1st para: "A predictive orientation encourages the decision-maker to focus on future experience and to ask "What will I feel then?" rather than "What do I want now?" [This is opposite to p. 1256 of Weinstein et al.1996 JAMA, claiming that community prefs, not patient prefs., should be used.] The former question, when answered with care, can be the more useful guide in difficult decisions."

They mention the hedonic experience of outcomes.

Then they go on to argue that experiences really following from a frame can be part of a normative analysis. For example, this can be applied to regret. I only partly agree, and am more paternalistic. Perception of goodness is not the criterion, but real goodness of the outcomes is. Perception of goodness only serves as a signal for real goodness of the outcomes. So, framing dependence is normatively acceptable only if it affects the goodness of outcomes, not if it only affects perception of goodness.

ratio-difference principle: people are more willing to drive 20 minutes to save $5 on a cheap calculator than on an expensive one. %}

Tversky, Amos & Daniel Kahneman (1983) "Extensional versus Intuitive Reasoning: The Conjunction Fallacy in Probability Judgment," *Psychological Review* 90, 293–315.

{% Central theme of paper: normative and descriptive models must be different, because normative requirements simply are not descriptive.

P. S252 "A descriptive model of choice is presented, which accounts for preferences that are anomalous in the normative theory."

P. S253 (= 168 in Bell et al.), under the subheading transitivity: "Thus transitivity is satisfied if it is possible to assign to each option a value that does not depend on the other available options."

P. S260: "A basic principle of economic thinking is that opportunity costs and out-of-pocket costs should be treated alike."

P. S262 2nd para: I do not like this experiment. Fairness concerns relative, not absolute, level.

Interesting is Footnote 3 on p. S 263, especially if compared to the corresponding Endnote 3 in the Bell et al. Chapter (p. 189 there). They discuss the extension to multiple outcomes: "The extension of the present analysis to prospects with many (nonzero) outcomes involves two additional steps. First, we assume that continuous (or multivalued) distributions are approximated, in the framing phase, by discrete distributions with a relatively small number of outcomes. For example, a uniform distribution on the interval (0,90) may be represented by the discrete prospect (0, .1; 10, .1; …, 90, .1). Second, in the multiple-outcome case the weighting function, $\pi_p(p_i)$, must depend on the probability vector p, not only on the component p_i, $i = 1, \ldots, n$. *For example, Quiggin (1982) uses the function* $\pi_p(p_i) = \pi(p_i)/[\pi(p_1) + \cdots + \pi(p_n)]$. As in the two-outcome case, the weighting function is assumed to satisfy subcertainty, $\pi_p(p_1) + \cdots + \pi_p(p_n) \leq 1$, and subproportionality." [italics added] The text shows that Tversky had understood part of Quiggin's analysis, such as Quiggin's intermediate step that the weight of outcome-probability p_i depends on the ranked probability vector $(p_1,\ldots,p_n)$, but had not understood Quiggin's rank dependence. Tversky (personal communication) told me that he had seen Quiggin's paper even before it was published, but had not understood it well then, in part because it was not well-written. Remarkable is that in Bell et al. the italicized text above was corrected and changed into: "For eample, Karmarkar (1978) used the function $\pi_p(p_i) = \pi(p_i)/[\pi(p_1) + \cdots + \pi(p_n)]$. A more elaborate extension that ensures stochastic dominance was proposed by Quiggin (1982)." (See endnote 3 on p. 189 there.) Which is correct. But in the 1992 publication Tversky will still make the mistake of thinking that the normalized $\pi(p_i)/[\pi(p_1) + \cdots + \pi(p_n)]$ can satisfy stochastic dominance (1992 p. 299, ℓ. –6), whereas Quiggin had already shown that it does not and that only his rank dependence does.

In the preceding footnotes, the claim on subcertainty, $\pi_p(p_1) + \cdots + \pi_p(p_n) \leq 1$, is strange for large n, if small probabilities are overweighted.

coalescing: P. S263 (p. 178 in Bell et al.), problem 7, is their famous example where by a clever splitting of outcomes (**coalescing**) stochastic dominance is violated. The general procedure for generating violations of this kind is in Birnbaum (1997).

P. S268 argues that Allais' paradox is driven more by probability weighting (the certainty effect) than by regret.

P. S272: "But since the viola- tions of dominance predicted by the theory have actually been ob- served (see problems 2 and 8), Machina's objection appears invalid." I disagree. Kahneman and Tversky did empirically show particular violations of stochastic dominance, but not most of the anomalous ones predicted by their formulas.

P. 279 discusses that cancellation and satisfaction of the sure-thing principle are followed more if common outcomes are transparent than if not.

real incentives/hypothetical choice: p. S274 (P. 187 in Bell et al.) suggests that real incentives are not important.

P. S251 abstract (not in Bell et al. it seems, where they, apparently, dropped the abstract), on invariance and dominance: "Because these rules are normatively essential but descriptively invalid, no theory of choice can be both normatively adequate and descriptively accurate."

P. S252: "The main argument for cancellation [Savage's sure-thing principle and von Neumann-Morgenstern independence] is that *only one state will actually be realized*, which makes it reasonable to evaluate the outcomes of options separately for each state. The choice between options should therefore depend only on states in which they yield different outcomes." [italics added] (**independence/sure-thing principle due to mutually exclusive events**)

P. S259 makes clear that reference dependence concerns changing the reference point without changing final wealth.

P. S266 ℓ. -4/-1: "Allais' problem has attracted the attention of numerous theorists, who *attempted* to provide a *normative rationale* for the certainty effect by relaxing the cancellation rule (see, e.g., Allais 1979; Fishnurn 1982, 1983; Machina 1982; Quiggin 1982; Chew 1983)." [italics added] P.s.: Fishburn did not relax cancellation, but transitivity.

P. S267: "called the *pseudocertainty effect*, that cannot be accommodated by relaxing cancellation because it also involves a violation of invariance." [italics from original] What they call violation of invariance amounts to dynamic decision principles incuding RCLA.

P. S268 gives evidence that nonlinearity of decision weights and framing, rather than regret, play empirical roles in their tests of the Allais paradox.

P. 270: "Attempts to rationalize the preferences in Allais' example by discarding the cancellation axiom face a major difficulty: they do not distinguish transparent formulations in which cancellation is obeyed from nontransparent ones in which it is violated." I disagree with this text for two reasons. (1) obeying cancellation in transparent formulations is a descriptive fact, not necessarily normative. (2) it has been pointed out before that obeying in transparent situations can be due to a heuristic rather than true preference. (Although after much searching I haven't been able to find a concrete reference, but I have surely seen it.)

P. S272 (p. 185 in Bell et al.), about prospect theory: "Prospect theory differs from the other models n being unabashedly descriptive and in making no normative claims." The para somewehat later on could use more nuances. They write that stochastic dominance has sometimes been violated and that, therefore, Machina's criticism of prospect theory as a descriptive theory for violating stochastic dominance is not valid. More nuances are desirable. That violations of stochastic dominance have been found does not justify every way to give it up. It must be given up in a way as found. Both Machina's criticism and T&K's defense should look into it.

The paper nowhere states that violations of expected utility can be normative. To the contrary, on p. S267 ff. they put, under term pseudocertainty effect, the dynamic principles forward that imply independence/sure-thing principle, preceding Hammond (1988; T&K had it already in their Science 1981 paper), and argue that these principles have a normative status similar to invariance, which is beyond dispute. P. S268 has nice discussion of regret. P. S270 credits Savage (1954, p. 101-104) and Raiffa (1968, pp. 80-86) for inspiration.

P. S272: "… as shown in the discussion of pseudocertainty. It appears that both cancellation [= s.th.pr. = independence] and dominance have normative appeal, although neither one is descriptively valid."

They agree with experimental economists that nonEU will be reduced by learning and proper incentives:

"Indeed, incentives sometimes improve the quality of decisions, experienced decision makers often do better than novices, and the forces of arbitrage and competition can nullify some effects of error and illusion. Whether these factors ensure rational choices in any particular situation is an empirical issue, to be settled by observation, not by supposition (p. S273)."

P. S274: "Incentives do not operate by magic: they work by focusing attention and by prolonging deliberation. Consequently, they are more likely to prevent *errors that arise from insufficient attention and effort than errors that arise from misperception or faulty intuition*. The example of visual illusion is instructive. There is no obvious mechanism by which the mere introduction of incentives (without the added opportunity to make measurements) would reduce the illusion observed in figure 3, and the illusion vanishes-even in the absence of incentives-when the display is altered in figure 4. The corrective power of incentives depends on the nature of the particular error and cannot be taken for granted." [italics added]

P. S275: "The main theme of this article has been that the normative and the descriptive analyses of choice should be viewed as separate enterprises."

{% **biseparable utility**

event/outcome driven ambiguity model: event driven

The purported plots of $W_i(p)$ versus p (Fig. 3) are actually of CE(x,p;0). The correct plot is shown in Tversky & Fox (1995).

PT: data on probability weighting; **tradeoff method** used theoretically.

P. 299, ℓ. –6, writes, unfortunately, that the violation of stochastic dominance of PT can be handled by normalizing the decision weights so that they add to unity. This is incorrect. There is no easy way to make this work. People again and again come up with the idea to consider $(\text{SUM } w(p_j)v(x_j))/\text{SUM}w(p_j)$, but this formula does not give sensible results and continues to violate stochastic dominance (Wakker 2010 Exercise 6.7.1). For two-outcome prospects it reduces to RDU with a symmetric weighting function, which itself is OK.

Many people erroneously think that diminishing sensitivity only refers to the value/utility of outcomes, but it is a general principle of numerical perception that applies to the weighting function as well. P. 303 2nd para: "The principle of diminishing sensitivity applies to the weighting functions as well." (**cognitive ability related to likelihood insensitivity (= inverse S))**

P. 303, beginning of 2nd para, on diminishing sensitivity for the weighting function: "The principle of diminishing sensitivity applies to the weighting functions as well. In the evaluation of outcomes, the reference point serves as a boundary that distinguishes gains from losses. In the evaluation of uncertainty, there are two natural boundaries-- certainty and impossibility--that correspond to the endpoints of the certainty scale. Diminishing sensitivity entails that the impact of a given change in probability diminishes with its distance from the boundary. For example, an increase of .1 in the probability of winning a given prize has more impact when it changes the probability of winning from .9 to 1.0 or from 0 to .1, than when it changes the probability of winning from .3 to .4 or from .6 to .7. Diminishing sensitivity, therefore, gives rise to a weighting function that is concave near 0 and convex near 1. For uncertain prospects, this principle yields subadditivity for very unlikely events and superadditivity near certainty."

P. 303 end of 2nd para: "However, the function [probability weighting function] is not well-behaved near the endpoints, and very small probabilities can be either greatly overweighted or neglected altogether."

Although experimental economists today (2010) usually credit Holt & Laury (2002) for introducing the *choice list mechanism for measuring indifferences*, this mechanism has been used long before. This T&K paper also uses it. Here is how the authors describe it: p. 305, ℓ. −4 till p. 306, ℓ.8: "The display also included a descending series of seven sure outcomes (gains or losses) logarithmically spaced between the extreme outcomes of the prospect. The subject indicated a preference between each of the seven sure outcomes and the risky prospect. To obtain a more refined estimate of the certainty equivalent, a new set of seven sure outcomes was then shown, linearly spaced between a value 25% higher than the lowest amount accepted in the first set and a value 25% lower than the highest amount rejected. The certainty equivalent of a prospect was estimated by the midpoint between the lowest accepted value and the highest rejected value in the second set of choices. We wish to emphasize that although the analysis is based on certainty equivalents, the data consisted of a series of choices between a given prospect and several sure outcomes. Thus, the cash equivalent of a prospect was derived from observed choices rather than assessed by the subject. The computer monitored the internal consistency"

P. 306, ℓ. −16, §2.2: "The most distinctive implication of prospect theory is the fourfold pattern of risk attitudes."

P. 306 ℓ. −11, on 4-fold pattern: "provided the outcomes are not extreme."

P. 306 ℓ. −11/−9, on partial reflection: "prospect theory does not imply perfect reflection in the sense that the preference between any two positive prospects is reversed when gains are replaced by losses."

§2.3, p. 311 2nd para gives argument for parameter-free estimation: "The estimation of a complex choice model, such as cumulative prospect theory, is problematic. If the functions associated with the theory are not constrained, the number of estimated parameters for each subject is too large. [**nonadditive measures are too general**] To reduce this number, it is common to assume a parametric form (e.g., a power utility function), but this approach confounds the general test of the theory with that of the specific parametric form. For this reason, we focused here on the qualitative properties of the data rather than on parameter estimates and measures of fit."

A suggestion similar to the penultimate sentence is in Edwards (1954, p. 396, next-to-last para), which writes, on parametric fitting: "confounds the general test of the theory with that of the specific parametric form."

P. 313: Figure 3 is an error. It gives CE(x,p,0), i.e., the weighting functions if utility were linear.

P. 316, §3: that coexistence of gambling and insurance is explained by overweighting of small probabilities.

P. 317: "The presence of systematic preferences for some sources of uncertainty calls for different weighting functions for different domains, and suggests that some of these functions lie entirely above others. The investigation of decision weights for uncertain events emerges as a promising domain for future research." Tversky probably has his two-stage model in mind, where the weighting functions transform nonadditive subjective probabilities. The source method is different. The weighting functions there transform additive a-neutral probabilities.

P. 317: "Despite its greater generality, the cumulative functional is unlikely to be accurate in detail. We suspect that decision weights may be sensitive to the formulation of the prospects, as well as to the number, the spacing and the level of outcomes. In particular, there is some evidence to suggest that the curvature of the weighting function is more pronounced when the outcomes are widely spaced (Camerer 1992). The present theory can be generalized to accommodate such effects but it is questionable whether the gain in descriptive validity, achieved by giving up the separability of values and weights, would justify the loss of predictive power and the cost of increased complexity. … The heuristics of choice do not readily lend themselves to formal analysis because their application depends on the formulation of the problem, the method of elicitation, and the context of choice."

P. 317 last para of main text nicely explains that PT is a departure from rationality, and that this need not be chaotic. "Prospect theory departs from the tradition that assumes the rationality of economic agents; it is proposed as a descriptive, not a normative, theory."

P. 318: "We chose Wakker's (1989a, 1989b) [axiomatization] because of its generality and compactness." ☺

decreasing ARA/increasing RRA: do not reject constant RRA and, hence, assume power utility **utility families parametric**: power family; **concave utility for gains, convex utility for losses**;

real incentives/hypothetical choice: §2.4 argues that hypothetical choice gives same results as real choices **inverse S**; **standard-sequence invariance**

biseparable utility if restricted to gains or to losses.

The paper uses an unfortunate notation with negative subscripts for states of nature with negative outcomes. I visited Tversky when he received the proofs for proof corrections of the paper. I convinced him that this notation is unfortunate and better be changed. Next day Amos told me that he could not change anymore. Such a change at the stage of proof corrections is too risky. It was too late. Anyway, this notation is better not followed. %}

Tversky, Amos & Daniel Kahneman (1992) "Advances in Prospect Theory: Cumulative Representation of Uncertainty," *Journal of Risk and Uncertainty* 5, 297–323.

{% **standard-sequence invariance**; references on preference reversal;

P. 372: they test prominence effect but the instructions, e.g., writing "technical knowledge is more important" of course just bring it in.

P. 373 1st column: Besides scale compatibility, also bargaining attitude plays a role. In the table, the entry of 26% surprises me.

Choice enhances noncompensatory heuristics: p. 375 last para nicely distinguishes ordinal (qualitative) and cardinal (quantitative) procedures, where choice enhances the former and matching the latter.

P. 376: I did not like the 2nd column top half.

P. 381: in the classical preference reversal, the main cause is the overpricing of the outcome gamble.

p. 382 writes: "Evidently, preference reversals are induced primarily by scale compatibility, not by the differential prominence of attributes that underlies the choice-matching discrepancy." Then the next sentence says, to my pleasure: "Indeed, there is no obvious reason to suppose that probability is more prominent than money or vice versa." This is contrary to Slovic (1985). Slovic, Griffin, & Tversky (1990), p. 22–23, however, write that they have changed their mind and believe that probability is indeed the prominent dimension.

P. 383 writes:

"But if different elicitation procedures produce different orderings of options, how can preferences and values be defined? And in what sense do they exist?" %}

Tversky, Amos, Shmuel Sattath, & Paul Slovic (1988) "Contingent Weighting in Judgment and Choice," *Psychological Review* 95, 371–384. https://doi.org/10.1037/0033-295X.95.3.371

{% About Samuelson's game, a fifty-fifty lottery for $200 or −$100 is done twice. Both if the first gives a win, and if it gives a loss, do people want to take the second. But if they don't yet know what the first will give they don't want the second.

The disjunction effect: Both if event E happens, and if it doesn't, you prefer f to g. But still a priori you prefer g to f. This is a particular violation of the sure-thing principle. Example: You did an exam. Don't know if you passed. Have to decide on taking vacation next week. If you get informed that you passed, you prefer to take the vacation, to celebrate. If you get informed that you failed, you prefer to take the vacation, for consolation. But you have to decide now, before getting informed. Important: You will be informed before vacation. Still, now you prefer not to take vacation. Subjects systematically violate the s.th.pr. this way if they are not aware of the structure of this. If, however, the structure is transparent, then they do not violate the s.th.pr.

P. 309 1st column middle writes: "This result shows that, like other axioms of choice such as substitution and stochastic dominance, STP tends to hold when its application is transparent, even though it is sometimes violated when its application is not obvious" This does not explicitly say whether satisfaction in the transparent case reflects true preference or heuristic. %}

Tversky, Amos & Eldar Shafir (1992) "The Disjunction Effect in Choice under Uncertainty," *Psychological Science* 3, 305–309.

{% Imagine that subjects choose between A and B, multidimensional objects. Some percentage chooses A. We now add an object C that is clearly inferior to A, and has no clear relation to B. Then people choose A more often than before. (The decoy effect or asymmetric dominance effect or attraction effect) This effect cannot be reconciled with rational economic revealed-preference principles under the usual ceteris paribus assumptions (such as no change in info about the intrinsic value of A).

The authors cite Huber, Payne, & Puto (1982) for having discovered this. %}

{% **conservation of influence**: tv series; photographer has to choose between lover an career, and chooses for career. She … well, let me avoid spoilers. %}

Twilight zone, Season 1, Episode 9, Little boy lost 18 Oct. 1985;

{% 33 adolecents are compared to 32 adults. Risk and ambiguity attitudes are measured by choices between (E:$X, E^c:x) and $5, with X > 5 > x. Used random incentive system. Ambiguity is by giving a probability interval. The exact details in the 3rd para of the 2nd column of p. 17136 were incomprehensible to me ("half of the trials"; do subjects know this?) and as far as I can tell, there could be suspicion (**suspicion under ambiguity**).

Adolescents are not more risk seeking, but more ambiguity seeking. The end of the abstract does what many papers in our domain do: speculate on policy implications. The second half of the abstract also goes into evolutionary speculations.

It is remarkable that this very thin and routine study could appear in PNAS. %}

Tymula, Agnieszka, Lior A. Rosenberg Belmaker, Amy K. Roy, Lital Ruderman, Kirk Manson, Paul W. Glimcher, & Ifat Levy (2012) "Adolescents' Risk-Taking Behavior is Driven by Tolerance to Ambiguity," *Proceedings of the National Academy of Sciences* 109, 17135–17140. https://doi.org/10.1073/pnas.1207144109

{% They measured risk and ambiguity attitudes for gains and losses from N = 135 healthy subjects, selected using flyers at universities, clinics, and senior communities. Note that also for the elderly only healthy subjects are sampled. They implemented RIS. Their main purpose is to investigate how these things depend on age. (**relation age-risk attitude**) They do a good and clean job (although ambiguity attitude is not modeled very well, being unaware of empirically found likelihood insensitivity; see below), but it is also purely routine.

Subjects chose between a sure $5 and either a risky or ambiguous prospect with one nonzero outcome. The risky/ambiguous payments ranged between $125 and –$125. Each subject was endowed with $125 at the beginning! (**Losses from prior endowment mechanism**). Probability levels ranged from 0.13 to 0.75. So, unfortunately for me, the paper gives no very direct insights into insensitivity and small probabilities. Ambiguity was generated by indicating an interval of probabilities (Figure 1).

suspicion under ambiguity: there was one fixed ambiguous urn (I guess: for each ambiguity level), and half the times one of the two colors was winning, and half the times the other color.

Utility for both gains and losses was power utility. No loss aversion parameter because no mixed prospects. P. 17143: They assumed EU for risk with power utility (CRRA) and then the power as index of risk aversion. For ambiguity they used biseparable utility (although they only refer to maxmin EU of Gilboa & Schmeidler 1989) with $w(p) = p - \beta A/2$, where A is a measure of ambiguity (the length of the probability interval) and β an index of ambiguity aversion for gains, and of ambiguity seeking for losses. Given β and A, this treats all probabilities p by substracting the same constant, which will not work well empirically given the common finding of insensitivity.

Note that their method amounts to using matching probabilities as recommended by Dimmock, Kouwenberg, & Wakker (2015), given that they use EU for risk. Then logistic function and maximum likelihood. Every choice is repeated 4 times, giving good estimates of consistency. Elderly are way more inconsistent, and violate stochastic dominance more often. Old and young are more risk averse than midlife. (**relation age-risk attitude**)

risk averse for gains, risk seeking for losses: p.17146: they find this clearly.

ambiguity seeking for losses: they find ambiguity neutrality for losses, and aversion for gains (P. 17145 & 17146).

correlation risk & ambiguity attitude: they find positive for gains ($\rho = 0.30$) and absent for losses (P. 17146).

reflection at individual level for risk: slightly positive correlation between risk aversion for gains and losses (P.17146).

reflection at individual level for ambiguity: slightly positive correlation between ambiguitiy aversion for gains and losses (P.17146)..

Cognitive measures: Numeracy did not correlate with risk or ambiguity aversion. It did correlate negatively with consistency and satisfying stochastic dominance (P. 17146). (**cognitive ability related to risk/ambiguity aversion**)

P. 17144: more violations of dominance under ambiguity than under risk.

ambiguity seeking for losses: the following is not directly related to it, but indirectly somewhat. P. 17147:

"Our results also make an important point: findings obtained studying preference in the domain of gains should not be immediately generalized to the domain of losses." P. 17146 2nd column ℓ. 5 wrote: "The most commonly used theoretical models of ambiguity assume that the individual ambiguity attitude is the same in the domain of gains and losses." The authors do not cite prospect theory for ambiguity, whereas all their findings confirm this theory.

(**Prospect theory not cited**)

gender differences in risk attitude: I should check it out. %}

{% Seems that they take issue with the silly viewpoint of Gold, Siegel, Russell, & Weinstein (1996) that utilities for medical treatments should always be inferred from the general public rather than from patients, and properly argue that there can be no general rule. %}

Ubel, Peter A., George F. Loewenstein, & Christopher Jepson (2003) “Whose Quality of Life? A Commentary Exploring Discrepancies between Health State Evaluations of Patients and the General Public,” *Quality of Life Research* 12, 599–607.

{% Paper about the failed Oregon implementation of C/E (cost-effectiveness). Gold et al. (1996) stated a consensus, unjustified I think, that quality of life estimations should be derived from the general public. Thus, for the Oregon project lay people were interviewed by telephone with questions such as “What chance of death would you be willing to take in order to try the treatment?” I would find about every judgment more valuable than the telephonic judgments of lay people. The TTO question “How much time would you be willing to give up in order to eliminate the meninggiorna pain and remain in perfect health?” will be even harder to interpret. Subjects cannot imagine how they can assume to have 75 years to live in total.

This paper presents these questions to economic students. Problem is that we as experimenters may understand what the question is about, but lay people and also the econ students cannot imagine any scenario where this question could be relevant. Their best guess may be that, hypothetically, they are getting the treatment, and then are asked to voluntarily take some risk of dying, where they

will of course choose risk 0. The authors find negative results for utility measurement and draw negative general conclusions. P. 114 last para of 1st column: "But our study raises questions about whether utility-elicitation methods accurately assign relative values on health outcomes." But these negative conclusions may only concern the measurements used here. %}

van Assen, Marcel A.L.M. & Chris Snijders (2001) "The Effect of Nonlinear Utility on Behavior in Repeated Prisoner's Dilemmas."

{% **free will/determinism**: The author was a masters' student in neuroscience & cognition. This text, published in a regular (!) general-public newspaper, is among my favorites on free-will/dterminism. (The author's expertise explains why the deterministic factors for him are signals in the brain, rather than forces and molecules as a physicist would have it, sets of equations as mathematicians would have it, emotions as psychologists would have it, and so on. (**ubiquity fallacy**) I give a translation of his text into English:

Daan Evers and Niels van Milten-Burg worry about the existence of a free will (this newspaper, 15 September), but for no reason. My thesis is that a free will obviously does not exists, but that this does not matter.

The idea of a free will results from our consciousness. We are aware that we are driven by certain motives, and we realize that we are acting organisms. But this does not mean that our consciousness (only an object and not a subject) can really influence the things we do and consciously experience. An order for action in our brains arises as a logical consequence of impulses that are already present there, and a coincidental observation of those impulses will not change this system. Even if we see our consciousness as a controlling system that can intervene if something is not going the way we want, then also this reaction is predictable beforehand on the basis of signals in our brains and, thus, our free will can be completely set aside.

What this amounts to, is that we will never be able to achieve this setting aside - not without powerful technologies and knowledge of really all variables influencing behavior. This means that there is a hole in what we understand of our own actions, and that hole we fill up with the illusion of a free will. The idea of a free will arises therefore if we do not fully understand why we do something [in causal terms] and then ascribe it to some sort of autonomous inspiration, an order

for action coming into existence in our brains in a magical manner.

Such an alchemy of brains has often been contested by Dick Swaab, but he too misses something important. That in theory a free will does not exist, does not matter. We will never be able to predict human behavior more precisely on the basis of currents in our brain and knowledge of external factors than we have been able to do for many years using a model for action called "free will." It is therefore extremely useful to be able to continue to assume a free will, purely because this works better in practice than a cold neurological determinism.

One of the many advantages of the belief in a free will is the fact that it gives happiness [utility]. Evers and Van Miltenburg can get themselves an icecream with no reason to worry and can have the pleasurable feeling that they decided entirely by themselves to do so. And this is how it is in fact: certain factors in their body - and more "self" than your own body you will never find - quite like to get that ice cream! However, philosophers desire a concept transpiring more autonomy, and the free will is that concept for them. Excellent, of course, because it makes them happy to have the feeling that in a moment of ultimate freedom (just do something crazy for a change) they could take three scoops of icre cream instead of two.

For me it is rather simple: I have no free will. Everything I do, is determined by an interaction of factors within and outside my body. But I do feel that I have a free will: it makes it very easy for me to accept what I do. And it makes me happy to think that I am free "to do what I want." Look, I know that falling in love consists of currents in the brain and materials in my blood, but this does not make the feeling generate less happinesss.

Thus Evers and van Miltenburg can rest assured and continue to order ice creams, and Dick Swaab can continue to scan brains. They should discriminate between research and daily life: belief in free will has no place in neuroscience, but setting it aside does not make life better. We need not pay much attention to the nonexistence of a free will: that only makes us less happy. Therefore consider the lack of a free will not to be a lack of freedom, but consider setting this nonexistence aside as a source of happiness. %}

{% **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**: Ask 300 subjects to mention six levels of income that are, respectively, very bad, bad, insufficient, sufficient, good, and very good. Assign "riskless" utility values 1/12, 3/12, …11/12 to these incomes. Then they fit a logarithmic and a lognormal-distribution à la Van Praag to these numbers. Next 50-50 lottery equivalence questions are asked. The authors assume that risky utility is the same as riskless and use this utility function to estimate the decision weight of .5. It is .45 for logarithmic utility and .47 for lognormal.

Remarkably, Fig. 1 proposes the **inverse S** probability weighting exactly as in Tversky & Kahneman (1992). %}

van de Stadt, Huib, Gerrit Antonides, & Bernard M.S. van Praag (1984) "Empirical Testing of the Expected Utility Model," *Journal of Economic Psychology* 5, 17–29.

{% Nice and clean application of decision analysis. "Clean" does not mean that one can do any useful applications without getting dirty hands. It is expected utility in full glory, with probability estimates, utility measurements, decision trees, and sophisticated software to analyze.

No probabilities are exactly known, of course, so we can call it ambiguity. The authors handle uncertainties about probabilities, like uncertainties about all other variables (probability is not special in this regard!), by using sensitivity analyses, univariate that is. I think that they are lucky in not knowing modern ambiguity theories …

They consider undescended testis (UDT) with baby-boys, mean that a testis is present but did not descend enough and did not make it to the scrotum; prevalence ±1%. Question is whether to operate, and if so, when (because often there is spontaneous cure, being in about 80% after a year). They find that operation is good, but best done only after 9 months. Pro of operation is cosmetic (keeping scrotum symmetric) and bigger fertility, but con is operation-complication risks (p. 912 end of 1st column). The result is highly sensitive to the subjective quality of life of asymmetric scrotum (p. 912 ℓ. −5) and, hence, the authors argue in several places that the patient, or probably his parents, should assess that. P. 917 last para explains that the medical profession did not want this, and one can read between the lines that the authors do not agree ("clinically counterintuitive"). They state their alternative view on p. 916 4th para and in the conclusion (p. 918) 1st para.

They measure probabilities from the literature and from expert judgments, and utility through introspective VAS scores transformed into decision-utilities based on Stiggelbout et al. (1996) (p. 911 & 916). Consider 0% and 3% discounting.

P. 911 Table 3 gives quality-of-life estimates for no paternity, having scar, dying, and so on. These were measured from the general public (so, not from patients or through doctors), with 41 complete questionnaires used (p. 911).

P. 916 para –3: that costs are too low to be very relevant here, suggesting a price of €20,000 to €40,000 for a QALY. %}

van der Pol, Marjon & John Cairns (2008) "Comparison of Two Methods of Eliciting Time Preference for Future Health States," *Social Science and Medicine* 67, 883–889.

{% N = 203; test stationarity by asking matching questions.

Details of stimuli: They describe illness to subjects, and then ask: How many days ill in X+2 years is equivalent to you to being ill for 30 days starting in X years? So, a matching question. Do this for X = 0 and some bigger Xs.

They find decreasing impatience throughout, not only at present. This falsifies not only constant discounting but also quasi-hyperbolic discounting. This need not violate generalized hyperbolic discounting of Loewenstein & Prelec (1992) although they, somewhat deviating from their title, do not test axioms of that theory and do only what I described above.

Similar tests of stationarity have often been done before, and they cite several, to which I would like to add Bleichrodt, Rohde, & Wakker (2009 GEB). They do cite the close Bleichrodt & Johannesson (2001).

They claim novelty in the combination of doing it for health rather than money and not being biased by subadditivity and similarity biases. The former claim is based on nothing but the fact that the delay between outcomes is kept constant and that the matching concerns the outcomes (p. 775 2nd last sentence above §4.1 & p. 779 ℓ. 2-5). The latter claim (fewer "similarity" biases) is based on nothing but the fact that they use matching questions, which they claim have fewer biases and then also fewer biases based on similarity (p. 775 last sentence above §4.1 & p. 779 ℓ. 2-5). Most people think that matching questions have more, and not fewer, biases than binary choices today (Bostic et al., 1990; Fischer et al. 1999; Noussair, Robbin, & Ruffieux 2004).

DC = stationarity: p. 771 ℓℓ. 6-7, & ℓ. –11/–9, and most clearly following Eq. 1.

Nice English: delay of nearest outcome versus delay between outcomes. %}

{% Have subjects (mostly students) answer certainty equivalent questions and speak aloud. Record and analyze these data to find the location of the reference point. Find that planned goals influence the reference point.

The authors argue that certainty equivalents (CE's) are perceived differently than found and/or claimed before, for instance by Bleichrodt, Pinto, & Wakker (2001). P. 344: "Our findings argue that the CE life-year gamble is very likely not perceived as an all gains gamble, as has been suggested by Bleichrodt and others."

However, Bleichrodt (& Pinto & Wakker, 2001) argued so for CE's measured through matching. When matching, then no sure outcome is available to serve as an easy reference point and this is crucial in the argument. Van Osch et al. did not use matching, but derived CE's from observed choices through bisection (p. 340 2nd para). Thus, subjects could focus on a sure outcome in every choice and take that as reference point. This was indeed found (p. 344: "most attention was paid to the offered CE. … Through the use of the chioce-bracketing procedure, we may have induced a changing reference point in the way one introduces a change in the reference point by offering

respondents a money amount to start with in money gambles."

They write on the difference between matching and choice bracketing on p 345: "A further important point is that the findings are applicable only to the choice-bracketing method. If utilities had been derived using the matching method, these findings might have been different." Thus, their finding does not contradict Bleichrodt et al., contrary to what they write, but it agrees with Bleichrodt et al..

In the equivalence y ~ $x_{0.5}z$, take (y-x)/(z-x) (PM, the proportional match) as index of risk aversion.

utility families parametric: Use a logistic family $U(t) = a/(1+(b/t)^c)$, which is convex below the inflection point $t^* = b\big((c-1)/(c+1)\big)^{1/c}$, and concave above. Use this family to fit the data. Where the inflection point of this fitted curve ends up, that is where they also assume a reference point to be. %}

{% The VC (Vapnik-Chervonenkis) dimension of a theory is calculated as follows, where the theory has some free parameters. Imagine a game between a falsifier F, who likes to see a particular theory violated, and a Theorist, who does not want the theory violated. First, a theorist chooses a natural number k. Second, the theorist moves again, choosing k binary choice situations. Third, the falsifier can choose, at will, what the observations in these choice situations are. Then, if the theory is not violated, T wins, and receives k from F. If the theory is violated, F wins, and nothing happens. The largest k that T can win is called the VC dimension. For example, if the theory only imposes weak ordering, and the preference domain is infinite, then the VC dimension is infinite. If the theory is single-peak preference and the preference domainie ℝ, then the VC dimension is 1. %}

{% This paper does not properly credit that most priority should go to Richter (1966).

Popularizes Afriat's revealed preference theorem and in fact uses Theorem 1 by Richter (1966). Main difference is that Richter considers completely general choice sets, for completely general objects, and not just choices from demand sets as in consumer theory. Another difference is that Richter wants all best elements to be in the choice set (where the idea is that then one is selected randomly) whereas Varian assumes that only one of the best is in the choice set; so, he gives the result from the final selection of selecting one element from the choice set.

Gives necessary and sufficient conditions for revealed preference to maximize a weak order and utility function. First, p. 946 gives Afriat's result in a more accessible form than Afriat did. Next it gives some variations, where the generalized axiom of revealed preference (GARP; Richter, 1966, calls it

congruency) in Fact 1 (p. 948) is most appealing. P. 947 announces: "there is an equivalent formulation of condition (2) which is quite easy to test. In addition this equivalent formulation is much more closely related to the traditional literature on the revealed preference approach to demand theory or Samuelson [24], Houthakker [12], Richter [21], and others."

This paper does not properly credit that most priority should go to Richter (1966). It does not explain what I explained above. Footnote 4 cites a Richer (1979) follow-up paper but is misleading and vague. Richer (1966) allows for any data set, finite or infinite. Richter (1966 Theorem 1) showed in full generality that GARP ("congruency") is equivalent to maximizing a weak order. Only difference, as explained before, is that Richter assumes a multi-element choice set.

Varian considers consumer theory and one-point demand functions, but allowing for other commodity bundles to be equivalent to the one demanded. And he assumes non-satiation. P. 946 gives Afriat's theorem with condition (2) "cyclical consistency" a version of GARP adapted to the context here. Given that the essential domain of chosen x^j's is assumed finite, any ordinal representing function can be turned into a concave function: Take the transitive extension of revealed preference over the x^i's, and make it complete over the x^i's. Give a utility value to the best indifference class, and somewhat lower to the 2nd best. Then give the 3rd best an extremely much lower value. Next, give the 4th best a yet way more extremely lower value. And so on, with each new utility difference way bigger than the ones before. This way Condition (3) can always get satisfied, with the lambda's all equal to 1 if one wants. Given that utility is ordinal, the interpretation of the lambda's as marginal utility (p. 946 ℓ. −10) is not meaningful. %}

{% Most of this paper I found not so interesting, being negative on the researcher Mr. Clark, cardinal utility saying nothing about the movements of markets or institutions. But there are some nice citations on economics being on living beings and teleology. Here are citations (italics added). The italicized parts reflect essentials of living beings that can exert influence by, for instance, interested discrimination (=observation), to make decision theory and economics different than natural sciences.

conservation of influence: The theory is confined to the ground of sufficient reason instead of proceeding on the ground of efficient cause ...

“ The immediate consequence is that the resulting economic theory is of a teleological character ... instead of being drawn in terms of cause and effect. The relation sought by this theory among the facts with which it is occupied is the control exercised by future (apprehended) events over present conduct. Current phenomena are dealt with as conditioned by their future consequences; and in strict marginal-utility theory they can be dealt with only in respect of their control of the present by consideration of the future. Such a (logical) relation of control or guidance between the future and the present of course involves an exercise of intelligence, a taking thought, and hence an intelligent agent through whose *discriminating* forethought the apprehended future may affect the current course of events; unless, indeed, one were to admit something in the way of a providential elements, the relation of sufficient reason runs by way of the *interested discrimination*, the forethought, of an agent who takes thought of the future and guides his present activity by regard for this future. The relation of sufficient reason runs only from the (apprehended) future into the present, and it is solely of an intellectual, subjective, personal, teleological character and force; while the relation of cause and effect runs only in the contrary direction, and it is solely of an objective, impersonal materialistic character and force. The modern scheme of knowledge, on the whole, rests for its definitive ground, on the relation of cause and effect; the relation of sufficient reason being admitted only provisionally and as a proximate factor in the analysis, always with the unambiguous reservation that the analysis must ultimately come to rest in terms of cause and effect. The merits of this scientific animus, of course, do not concern the present argument.

Now, it happens that the relation of sufficient reason enters very substantially into human conduct. It is this element of discriminating forethought that distinguishes human conduct from brute behavior. And since the economist’s subject of inquiry is this human conduct, that relation necessarily comes in for a large share of his attention in any theoretical formulation of economic phenomena, whether hedonistic or otherwise. B*ut while modern science at large has made the causal relation the sole ultimate ground of theoretical formulation; and while the other sciences*

that deal with human life admit the relation of sufficient reason as a proximate, supplementary, or intermediate ground, subsidiary, and subservient to the argument from cause and effect; [after a marvelous beginning of the sentence, aggression takes over and nonsense follows] economics has had the misfortune -- as seen from the scientific point of view -- to let the former supplant the latter. It is, of course, true that human conduct is distinguished from other natural phenomena by the human faculty for taking thought, and any science that has to do with human conduct must face the patent fact that the details of such conduct consequently fall into the teleological form; but it is the peculiarity of the hedonistic economics that by force of its postulated its attention is confined to this teleological bearing of conduct alone. It deals with this conduct only in so far as it may be construed in rationalistic, teleological terms of calculation and choice. But it is at the same time no less true that human conduct, economic or otherwise, is subject to the sequence of cause and effect, by force of such elements as habituation and conventional requirements. But facts of this order, which are to modern science of graver interest than the teleological details of conduct, necessarily fall outside the attention of the hedonistic economist, because they cannot be construed in terms of sufficient reason, such as his postulates demand, or be fitted into a scheme of teleological doctrines." %}

Vieider, Ferdinand M. (2021) “Noisy Coding of Time Delays and Reward Discounting,” Working Paper21/1036 FEB, Ghent University, Belgium.

{% Most empirical papers test what is the best-fitting core theory (deterministic) in combination with an error theory, where an implicit assumption often is that these are two independent components with independent answers. However, there obviously will be dependencies and interactions. What is the best error theory may depend on the core theory. More problematic, the best core theory may depend on the error theory chosen, as with the keyword in this annotated bibliography: **Best core theory depends on error theory**. The latter is more problematic because the core theory is of primary interest. The model of this paper, Bayesian inference model (BIM) does not try to separate but has parameters that at the same time affect core theory and

error theory, and those are not separated.

The BIM model takes inputs such as probabilities and money amounts as noisy signals and uses psychologically oriented theories with mental coding and decoding noisy inputs. This makes it harder to separate out the core theory, which is of primary interest. It supports: **cognitive ability related to likelihood insensitivity (= inverse S)**. There is most insensitivity for probability, but, as emphasized by the author, also for outcomes. The author emphasizes that there is no independence between the processing of outcomes and of (ambiguous!?) probabilities, giving up yet another property of prospect theory.

The paper agrees with my 2010 book and Abdellaoui, Baillon, Placido, & Wakker (2011) that there is no categorical difference between risk and ambiguity but that risk is an extreme of a continuum. The paper uses the term complexity, vague but fashionable in 2023. I did not study the paper enough to know how the theory is exactly defined. Probability transformations seem to be central, as in source theory of Baillon, Bleichrodt, Li, & Wakker (2025).

The paper compares risky choices with Oprea's mirror simplicity equivalents and again finds similar phenomena. The paper, unfortunately, is similar to Oprea's by the incorrect claim that risk theories would predict that mirror simplicity equivalents would be very different than risk attitudes. To the contrary, Kahneman and Tversky more than anyone else emphasized that many aspects of risk attitudes are based on *general* properties of cognition and perception.

The paper has in common with TAX and RAM models by Birnbaum, BEAST model by Erev, and others that it can better fit and predict than prospect theory, but that it is more complex with harder-to-interpret parameters. All common economics and decision analysis models use a deterministic ccore model satisfying basic properties such as transitivity. The author's BIM model cannot be used there. Neither can the models by Birnbaum or Erev, and this is a drawback of these models.

The intro ends with an enthusiastic para opening with: "The insights I present have potentially far-reaching policy implications." %}

Vieider, Ferdinand (2024) "Decisions under Uncertainty as Bayesian Inference on Choice Options," *Management Science* 70, 9014–9030.
https://doi.org/10.1287/mnsc.2023.00265

{% Use choice lists to determine CEs (certainty equivalents) of two-outcome prospects. Use RIS for real payment. Study within- and between-country differences, by doing two cities in China (Shanghai & Bejing) and two in Egypt. Find no within-country difference, but clear between-country difference. They point out that this suggests that randomization within a country, often difficult to do in intercultural studies, may not be a big problem. %}

Vieider, Ferdinand M., Thorsten Chmura, Tyler Fisher, Takao Kusakawa, Peter Martinsson, Frauke M. Thompson, & Adewara Sunday (2015) "Within- versus between-Country Differences in Risk Attitudes: Implications for Cultural Comparisons," *Theory and Decision* 78, 209–218.

{% **losses from prior endowment mechanism**: Did this. The prior endowment, conditional on a loss question implemented for real, was equal to the maximum loss, being €20c (p. 426). Used RIS.

Collected data of 2,939 subjects from 30 countries from all continents except Antarctica. They always take students. This makes the sample less representative for the world population as a whole, but makes between-country comparisons more reliable because for this purpose it is good to have little within-country heterogeneity.

Various teams and the main organizer, Vieider, wrote a number of papers on it. This paper verifies construct and convergence validity (my terms) of the measurements, by studying correlations between different ways to measure things. For each subject, 44 CEs of lotteries with gains, losses, mixed, and risk and uncertainty. (I did not find if/how they control for suspicion.) They analyze the CEs of the uncertain options, capturing general uncertainty attitude. To capture ambiguity attitude, which is the difference between uncertainty and risk, they could inspect differences of CEs under uncertainty and risk. Further intospective questions about general risk attitude and other things. They find that corresponding measures, both behaviorally and introspectively, are always positively related, though sometimes not strongly. This also holds between countries (taking each country as an individual).

Section 3.1, p. 428: They take unnormalized risk premium as index of risk aversion, and mention that normalizing by dividing by expected value (I: what if that is 0?; better divide by standard deviation) would not affect the results. As they will explain later (p. 446 last para of paper), this is not suited to test likelihood insensitivity (which they, unfortunately, call likelihood dependence), because to get that right you need different parameters.

inverse S: is found (p. 430 top);

Section 3.3, p. 439, end of 1st para: the uncertainty attitudes are more related to introspective questions than the risk attitudes.

Section 3.4, Table 3, gives correlations between the preference-based indexes, taking all countries together. It also considers many introspection-based indexes. Risk and uncertainty aversion for gains are strongly related (0.68), which is no surprise because uncertainty aversion comprises risk aversion (**correlation risk & ambiguity attitude**).

reflection at individual level for risk: They find a positive relation between risk aversion for gains and for losses. They also find that, stronger, for uncertainty aversion (p. 440; **uncertainty amplifies risk**).

gender differences in risk attitude: p. 443 reports more risk aversion for women and gains, but no significant result for losses.

P. 443 reports more uncertainty aversion (note that this comprises risk + ambiguity) for RICH countries. P. 445 last para will state the same for risk aversion.

P. 444 2nd para has nice discussion of context dependence being popular among psychologists. The finding of correlations of this paper shows that not everything is completely context dependent, but still to some degree.

P. 444 3rd para has nice discussion of constructive view of preference and writes: "We thus conclude that preferences are indeed discovered and derived from an underlying preference, rather than constructed *ex nihilo*."

P. 445 2nd para has an, again nice, discussion of the drawback of introspective measures that they are not clearly related to decision-theory components.

P. 445 last para: Risk aversion is decreasing in wealth between individuals, but increasing in wealth between countries. This is a risk-income paradox. They cite preceding papers on it. %}

Translated into English by Peter K. Newman (1952) “The Existence-Conditions of a Total Utility Function,” *Review of Economic Studies* 19, 123–128.

{% **ordering of subsets**; P. 1787 3rd para makes the misleading claim that, given that fine and tight qualitative probabilities are embeddable (requiring only compatibility w.r.t. finite unions!) in monotonely continuous (countably additive) qualitative probability structures, it is no loss of generality to consider only the latter. Example: Space is ℕ. Algebra contains all finite and co-finite subsets. P(A) = 0 if A is finite, and P(A) = 1 if A is cofinite. This structure can only be embedded in a countably additive probability structure if we merely respect finite unions and not infinite ones; i.e., merely if we take isomorphism as an algebra, and not as a σ-algebra. The author’s ensuring mathematical claims on such embeddability are incorrect (which fortunately does not affect his main Theorem 4.3):

(1) Counterexample to Remark on bottom of p. 1793: let $\mathcal{A}_0$ contain all measurable subsets of [0,1] for which there exists ε > 0 such that [0,1/4+ε) is entirely in or entirely out of the set. Take A = [0,1/4]. P(A}) = ¼, but the sup there is 0.

(2) Counterexample to claim directly preceding Theorem 4.5 on p. 1795: Let $\mathcal{U}$ be an ultra-filter on ℕ, containing all finite subsets. Let, for A ⊂ ℕ, P(A) = 0 if A ∈ $\mathcal{U}$, P(A) = 1 if A ∉ $\mathcal{U}$. Let ≽ be represented by P. ℕ itself is an atom, provides the finite (one-element!) partition into atoms, but ≽ is not monotonely continuous and we have no qualitative probability σ-algebra.

Theorem 4.2 shows that a finitely additive probability measure is countably additive if and only if the generated qualitative probability relation satisfies what I often call set continuity, and what Villegas calls monotonce continuity. Theorem 4.3 p. 1794 is the main representation theorem. %}

{% So here then is, at long last, the book containing Vind's result on mean groupoids. A first version appeared as a working paper in 1969! Now, shortly before the anticipated passing away of Karl's co-author and life-long friend Birgit Grodal, the book went public.

endogenous midpoints: Mean groupoid means an endogenous subjective utility-midpoint operation, giving a grip on cardinal utility. Here is how it works under subjective expected utility, with E denoting an event, and $x_{1_E}x_2$ the act yielding outcome x_1 under event E and outcome x_2 otherwise. Then y is the utility midpoint between x and z if the following indifferences hold:

$$x \sim x_{1_E}x_2,\ z \sim z_{1_E}z_2, \text{ and } x_{1_E}z_2 \sim z_{1_E}x_2 \sim y.$$

The method holds under prospect theory if we add the requirement that $x_1 > x_2$, $x_1 > z_2$, $z_1 > z_2$, and $z_1 > x_2$, assuming only gains.

It provides an appealing and powerful tool to axiomatize many decision models. Basically, it is an alternative, and close relative, to the tradeoff technique that I often used and that is close to the standard sequence approach of Krantz et al. (1971). Current (2019) generations do not use such knowledge, because of which they work with the Anscombe-Aumann framework which amounts to assuming linear utility. Vind is more general than others in relaxing completeness and transitivity. In this respect he is close to Fishburn, who used similar techniques for relaxing transitivity in his papers on skew-symmetric bilinear utility.

One thing I never understood in the maths of mean groupoids. When the mean groupoid operation is transferred from elements to indifference classes, how is continuity maintained? Shouldn't this require some uniform continuity at the level of elements? %}

Vind, Karl (2003) "*Independence, Additivity, Uncertainty.*" With contributions by Birgit Grodal. Springer, Berlin.

{% In personal communication I (Peter Wakker) told Ghirardato, Maccheroni, Marinacci, Siniscalchi, and Vind, shortly after appearance of the Econometrica paper of the former 4 authors in 2003, that Karl Vind had found an alternative endogenous midpoint operation before. Karl then put this into writing, shortly before he died. %}

{% **paternalism/Humean-view-of-preference**: Last paragraph of paper (p. 108) is relevant, not only to insurance but to the whole decision theory. It points out that not only the existence of biases and deviations from rationality should be signaled but a better sense of the magnitudes of these is needed so as to mitigate these inadequacies:

"These results suggest that examination of theoretical characteristics of biases in decisions resulting from irrational choices of various kinds should not be restricted to the theoretical explorations alone. We need to obtain a better sense of the magnitudes of the biases that result from flaws in decision making and to identify which biases appear to have the greatest effect in distorting individual decisions. Assessing the incidence of the market failures resulting from irrational choices under uncertainty will also identify the locus of the market failure and assist in targeting government interventions intended to alleviate these inadequacies."

Also argues (p. 107, conclusion, first phrase) that most aspects of insurance are based on probability perception: "Most aspects of risk taking and insurance-related decisions hinge on the relationship between the perceived probability by the individual and the actual risk." %}

{% **updating under ambiguity with sampling**; Two-armed bandit. Only, after first loss, game immediately stops (≈ dead). Subjects reactions to changes of parameters in the decision problems give a mix of rationality and irrationality. The most remarkable irrationality is that subjects do not improve their performance in repeated games, but continue to be as irrational as at the beginning. In this game, somewhat seemingly paradoxical, the more ambiguity the better, because with more ambiguity there is more to learn. The authors write: "Despite the asymmetric nature of the learning process, ambiguity and learning are consequential. In particular, for any given mean probability of success, greater ambiguity is desirable. Increases in ambiguity with respect to the probability of success offer greater opportunities for long-term gains because of the greater chance that the underlying probability of success for that option offers a high chance of success on each trial (Viscusi 1979; Berry and Viscusi 1981)." {% It uses the choice list to find indifferences between two-outcome gain prospects.

1. MAIN FINDING

Uses the representative Dutch LISS panel with N = 1422 subjects. It nicely tests Kreps & Porteus (1978), by having payment in three months, but resolving the uncertainty immediately or in three months. Will not find serious differences here (**source-dependent utility**: not found). The further main findings presented are that there are no clear predictions from demographics or otherwise because of unobserved heterogeneity of risk attitude.

2. SOME KEYWORDS

real incentives/hypothetical choice & random incentive system between-subjects: One group did hypothetical choice, and one group had real incentives, with one of every 10 subjects paid. (There was also a group with small real incentives.) No differences are found, also not in choice errors (p. 681).

losses from prior endowment mechanism: this they do.

P. 677: they use the good econometric technique of Conte, Hey, & Moffatt (2011).

concave utility for gains, convex utility for losses: this paper does not provide evidence on this topic (see below).

3. THEORETICAL ANALYSIS AND ITS LIMITATIONS

The authors consider risky choices with payments in 3 months, and two treatments (within-subject): either the uncertainty is resolved immediately (treatment 1) or in 3 months (treatment 2). They assume PT without probability weighting and with a fixed reference point 0. That is, they assume expected utility with a kink of utility at 0 (loss aversion). Then they test whether utility in one treatment is more or less conave than in the other, to test Kreps & Porteus

(1978). For treatment 2, late resolution, they assume exponential utility $-e^{-\gamma z}$, with the same γ for gains and losses (discussed below), and loss aversion added by multiplying loss utility by λ (adding the appropriate constant to have continuity at 0); see their Eq. 2. (Their function h in the second line of Eq. 3 can be dropped.) For treatment 1, early resolution, they also assume, in my notation, exponential utility $-e^{-\gamma' z}$. Then $\gamma' > \gamma$ gives more concave utility, and thus less preference, for early resolution. The authors use γ'/γ as an index. Because of this division by γ, effects depend on the sign of γ. Thus for $\gamma > 0$, a large ratio means preference for late resolution, and for $\gamma < 0$ it is the other way around. The authors therefore impose the following restrictions:

(1) They do not allow a sign-change between γ and γ'. In particular, for $\gamma = 0$ (linear utility) they allow no difference between early and late resolution.

(2) They assume the same loss aversion in both treatments. (Loss aversion is a substantial part of utility curvature and in general Kreps-Porteus comparisons would have to be incorporated in the comparison.)

(3) For positive γ and γ' they take the ratio $\gamma'/\gamma = \rho$ as index of preference for late resolution (Eq. 8, p. 691).

(4) For negative γ and γ' they take the ratio $\gamma/\gamma' = \rho$ (so, here γ is different than, reciproke to, the one for positive γ, γ') as index of preference for late resolution (Eq. 8, p. 691).

The particular way of comparing concavity of utility chosen by the authors imposes a further restriction, the most serious one, being

(5) Utility must have the same γ for gains as for losses (mentioned above), and also the same γ' for gains and for losses. Hence, it must either be concave for both gains and losses, or convex for both, and the majority pattern of utility, concave for gains and convex for losses, cannot be considered. Especially this last restriction imposes a limitation on the empirical relevance of the findings of this paper, and they should be taken only within this modeling assumption.

P. 665 end of 1st para: for further studies measuring loss aversion by measuring utility and then a kink at 0, see Abdellaoui, Bleichrodt, & Paraschiv (2007) and their references.

4. THE FINDINGS GIVEN THE THEORETICAL MODEL

P. 666 end of penultimate para & p. 683: demographic variables do not explain much variance in risk attitudes; pp. 684-685 discusses relations found. P. 684: "The individual choices thus contain much more information than what is captured by sociodemographic goups."

gender differences in risk attitudes: pp. 684-685: women are more loss averse.

It finds utility -exp(−0.032α) where the unit if money α is, I guess, euro (given the Dutch population). It means that the risk tolerance is €30. Risk tolerance α means, for instance, that a gamble (0.5:2α, 0.5: −α) is neutral (equivalent to not gambling), giving a nice and well-known interpretation to the utility parameters. The authors do not use this interpretation (p. 680 beginning of 3rd para; p. 682 ℓ. 3), but instead use risk premiums that, of course, depend on the prospects chosen.

Loss aversion is $\lambda = 2.38$. They find 8% inconsistency (p. 680), which is less than usual (**inconsistency in repeated risky choice**). The choice list method may have enhanced consistent choice.

It, nicely, finds that loss aversion is most volatile (p. 681), and utility is less volatile (p. 686 middle).

5. TOPIC FOR FUTURE RESEARCH

An obvious topic for future research is modifications of the above utility restrictions, for example by comparing differences rather than ratios of the Pratt-Arrow indexes γ and γ´, or even better, differences of their reciprokes, being risk tolerances, or by using other concave transformations such as exponential (leading to expexp utility for early resolution) to relate the utilities of the two treatments to more easily handle sign-dependence, or by separate comparisons for gains and for losses, preferably by also allowing for different loss aversion and then comparisons between those.

6. ALTERNATIVE UTILITY SPECIFICATIONS ANALYZED IN THE WEB APPENDIX

The web appendix pp. 4 ff. discusses alternative utilities. Unlike what was suggested in the main text, they do not really consider the utility function common in PT (see their Eqs. 11 & 12). Common in PT, if taking only one parameter for basic utility (= utility without the loss aversion parameter), is to take reflected utility, with:

for x < 0, u(x) = –u(–x) (*)

The authors use this formula only if utility is concave for gains. If utility for gains is convex then they add a flip, and let utility for losses be convex rather than concave by multiplying the exponential parameter by –1 for losses. (Their claim that prospect theory is silent on convex functions for gains, on p. 4 ℓ. –5 of the web appendix, I did not understand.) Thus, for losses, gamma and -gamma give the same utility function, and for losses no concave utility is possible. This is an unconventional model of utility that I haven't seen before. This paper finds that it does not perform well.

P. 669 seems to point out that their adaptive measurement is not incentive compatible.

P. 681: more noise for LISS panel than for students. %}

von Gaudecker, Hans-Martin, Arthur van Soest, & Erik Wengström (2011) "Heterogeneity in Risky Choice Behavior in a Broad Population," *American Economic Review* 101, 664–694.

{% **losses from prior endowment mechanism; random incentive system between-subjects** (paid 1 of every 10 subjects in the real incentive treatment)

Measure risk attitudes in usual ways, using choice lists and a variation of Binswanger (1981), with a student sample and a CentER panel data set representative of the general population. There are considerable differences between the students and the population, showing that the external validity of student experiments is questionable. Self-selection is less of a problem. Risk aversion and loss aversion is much larger in the general population than with students. They use usual PT parameter estimations as in their 2011 American Economic Review paper, but do not report their results here; for that see American Economic Review. %}

von Gaudecker, Hans-Martin, Arthur van Soest, & Erik Wengström (2012) "Experts in Experiments: How Selection Matters for Estimated Distributions of Risk Preferences," *Journal of Risk and Uncertainty* 45, 159–190.

{% **natural sources of ambiguity**: finance and climate change.

They use the method of Baillon, Huang, Selim, & Wakker (2018 Econometrica) to measure ambiguity attitudes. That is, they measure matching probabilities to measure ambiguity attitudes, both regarding ambguity aversion and ambiguity attitudes. The experimental implementation is impressive, using the marvelous LISS panel. They use high real incentives (€51 per hour), a very big sample N = 2200), good stimuli measuring ambiguity attitudes both for finance uncertainty and for temperature change, measuring risk aversion, many demographic variables, info about potfolio decisions, and they use solid statistical analysis techniques.

They find roughly four types, each about 20%, being subjective expected utility maximizers, likelihood insensitive subjects with considerable ambiguity aversion, likelihood insensitive subjects with moderate ambiguity seeking (**ambiguity seeking**:), and highly noisy subjects.

The paper finds similar ambiguity aversion and choice errors for finance and temperature change, suggesting person-dependence but source independence of these. Insensitivity depends on both.

Intelligence is negatively related with ambiguity attitudes and risk aversion (**cognitive ability related to risk/ambiguity aversion**).

It is encouraging that the parameters measured are stable over time. Also that the ambiguity indexes better predict portfolio decisions than risk attitude indexes, although this may also be because risk aversion measurements involved fewer observations.

correlation risk & ambiguity attitude: ambiguity neutrality (called near-SEU by the authors in the Nov’22 version of the paper but it should be near-ambiguity neutral) brings low risk aversion, and both ambiguity aversion and seeking bring more risk aversion. S, insensitivity brings risk aversion, and not so much ambiguity aversion or seeking.

It would have been very interesting if the authors had measured insensitivity not only w.r.t. ambiguity, but also for risk attitudes where it similarly is central. %}

{% Seems to write on p. 11, translated: "We can say nothing about the probability of death of an individual even if we know his condition of life and death in detail. The phrase 'probability of death,' when it refers to a single person, has no meaning at all for us." The claim is true for a strict frequentist interpretation, but is very false for every interpretation that I like. %}

von Mises, Richard (1928) "*Wahrscheinlichkeit, Statistik, und Wahrheit.*" Springer, Berlin. (Translated into English in 1939 as "Probability, Statistics and Truth," Hodge, London. Republished in 1957 by Allen & Unwin.)

{% %}

von Mises, Richard (1957) "*Probability, Statistics, and Truth.*" Allen & Unwin, London.

{% Seems to have shown that mixed Nash-equilibrium already exists in noncooperative game theory if preferences are quasi-concave w.r.t. probabilistic mixing. See also Debreu (1952 §4). %}

von Neumann, John (1928) "Zur Theorie der Gesellschaftsspiele," *Mathematische Annalen* 100, 295–320.

{% P. 8 (on unit of exchange between players): "substitutable, freely transferable and identical, even in the quantitative sense, with whatever 'satisfaction' or 'utility' is desired by each participant."

Pp. 8-9 write, about utility being a theoretical construct but then becoming as real as energy: "It is sometimes claimed in the economic literature that discussions of the notions of utility and preference are altogether unnecessary, since these are purely verbal definitions with no empirically observable consequences, i.e., entirely tautological. It does not seem to us that these notions are qualitatively inferior to certain well established and indispensable notions in physics, like force, mass, charge, etc. That is, while they are in their immediate form merely definitions, they become subject to empirical control through the theories which are built upon them—and in no other way."

game theory can/cannot be viewed as decision under uncertainty: p. 11 (that no probabilities should be assigned to strategy choices of others): "One would be mistaken to believe that it can be obviated, like the difficulty in the Crusoe case ... by a mere recourse to the devices of the theory of probability. Every participant can determine the variables which describe his own actions but not those of the others. Nevertheless those "alien" variables cannot, from his point of view, be described by statistical assumptions. This is because the others are guided, just as he himself, by rational principles-whatever that may mean-and no *modus procedendi* can be correct which does not attempt to understand those principles and the interactions of the conflicting interests of all participants." [italics from original]

risky utility u = strength of preference v: Ch. 3 writes in the spirit of utility being one concept, and not that there are various concepts of utility, but it is not explicit.

independence/sure-thing principle due to mutually exclusive events: §3.3.2, p. 18, mutual exclusiveness of events to avoid complementarity is emphasized (see also p. 628). They write, on the 50-50 probabilistic mix of B and C: "We stress that the two alternatives are mutually exclusive, so that no possibility of complementarity and the like exists."

risky utility u = strength of preference v: §3.3 writes that with probabilities available, we can give meaning to utility difference comparisons. Their term utility difference does not mean that they commit to the interpretations of riskless strength of preference.

§3.3.2, p. 18, footnote 3 describes the probability equivalent method to elicit U.

P. 19 (on incompleteness of preference): "It is conceivable—and may even in a way be more realistic—to allow for cases where the individual is neither able to state which of two alternatives he prefers nor that they are equally desirable"

P. 19 footnote 3 announces the Savage (1954) work: "If one objects to the frequency interpretation of probability then the two concepts (probability and preference) can be axiomatized together."

P. 20 footnote 1: "Points on the same indifference curve *must be identified* and" [italics added] This is part of how independence slips in into their analysis implicitly.

Pp. 23-24: they seem to write that their utility differences have no primitive meaning.

PP. 24-25, §3.5.1: utility is treated as an abstract concept, yet to be quantified. P. 29 will make it numerical; see below.

P. 26, §3.6: antisymmetry is assumed on preferences over utility, which is part of how independence slips in into their analysis implicitly.

P. 29 "we feel free to make use of a numerical concept of utility."

P. 32: Here is a text of vNM (already in the 44 version) that captures some of Nash's equilibrium. It still is different because it does not consider individual deviations but, apparently, also joint deviations by subgroups, which makes the concept less interesting, and more like the CORE:

"Second, and this is even more fundamental, the rules of rational behavior must provide definitely for the possibility of irrational conduct on the part of others. In other words: Imagine that we have discovered a set of rules for all participants to be termed as "optimal" or "rational" each of which is indeed optimal provided that the other participants conform. Then the question remains as to what will happen if some of the participants do not conform. If that should turn out to be advantageous for them and, quite particularly, disadvantageous to the conformists then the above "solution" would seem very questionable. We are in no position to give a positive discussion of these things as yet but we want to make it clear that under such conditions the "solution," or at least its motivation, must be considered as imperfect and incomplete. In whatever way we formulate the guiding principles and the objective justification of "rational behavior," provisos will have to be made for every possible conduct of "the others." Only in this way can a satisfactory and exhaustive theory be developed. But if the superiority of "rational behavior" over any other kind is to be established, then its description must include rules of conduct for all conceivable situations including those where “the others” behaved irrationally, in the sense of the standards which the theory will set for them. [underlining added].”

P. 66-84: description of decision trees

game theory can/cannot be viewed as decision under uncertainty: P. 99 seems to write: “from the point of view of player I who chooses a variable … the other variable can certainly not be considered as a chance event. The other variable … is dependent upon the will of the other player, which must be regarded in the same light of “rationality” as his own.”

P. 604 writes: “We have ... assumed that it [utility] is numerical ... but also that it is substitutable and unrestrictedly transferable between the various players.”

P. 617, §A.1.2: We do not axiomatize the relation =, but interpret it as *true identity*. [italics from original] This is part of how independence slips in into their analysis implicitly.

independence/sure-thing principle due to mutually exclusive events: P. 628, Remark A3.2 mutual exclusiveness of events to avoid complementarity is emphasized (see also p. 18). They write: “A.3.2. The first one [remark] deals with the relationship between our procedure and the concept of complementarity. Simply additive formulae, like (3:1:b) [$V(\alpha u + (1-\alpha)v) = \alpha V(u) + (1-\alpha)U(v)$], would seem to indicate that we are assuming absence of any form of complementarity between the things the utilities of which we are combining. It is important to realize, that we are doing this solely in a situation where there can indeed be no complementarity. As pointed out in the first part of 3.3.2, our u, v are the utilities not of definite—and possibly coexisiting—goods or services, but of imagined events. The u,v of (3:1:b) in particular refer to alternatively conceived events u,v, of which only one can and will become real. I.e. (3:1:b) deals with either having u (with the probability α) or v (with the remaining probability $1 - \alpha$)—but since the two are in no case conceived as taking place together, they can never complement each other in the ordinary sense.”

P. 631 (**risky utility u = strength of preference v**): “The reader will also note that we are talkinhg of entities like “the excess of v over u” or … merely to facilitate the verbal discussion—they are not part of our rigorous, axiomatic system.

P. 632 “how one should treat situations that involve probabilities, which are inevitably associated with expected utility.” Suggests a bit, just a bit, that they take EU for risk as normative.

biseparable utility: for their EU

Moscati (2019) writes that the EU axiomatization was done on 14 April 1942, and that Morgenstern noted in his diary: “Today at Johnny’s: axiomatization of

measurable utility . . . . It developed slowly, more and more quickly, and at the end, after two hours (!) it was nearly completely finished.” %}

{% Call attention to the flat maxima phenomenon, that near the optimum in a decision task deviations do not cost much. %}
von Winterfeldt, Detlof & Ward Edwards (1982) "Costs and Payoffs in Perceptual Research," *Psychological Bulletin* 91, 609–622.

{% The text is often verbose and not much structured, and not very formal/accurate. It is often not clear if a model is static or dynamic. The nice and special thing of this book is the many practical asides based on experiences of primarily von Winterfeldt. To get a sense of decision analysis in practice, this book is very good. To get a sense of concepts and models, less so.

P. xiii 3rd para: The authors do not seem to understand reference dependence. Maybe they automatically take outcomes as changes w.r.t. the reference point, in which case to get total wealth one has to add this "outcome" to the reference point of course. But then the dependence is very particular and not general, and their opening sentence distinguishing from total wealth is not right. Best I can think of is that they are confused. The elaborated discussion on pp. 373 ff. does not help, although bounded rationality plays some role.

Pp. 3-4: DUU as if the universal model of all life.

simple decision analysis cases using EU: pp. 8-15: Nice practical example of decision making. Ch. 12 (p. 448 ff.) gives 11 applications of decision analysis, not very simple. §3.6 (p. 86 ff.) has an example on a law suite.

utility elicitation

Ch. 2 is on structuring in general, with Ch. 3 focusing on decision trees.

Second sentence of §2.1: in the experience of most decision analysts, structuring problems and identifying options and objectives are the most difficult parts of most problems.

Ch. 4 is on measurement of uncertainty.

Ch. 5: Bayesian statistics.

P. 65/66: that money is a complex outcome.

P. 82: **value of information**

P. 112: **probability elicitation**; UAI p. 122, calibration (see Yates)

questionnaire versus choice utility: p. 216 ff.

P. 133 (in context of probability measurement): use interaction with client and exploit inconsistencies.

P. 144 is on the likelihood principle, on which Edwards has written more.

Ch. 6 is on general inference when not statistical and, as the authors say, is "frustrating" (p. 163) with little of general conclusions. They draw upon work in the legal literature, using scenarios.

Ch. 7: value and utility measurement. Pp. 312-313 give a useful summary of doing MAUT with recommendations such as having no more than 10 attributes per level. P. 313 point 6 discusses how to handle and benefit from inconsistencies.

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): §7.1, p. 215:

"The conclusion of our four assertions is that for theoretical, psychological, and practical reasons the distinctions between utility and value are spurious."

Pp. 222/223: suggests use of psychophysical scales in utility assessment

P. 236: "However, in general three carefully assessed points of the value function should provide sufficient information to smooth a value curve."

P. 238 (in context of direct rating): "Different techniques almost inevitably produce different responses. Rather than finding such differences distressing, we consider them useful for gaining insights into the nature of the value scale and the reasons for technique, stimulus, and response mode effects. Such discrepancies should be carefully examined and resolved through direct interrogation of the respondent or decision maker."

P. 254: "If a natural scale exists, three or five points between the corner points are usually sufficient for smoothing a utility function."

Ch. 8 MAUT.

P. 256/257: "We speculate that formally justified **utility elicitation** methods deviate at least as much from one another as the utility methods do from the value scaling methods."

P. 267 uses the term dual standard sequence for the MAUT version of the standard sequences that Wakker & Deneffe (1996) use in their **tradeoff method**.

P. 296 illustrates method for eliciting standard sequences, à la tradeoff method of Wakker & Deneffe (1996) for MAUT

Ch. 9 does theory on utility measurement.

Ch. 10: biases.

conservation of influence: p. 545 refers to Piaget's work on conservation laws of quantity, length, number, and so on, how it is recognized by children at certain ages.

Use the, nice, term "joint independence" for separability.

Ch. 11, on sensitivity analysis: Glenn Harrison (2007, personal communication) pointed out to me that they (§11.4 and 11.5) preceded his influential 1989-paper on the flat optimal payoff problem.

Ch. 12 many applications.

Ch. 13 cognitive illusions.
Ch. 14 history. %}

Vovk, Vladimir G. (1993) "A Logic of Probability, with Application to the Foundations of Statistics" with discussion, *Journal of the Royal Statistical Society* B 55, 317–351.

{% This paper analyzes e-values and helps much to popularize the concept in statistics, as does related work by Peter Grünwald. The concept had appeared before in works by Vovk. An e-value E is defined as a function defined on a statistic, so a transform thereof, that is nonnegative and under every parameter in H_0 has expected value ≤ 1. The idea is that the bigger E is, the stronger it is evidence against H_0. We have $P(E \geq 1/\alpha) \leq \alpha$ for every $0 \leq \alpha \leq 1$, i.e. $P(1/E \leq \alpha) \leq \alpha$. This way, rejecting H_0 if $E \geq 1/\alpha$ has significance probability $\leq \alpha$. But it is, of course, conservative. For simple H_0 and H_1, the liklihood ratio = Bayes factor is an e-value. For every simple H_0 and -value there exists a single H_1 such that the e-value is a likelihood rato, and in this existence sense every e-value then is a likelihood ratioo. A betting interpretation: a bet of E−1 has negative expected value under each parameter in H_0. A big pro of e-values is that they avoid the stopping rule paradox. One can decide to sample more or not depending on the observations made, and develop compounded e-values that remain e-values. But then, little wonder given their conservatism. For believers in the likelihood principle like me, Bayes factors usually are not e-values, and the ignoring of H_1 in the definition of e-values is not encouraging either.

This paper analyzes mathematical properties of e-values and p-values. It considers in particular combining several, as can be relevant for multiple hypothesis testing. %}

{% Models of total absence of information, with acts specified only by set of consequences, à la Barberà, Bossert, Pattanaik, Jaffray. Seems to show experimentally that the models depending only on min and max of set of consequence does not work well, and average utility model works better. %}

Vrijdags, Armélie (2013) "Min- and Max-Induced Rankings: An Experimental Study," *Theory and Decision 64/65*, 76–86.

{% Models of total absence of information, with acts specified only by set of consequences, à la Barberà, Bossert, Pattanaik, Jaffray. Tests average utility model. Finds that averaging axiom (A and B disjoint then $A \cup B$ is between them in preference, which, identifying sets with uniform lotteries, amounts to betweenness) is violated and that a considerable minority of subjects rather prefer what the authors call diversification, but what can also be taken as subjects considering sums rather than averages of utility. The paper also tests restricted independence (adding a disjoint set does not affect preference if the original sets have the same number of elements), but only comonotonic versions of it, and finds violations.

The paper then proposes a variation of RDU where for each n an n-dimensional weight vector is assigned. These weights can but need not be derived from an RDU functional (contrary to what is suggested on p. 83 2nd and 3rd para; there Yager's model in fact is a special case of RDU that does not comprise the nonRDU versions of the authors' model with linear utility). It is RDU if and only if, taking n-sets as uniform lotteries, stochastic dominance holds, as can be seen. It implies also that the first m elements of an n-tuple have the same weight as the first 2m elements from a 2n tuple. The dominance condition that the authors characterize in Proposition 1 is weaker than this stochastic dominance. %}

{% **foundations of statistics**: Criticize a Bem (2011) paper in the same journal that claimed evidence for psi (that people can predict the future a little bit) and that gave statistically significant evidence. This paper criticizes the Bem paper, using Bayesian views (I sympathize with the latter):

Problem 1: Bem did exploratory (data mining; getting hypothesis from data and then testing using that same data), and not confirmatory (specifying statistical test before getting data).

Problem 2: it has the problem of all classical statistics, of dealing with probabilities over data given hypothesis, whereas one wants that reversed. The authors consider Bayesian updating with some extremely small prior probabilities for psi, in which case the posterior remains small. (**updating: discussing conditional probability and/or updating**)

Problem 3: P-values overstate for big samples. They put forward the Bayesian argument that one better consider Bayes factors, and I could not agree more. But difficult question for Bayesian factors is which H_1 to take. The authors take one called default that I do not understand (they cite papers I do not know) in which case the data more support H_0 (no psi) than H_1 (a specific degtee of psi, or a more subtle variation of this H_1). It is the known phenomenon of statistical significance but not economic significance (or a variation of this phenomenon for noneconomists).

Then the authors argue for more rigid statistics in psychology that more often should be confirmatory. In the last para the authors write that Bem played by the implicit rules of statistics in psychology and that they, therefore, aim to criticize those implicit tules rather than Bem.

The paper is too strict in imposing requirements on the Bem study that virtually no psychology study can satisfy. Note here that psychology, unlike medicine for instance, by nature is mostly exploratory.

It may be refreshing that authors are more explicit in criticizing others than is common in our overly diplomatic and nonexplicit field, but this paper goes too far. Many sentences add nothing to the content but only aim to ridiculize Bem, contrary to what the last para of the paper writes. Probably because many traditional researchers will like hostility towards psi anyhow, the authors could get away with it. Examples: P. 427 1st column 1st para ("anecdotal," also kown as "worth no more than a bare mention") P. 428 2nd column end of 1st para "a psychic's night out at the casino," p. 429 1st column 1st para ("infinite wealth"). %}

{% **Dutch book**.
The last para of this paper is as follows:
This paper is based on the observation that the same mathematical structure is underlying many problems in decision making under uncertainty and in game theory. By simple translations, mainly by interchanging "state of nature" and "player," many results derived for decision making under uncertainty and game theory can be interchanged. This paper gave some examples. Admittedly, sometimes, such as in Definition 3.3, a minimal amount of creativity was needed. Still, an author in lack of inspiration, but in need of publications, may succeed with the following algorithm:
Take any theorems from a journal dealing with the topic of game theory, or probability theory/decision making under uncertainty.
Carry out the translations as described in this paper.

Send the resulting theorems to a journal dealing with the other topic than the original journal.

Do not refer to the original journal.

Do not refer to this paper. %}

{% **dynamic consistency**; **information aversion**

P. 173 first objection in §4, puts forward that forgone-event independence (often called consequentialism nowadays, i.e., after 1990) is assumed. It is part of the ceteris paribus condition there. I admit that my text is not easy to interpret. That this text entails forgone-event independence appears from the requirement that information should be free of charge. If information were to cost money then dynamic consistency would not be affected because the costs would be foreseen, but forgone-event independence would be violated because the ex post situation would differ from the de novo situation by subtraction of the cost of information. As an excuse for my vague text, there was no clear terminology yet in those days and it is hard to formulate forgone-event independence without formal terminology. Other verbal discussions of these principles in the literature are also hard to interpret. %}

cancellation axioms: Pp. 33-34 gives necessary and sufficient conditions for additive representation of a weak order on a finite product set. The result can be extended to any finite set of (incomplete) preferences on any (subset of) a product set, as shown by Fishburn (1970 Theorem 4.1B), Scott (1964), and other places indicated by the keyword cancellation axioms in this bibliography.

completeness criticisms: §III.1, p. 42.

revealed preference; **standard-sequence invariance**; **strength-of-preference representation**; **tradeoff method**; **Dutch book**: Theorem A2.1.

That for most preference conditions, versions with indifferences suffice, can be derived from Theorem III.6.6 (p. 70), Statement (ii), together with Remark III.7.3. The only nonindifference condition needed is weak separability, which for monetary outcomes is implied by monotonicity. Other than that, for two nonnull coordinates one needs the hexagon condition which only involves indifferences. For more than two nonnull coordinates Statement (ii) puts up CI (coordinate independence, which is sure-thing principle, or preference separability), a condition that involves more than indifference. Remark III.7.3 however shows that, given weak sparability, only the version of that condition with indifferences is used. This way conditions with only indifferences give additive representability. Usually, whatever more is needed is not very dififcult to do. %}

paperback: ISBN-13:9780521748681; hardcover ISBN-13:9780521765015
P. 2, penultimate para: "At this moment of writing, 30 years after its invention, prospect theory is still the only theory that can deliver the full spectrum of what is required for decision under uncertainty, with a natural integration of risk and ambiguity."
Assumption 2.1.2: decision under risk assumption.
substitution-derivation of EU: Appendix 2.9.
source-dependent utility is criticized on p. 337 4th para.
questionnaire for measuring risk aversion; Exercise 3.6.3: Use choices between some lottery pairs with a big variation in outcomes and probabilities.

Then count the number of times the more risky lottery is chosen. Can relate to the well-known CRRA index by taking the index that would generate the same number of risky choices. This is better way to measure risk aversion index than the usual choice lists, which intensively and inefficiently probe in a small part of the domain. It was used by Wakker, Timmermans, & Machielse (2007).

inverse S: §7.1, p. 204, reviews empirical evidence for risk.

P. 208: for probability weighting for gains, the parameters $\gamma^+ = 0.69$ and $\delta^+ = 0.77$ best fit the current empirical findings.

P. 236: **linear utility for small stakes**: claims it normatively, with only two references and no extensive review.

§8.8 Problem 2 (p. 247) discusses the modeling of loss aversion through piece-wise linear utility with a kink at 0.

Somewhat hidden away, p. 272 Eqs. 9.7.1 - 9.7.3, are the general integral formulas for PT for risk.

criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity: §10.7.3, pp. 301-304.

uncertainty amplifies risk: §10.4, p. 292, reviews empirical evidence, but only for insensitivity

ambiguity seeking for unlikely: Section 10.4.2 cites evidence on insensitivity, which comprises ambiguity seeking for unlikely.

biseparable utility for uncertainty: §10.6, pp. 298-299, presents it

criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity: §10.7, p. 302, Figure 10.7.1.

nonadditive measures are too general:Section 11.2

Example 11.2.2 (p. 321) illustrates how matching probabilities easily capture ambiguity.

Pp. 338-342, §9.6, shows that power (CRRA) utility gives analytical problems when defining loss aversion.

P. 298, §10.6, Exercise 10.6.1: RDU for two outcome-prospects is identical to: $\gamma_E\beta \mapsto pU(\gamma) + (1-p)U(\beta) - \mu|U(\gamma)-U(\beta)|$ with $|\mu| < \min\{p,1-p\}$ an index of pessimism, $\mu < 0$ giving optimism.

P. 231, Observation 7.11.1 shows that many risk theories are special cases of binary RDU, as pointed out by Miyamoto (1988). §10.6 will extend this point to uncertainty, where the model is often called biseparable utility.

P. 354, §12.7, reviews the literature finding **ambiguity seeking for losses,** confirming reflection. %}

{% On **Prospect theory not cited**: Pp. 195-196 properly criticize the way experimental economists cite Holt & Laury (2002):

"As an historical and socio-academic digression, the authors follow the common convention in experimental economics of crediting authors recognized as experimental economists, Holt and Laury (2002), rather than "outsiders," for using choice lists, assuming expected utility, and then fitting parametrically (assuming, e.g., a Constant Relative Risk Aversion utility function) to measure risk aversion. Yet, this has been a common procedure for many decades, and drawbacks have also been known for many decades. The procedure was used for instance in the more comprehensive Cohen, Jaffray, and Said (1987). These authors, like Holt and Laury, used real incentives, but, unlike Holt and Laury, expressed awareness of the deficiencies of expected utility, writing:

"The reason why subjects' risk attitudes are not correctly conveyed by the conventional definitions may simply be that these definitions, despite their intrinsic character, take their origins in the EU [expected utility] model, and therefore share in its deficiencies." (Cohen, Jaffray, and Said, 10-11)

The survey by Farquhar (1984) gives further references. That socio-academic conventions of this kind occur in every field and every generation again can be inferred from Carver (1918) who, over a century ago, concluded his paper writing:

"But if they think that they have built up a complete system and can dispense with all that has gone before, they must be placed in the class with men in other fields, such as chemistry, physics, medicine, or zoölogy, who, because of some new observations, hasten to announce that all previous work is of no account." (Carver, 1918, 200)

Indeed, if ignoring previous work can be legitimized in any manner, then this saves much reading time and facilitates priority claims, providing irresistible benefits. The authors do cite Cohen et al. and Farquhar, but, understandably, do not enter the debate on priority as done in this digression."

{% The authors that often choices involve incommensurable goods and then we should not try to commensure them. They write on p. 3012: "We also discuss what types of decision model could accommodate the lack of common currency of value. Such models include lexicographic (noncompensatory) heuristics, which do not require decision-makers to trade off attribute values to make a choice. Our conclusion is that although some heuristics may help decision-makers to choose, value incommensurability necessitates the use of rank-based processes for decision-making. Finally, we note that reliance on rank-based strategies leads

inevitably (by Arrow's impossibility theorem) to inconsistences in decisionmaking, such as preference reversals, of the type that are typically observed in experimental studies of choice."

Many psychologists may like the anarchistic nature of these ideas, and just accept preference reversals in what they still qualify as rational choice, as do these authors, but I couldn't be farther from it. When the first author presented this work online on 24 Oct. 2024 in the 3rd SJDM and EADM joint virtual symposium, I asked him the following question, which I qualified as critical: "I can't think of values more incommensurable than human lives versus money. I worked eight years in a hospital and there they are treated as commensurable on a daily basis. My first question to you is: "Do you agree that nothing is more incommensurable than money versus human lives, and, if so, do you think that my hospital and I have been doing bad things?" %}

Walasek, Lukasz & Gordon D. A. Brown (2024) "Incomparability and Incommensurability in Choice: No Common Currency of Value?" *Perspectives on Psychological Science* 19, 1011–1030. https://doi.org/10.1177/17456916231192828

{% Write that only few papers have useful data on it. Use 19 data sets from 17 papers. Find $\lambda = 1.31$, with a 95% confidence interval of 1.10, 1.53]. They assume logpower (CRRA) utility with same power for gains and losses, and also the same probability weighting for gains and losses.

Prospect theory/Rank-Dependent Utility most popular for risk: "prospect theory and, later, cumulative prospect theory (PT and CPT, Kahneman & Tversky, 1979; Tversky & Kahneman, 1992), the most influential descriptive model of choice under risk and uncertainty." (p. 1) %}

Walasek, Lukasz, Tim L Mullett, & Neil Stewart (2024) "A Meta-Analysis of Loss Aversion in Risky Contexts," *Journal of Economic Psychology* 103, 102740. https://doi.org/10.1016/j.joep.2024.102740

{% Subjects in hypothetical choice on internet should say for each of a set of lotteries whether they are acceptable or not. If gains range from 0 to 40, and losses from 0 to −20, then we find the usual loss aversion. If, however, gains range from 0 to 20, and losses from 0 to −40, then we find the opposite, gain seeking. These findings are in agreement with decision by sampling. My main problem is that, especially in view of the hypothetical nature of the experiment, it is not clear to

subjects what "accept" means. They are meant to take it as "preferring to a sure 0." But they may take it as "better than average among the lotteries presented to me." So, the decision situation is not made sufficiently clear. %}

Walasek, Lukasz & Neil Stewart (2015) "How to Make Loss Aversion Disappear and Reverse: Tests of the Decision by Sampling Origin of Loss Aversion," *Journal of Experimental Psychology: General* 144, 7–11.

{% P. 302 seems to have written, on loss function having to be determined by extraneous nonstatistical factors and using term weight for loss: "The question as to how the form of the weight function W(θ,ω) should be determined is not a mathematical or statistical one. The statistician who wants to test certain hypotheses must first determine the relative importance of all possible errors, which will entirely depend on the special purposes of his investigation." (**foundations of statistics**)

Seems to have proposed maxmin (minmax in terms of loss function). %}

Wald, Abraham (1939) "Contributions to the Theory of Statistical Estimation and Testing Hypotheses," *Annals of Mathematical Statistics* 10, 299–326. https://www.jstor.org/stable/2235609

{% It seems that here he proved his famous result, his "complete class theorem," that each undominated choice in decision under uncertainty can be taken as maximizing Bayesian subjective expected utility and even subjective expected value. %}

{% %}

Wald, Abraham (1949) "Statistical Decision Functions," *Annals of Mathematical Statistics* 20, 165–205.

{% **event/outcome driven ambiguity model: event driven**: Proposed maxmin EU (minmax in terms of loss function) on pp. 18, 26-27. On p. 27, F denotes the prior, and Ω the set of priors. P. 1 explained that Ω need not be the set of all possible priors, but can be a subset of it.

Dutch book (end of Ch. II)

Seems to have shown that for finite state spaces, for a risk set that is bounded and closed from below, the set of Bayesian decision rules is complete. The idea is that we choose a Pareto-optimal option, take the tangential hyperplane (in view of the possibility to take mixes of options, the set is convex), then take the orthogonal probability vector, and then take the option chosen as minimizer of expected loss w.r.t. the probabilities generated. Mathematical generalizations are given. This result has often been used to justify the Bayesian use of subjective probabilities.

Seems to take as decision under uncertainty model a more general setup than Savage (1954): There is a state space S and an action space A. The "preconsequence space" (my term) is the product set A x S. Then there is a function f mapping A x S to a consequence space C. Savage's 1954 model can be considered to be the special case where acts with same consequences for each s are identified and, next, all maps from S to C are available. Conversely, one can interpret the Wald action space as a subset of the Savage act space. Oh well.

{% Considers between-agent comparisons of ambiguity attitudes in the Anscombe-Aumann framework. Assumes EU maximization for risk. Then uses probability equivalents (matching probabilities) to compare ambiguity attitudes. The utility functions of the agents need not be the same here. %}

Wang, Fan (2019) "Comparative Ambiguity Attitudes," working paper.

{% **Prospect theory/Rank-Dependent Utility most popular for risk**: p. 8166 writes: "Tversky and Kahneman (1992) formulated cumulative prospect theory, which is nowadays the most widely accepted descriptive theory for decision making under risk." Note that T&K92 also handle ambiguity.

This paper considers an Anscombe-Aumann two-stage framework. It introduces the R-maxmin model, generalizing maxmin EU into maxmin RDU, giving the functional

$\min_{P \in \mathcal{P}} \int RDU(f(s))dP$

where $\mathcal{P}$ is a set of priors and only one RDU model, i.e., only one utility function U and one probability weighting function w are involved. Drawbacks are that the model is very general and has the problematic backward induction of the Anscombe-Aumann framework. Further, it treats ambiguity (through maxmin) differently than risk (rank-dependence), where I prefer the same, say rank-dependent, treatment of both.

Dean & Ortoleva (2017) also considered maxmin RDU but used a set of probability measures and a SET OF probability weighting functions. Further, D&O entirely focused on risk aversion, pessimism, and ambiguity aversion, which is too narrow empirically, and this paper to the contrary allows for the desirable insensitivity.

The paper uses the likelihood method, i.e., it uses the richness of probabilities, without needing richness of outcomes. This is desirable because the richness of probabilities is available anyhow. Abellaoui & Wakker (2005) pleaded for this approach. The author, therefore, does need continuous probability weighting. He, thus, applies the **tradeoff method** to probabilities. Section 2.6 shows how these techniques can be used to handle variational and multiplier preferences. Section 3 shows that we can now compare ambiguity attitudes without needing to assume the same risk attitudes, which is a highly desirable move. Section 4 accommodates Machina's counterexamples to rank dependence under ambiguity. %}

{% Analyze the famous RAND ("US") data set on heath insurance, and a similarly nice data set on health insurance from China.

real incentives/hypothetical choice: hypothetical choice

error theory for risky choice: The novelty of this study is what they call the "mixture model approach." That is, they do not assume a universal framing as gains or losses etc., but take as an extra parameter in their study whether the subjects perceive the outcomes as gains or losses, and in that manner derive from data who have a gains- and who a loss frame.

They estimate costs-probability distributions. For RAND data, their observable is preferred insurance by subjects, for Chinese data set it is WTP.

risk averse for gains, risk seeking for losses: US respondents: Risk averse for gains, and risk neutral or maybe some risk averse for losses. Chinese seemed to be risk neutral for gains and risk seeking for losses. This can be reconciled with the fourfold pattern if we assume that the framing in the context of insurance makes people more risk averse, which is well known (see keyword **insurance frame increases risk aversion**), and that in the Chinese group, who had to do WTP and not choice, WTP had the known biases downward. The authors instead resort to cultural differences. %}

Wang, Mei & Paul S. Fischbeck (2004) "Incorporating Framing into Prospect Theory Modeling: A Mixture-Model Approach," *Journal of Risk and Uncertainty* 29, 181–197.

{% Measure loss aversion in 53 countries around the world, using the data set also used by Rieger, Wang, & Hens (2015), and using Hofstede's indexes. They, properly, control for other components in loss aversion. They used hypothetical choice. I agree that for losses hypothetical is better than the common prior-endowment-and-then-paying-back procedure. Also, a study at this scale is hard to organize anyhow. Individualism, power distance, and masculinity increase loss aversion. Uncertainty avoidance and macroeconomic variables do not have effect.

Footnote 6 thanks anonymous referees for the addition of a comment, and, as usual, one can feel that it is a silly remark that was imposed on the authors because referees have too much power on writing subjective opinions today. %}

{% This paper analyzes the convex level sets (CxLS) property of risk functionals, which is necessary for elicitability, identifiability, and testability. The property is the analog of betweenness in decision theory: if F and G have the same functional value, then so does every convex combination of them.
Signed Choquet integrals play a special role. Identifiability means that a scoring rule can be devised such that the functional value of each distribution can be elicited in what economists call an incentive compatible manner. Identifiability means that a perfect accuracy score can be devised. %}
Wang, Ruodu & Yunran Wei (2020) "Risk Functionals with Convex Level Sets," *Mathematical Finance* 30, 1337–1367. https://doi.org/10.1111/mafi.12270

{% This paper is on nonmonotonic, signed, law-invariant Choquet integrals, denoted Ih, where h denotes a probability transformation function (I usually write w). Law-invariance means probabilistic sophistication. Here probabilities are assumed available, so that it is a Yaari (1987) type functional, generalized to be signed and nonmonotonic (so h need not be monotonic). The paper shows that many results assuming monotonicity go through unaltered if monotonicity is dropped, such as on convexity and on axiomatization through comonotonic additivity. Regarding monotonicity, this can often be gotten back by adding a strongly increasing linear functional, which does not affect many properties but brings back monotonicity. For instance, with λ the right derivative of h at q for q

≤ 1, we can add λp to h and have monotonicity on [0,q].

The paper cites much literature. It characterizes the functionals mainly by comonotonic additivity. Bounded variation, continuity, and convexity are studied.

Theorem 3 gives many properties that are equivalent to convexity of the probability transformation function h. Those are; (ii) convex order consistency (this is a version of aversion to mean-preserving spreads, or 2nd stochastic dominance), (iii) subadditivity, (iv) convexity of the functional w.r.t. outcome mixing, (v) quasi-convexity of the functional w.r.t. outcome mixing; (vi) concavity w.r.t. probabilistic mixtures. Wakker & Yang (2021) have related results but one difference concerns Statement (vi), where they have quasi-concavity rather than concavity w.r.t. probabilistic mixtures. This can be because W&Y only consider *strictly* increasing h. For nondecreasing h, W&Y's result would not hold (with quantile functions as counterexample, as pointed out by Wang 2021 personal communication), and this paper considers even more general h.

The paper also considers aggregations of risks where some marginal distributions are known but their joint distribution is unknown. %}

Wang, Ruodu, Yunran Wei, & Gordon E. Willmot (2020) "Characterization, Robustness, and Aggregation of Signed Choquet Integrals, *Mathematics of Operations Research* 45, 993–1015. https://doi.org/10.1287/moor.2019.1020

{% $(\Omega,\mathcal{F},P)$ is a probability space with P the "true" but maybe unknown probability measure. There is a set K of what are called scenarios. It is a partition of Ω. For $\theta \in K$, Q_θ denotes the conditional probability P conditioned on θ. If a functional ρ on the random variables on Ω assigns the same value to two random variables whenever those two have the same Q_θ distributions for all θ in a set $\mathcal{Q}$ of probability distributions over Ω, then ρ is called $\mathcal{Q}$-based. It is then like a multiple priors model with $\mathcal{Q}$ the set of priors. Thus, the paper provides a kind of general framework capturing multiple priors approaches. It then provides theorems characterizing ρ being a Choquet integral, convex, and other properties. %}

{% **SPT instead of OPT**: Eq. (5) in this paper.

P. 7 explains why 1979 prospect theory does not work: "A straightforward idea to solve the above problem is to discretize the continuous distribution into multiple outcomes and calculate the probability of each outcome, but this idea cannot work well because the discretized probabilities are usually very low, e.g., 0.001. In the classical PT method, these low probabilities will be transformed into subjective probabilities by the weighting function. Because the classical PT tends to overestimate the likelihood of small probability conditions, all these probabilities will likely be overestimated, and thus a distortion effect will be mistakenly imposed." They then propose a fractional modification, which involves separating a prospect into a deterministic and uncertain part. Is reminiscent of 1979 prospect theory for prospects with only positive or only negative outcomes, where also the sure (closest to 0) gain or loss is separated, but I did not check out carefully. %}

{% Criticizes Rabin & Thaler (2001) "Anomalies: Risk Aversion," *Journal of Economic Perspectives*. Argues that reasonable persons *should* not exhibit the risk aversion assumed by Rabin & Thaler. Rabin & Thaler, in their reply, correctly point out that this is irrelevant because their analysis is descriptive and not normative. Next the author argues that the phenomena assumed by Rabin & Thaler would require extremely high indexes of RRA (also argued by Palacios-Huerta & Serrano 2006) for some gambles and that this is not realistic. Rabin & Thaler, in their reply, correctly point out that they know this, agree with it, and always have done so, and that it is part of their reasoning (see, for example, Rabin (2000, Econometrica), p. 1287 2nd paragraph). The point is that this shows that the relative index of risk aversion is not suited for comparing small-stake gambles to high-stake gambles, or choices at different levels of wealth, the index being so very sensitive to where the origin of the scale is located. I expect that the latter deficiency of constant RRA has been known to many people in the present and past.

This paper is typical of many economists' thinking. Rabin & Thaler show that, for a plausible assumption denoted PA here ($11_{0.5}{-}10 \prec 0$ at various wealth levels), [EU & PA] $\Rightarrow$ implausible implications. They, correctly, conclude that EU is implausible. But many economists are just not able to make this step; they are not able to abandon EU. Instead, they enter their common way of thinking and come out with the conclusion that PA must be implausible. %}

{% This paper considers timed outcomes (α,t), and then probability distributions over those, $(p_1:(\alpha_1,t_1),\ldots, p_n:(\alpha_n,t_n))$. It gives characterizations of expected exponentially discounted utility, through dynamically interpretable conditions. It would be interesting to apply theorems of Keeney & Raiffa (1976) (not cited), on expected utility for multiattribute objects, two-attribute in this case. For instance, invariance under same delay is like constant absolute risk aversion. Theorem 1 on pp. 932-933 summarizes the five axiomatizations. %}

Webb, Craig S. (2024) "Dynamic Preference Foundations of Expected Exponentially-Discounted Utility," *Economic Theory* 77, 921–940. https://doi.org/10.1007/s00199-023-01523-y

{% **EU+a*sup+b*inf**: Novelty is that they do it using richness of probabilities and not of outcomes. Nice way to easily measure the jumps at 0 and 1. Propose to take these jumps, divided by 1 minus the jumps, as indexes of optimism and pessimism. That is, in the above a-b notation, a/(1–a–b) and b/(1–a–b). Thus, if a and b tend to 0.5, both optimism and pessimism tend to ∞, and optimism is for instance, for constant a, an increasing function of b and pessimism. They assume a finite outcome set and, hence, problems about null sets in the Chateauneuf, Eichberger, & Grant (2007) paper do not arise here.

They essentially impose vNM independence (≈ independence of common probability shifts, which in fact is the sure-thing principle for risk), and consistent optimism- and pessimism attitudes, which can be measured from limiting probability-shift properties and then be required to be consistent. %}

{% Consider the interaction of risk and time, in particular regarding the topic mentioned in the title. In direct binary choices, where subjects can by heuristic delete common components, they do not find reductions of the certainty effect if delay is added, or of the immediacy effect if risk is added. Here they do not replicate Keren & Roelofsma (1995). In CE or present value evaluation, they still find no reduction of the certainty effect if adding delay when the certainty effect concerns the common consequence version of the Allais paradox (the authors use the term Allais paradox only for the common consequence version). They do find it for the common ratio version of the Allais paradox. They also find reduction of the immediacy effect if adding risk. Hence, the effects are found a bit but not very clearly. %}

Weber, Bethany J. & Gretchen B. Chapman (2005) "The Combined Effects of Risk and Time on Choice: Does Uncertainty Eliminate the Immediacy Effect? Does Delay Eliminate the Certainty Effect?," *Organizational Behavior and Human Decision Processes* 96, 104–118.

{% Do 3-color Ellsberg paradox for monetary outcomes and for waiting time (for delivery of a good). Choices are hypothetical. In the waiting time setup subjects seem to choose between sure waiting times and ambiguous waiting times (only specified up to an interval), without very clear rationality/ambiguity-neutrality point, and the results are not easily comparable. %}

{% The main point of this paper, stated immediately in the intro, is that an asymmetric loss function, also studied by Birnbaum, can give a motivational (deliberate, not due to misperceptions/biases) justification for nonlinear decision weights. The idea is that for some internal or external reason a person dislikes more underestimating some probability than overestimating it. It is analogous to statistical estimation theory where not the outcome of the gamble but the error of your estimation (whether too high or too low) matters for you. This internal/external reason may be psychologically plausible but it is not part of the decision model and its outcomes. It is something like "your colleague might blame you or you might feel silly the morning after you received the outcome of the gamble if it was way more than you estimated," and this approach is not decision-theoretic. Therefore, while psychologically plausible, this main point is not of direct interest to me. This notwithstanding, there are many comments and discussions about decision theory that are subtle and valuable, and the paper is very well written. I therefore read it several times and often cite it.

SPT instead of OPT: p. 231 last para

uncertainty amplifies risk: p. 237/238 suggests more deviation (**inverse S**) from EU under uncertainty than under risk.

P. 237 next-to-last paragraph, on pessimism, cites evidence from “impression formation” where cues receive more attention as they are ranked lower between the other cues.

P. 238 last paragraph expresses preference for decision weights depending on outcomes over utilities depending on probabilities/events and, thus, for rank-dependent utility over lottery-dependent utility of Becker & Sarin. Footnote 9 gives several refs on utility depending on probability.

P. 239 1st column: two-stage model of, first, estimation of probability and, second, configural weighting.

questionnaire versus choice utility: p. 239 2nd column end of first para: “Thus, decision analysts’ dogmatic refusal to consider introspective judgements of perceived probability as valid evidence may one day seem as unnecessary in its self-imposed limitations as a behaviorist approach to, say, language acquisition.”

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): Many suggestions on p. 239/240, in particular p. 239 2nd column middle of page. Nice is p. 239 2nd column ℓ. –10/–3: “By separating the utility of the outcome itself from the weight given to the outcome as a function of its relative rank or the nature of the task …, changes in preference as a function of elicitation method can be attributed to changes in configural weighting, while allowing the utility of the outcome to remain invariant.”: This citation expresses what Birnbaum calls scale convergence and what I argued for in my ’94 Theory and Decision paper and used in Wakker & Deneffe (1996). See also discussion of Weber, Anderson, & Birnbaum some lines above.)

P. 240 discusses, twice, that people may want to change the internal constraints that they are imposing upon themselves, which I interpret as meaning that we shouldn’t take any utility function as normatively acceptable.

paternalism/Humean-view-of-preference: last sentence, on use of configural-weighting models (is approximately the same as rank-dependence): “and finally help to provide more accurate and consistent estimates of subjective probabilities and utilities in situations where all parties agree on the appropriateness of the expected-utility framework as the normative model of choice.” %}

{% Redoes Wakker, Erev & Weber (1994), with several modifications. Shows that, if you deliberately bring in perceptional framing effects by highlighting, boldprinting, larger-font printing, etc. lowest or highest outcomes, then in that manner you can generate rank-dependence. Similarly, if you deliberately bring in motivational effects by letting lotteries be evaluated as buyer or seller etc., then this can also generate rank-dependence effects. This way they can distinguish

perceptual and motivational effects.

They often use an asymmetric loss model, also used by the psychologist Birnbaum. It is psychologically realistic and interesting, but has no clear role in revealed preference and, hence, will be of less interest to economists.

One of the findings of this paper is that the absence of rank dependence in Wakker, Erev, & Weber (1994) (WEW) may be due to the cancellation heuristic. That is, the common outcome was always so clear that subjects canceled it, not because it is their true preference, but only a heuristic to simplify choice. The paper suggests so because in direct choice they quite replicate the absence of rank dependence, but if they do pricing, where cancellation cannot be, then they get rank dependence.

WEW found no differences between four displays. Hence, this paper uses only the graphical display, which seems to be clearest and had the best consistency in WEW. This paper used many fillers to reduce heuristics.

P. 57 top (§5.1): "The current modification of their study was designed to test whether the cancellation of common outcomes in choice pairs may be partially responsible for their null results."

P. 57 (§5.12 1st para), writes a text that can be interpreted as saying that cancellation of common outcomes does not reflect true preference, but is only a heuristic. The last sentence strongly suggsts so, although it does not fully commit to the existence of "true preference": "The reversals between choice-based and price-inferred preference observed in this study were, at least partly, due to the fact that a significant portion of respondents seemed to cancel the COs of the lottery pairs in the choice task but incorporated them into their pricing judgments. If people were EU maximizers, such cancellation could not lead to a reversal in the rank order of preference between the two elicitation modes. When alternatives are evaluated in a rank-dependent fashion, on the other hand, CO cancellation can have this effect."

P. 59, §5.4, nicely discusses normative implications of rank dependence. %}

{% This paper presents a model of inductive observation and updating, with expected value maximization based on subjective probabilities. There are some cases, with total probability assumed less than some α, where the agent does not do Bayesian updating (called a shift or a paradigmatic shift). It is not specified what happens after a shift. It is shown in two propositions that the *normalized* expected losses due to arbitrage (if normalized by dividing by (roughly) the absolute value of the largest outcome involved) then cannot exceed α.

The author relates his α to the significance level α in statistics, proposing his result as a foundation of classical statistics. But there remain differences and the two αs are not the same. In hypothesis testing, alpha is the supremum of probabilities, *conditioned* over parameters in the null, of observations at which the null is rejected. The alpha in the author's model is not close to that.

The author points out that you need not know the whole subjective probability distribution, but only the probability α, to apply his result, and relates this to bounded rationality.

Violation of Bayesian updating is equated with dynamic consistency, implicitly taking the other dynamic conditions required to derive Bayesianism from dynamic consistency as given.

Proposition 4 modifies Proposition 3 by, first, defining as shift-protected bets the bets that have constant payoffs after shifts, so that shifts do not affect their

value. Proposition 14 then adds that for Dutch books we should look at the non-shift-protected (shift-exposed) bets. %}

{% Assume one fixed probability vector ($p_1,\ldots,p_n$), and prospects for those with real-valued outcomes. Assume an additively decomposable representation $V_1(x_1) + \ldots + V_n(x_n)$, so, kind of **state-dependent utility**. If risk aversion (preference of

expected value over prospect) holds on this limited domain, then already state independent EU holds, with respect to the given probabilities. %}

Werner, Jan (2005) "A Simple Axiomatization of Risk-Averse Expected Utility," *Economics Letters* 88, 73–77.

{% Introduces mean-independent risk aversion. ε is *mean-independent risk at* z if conditional expectation of ε given z is 0 (for readers who know the concept of conditioning on a random variable). So, in discrete case, the conditional expectation of ε given each value of z is 0. x *differs from* y by *mean-independent risk* if then x = z+ε and y = z+λε with 0≤λ≤1, where this is transitively extended. This condition is studied in DUU with states of nature with, obviously, probabilities given, but dropping the DUR assumption that only the probability distributions generated over outcomes matter. So, state-dependence could in principle be. Shows that under sure-thing principle (implying state-dependent EU) the condition will imply EU, so, state independence, after all. Under EU, aversion to mean-independent risk is equivalent to risk aversion (i.e., concave U). In general it is implied by Rotschild-Stiglitz aversion to mean-preserving spreads. NonEU, with violation of the sure-thing principle, can also be in this model. This paper denotes the general representing functional by U (I usually denote it by V), which is what I will do here. For every prospect x, the condition is, under differentiability, equivalent to the derivative of U w.r.t. x(s) (s state of nature) being anticomonotonic (the author says negatively comonotonic) with x(s): The worse an outcome is ranked within a prospect, the more impact it has on the preference value. §6 extends to nondifferentiability using superdifferentials.

A restriction of the analysis of this paper is that its playing ground, with probabilities needed to be available but DUR not holding, is not big. %}

Werner, Jan (2009) "Risk and Risk Aversion when States of Nature Matter," *Economic Theory* 41, 231–246.

{% This paper is on decision under risk. Several papers have shown how endogenous utility-midpoint outcomes can be derived for outcomes under EU, RDU, and PT. Then, under continuity of utility, preference foundations can be obtained of the models of interest by imposing consistency on such endogenous midpoints. This

paper uses a duality between outcomes and goodnews probabilities (for losses: badnews probabilities) to obtain an endogenous weighting-function-midpoint probability. It will thus provide a generalization of the appealing derivations of RDU by Nakamura (1995), Abdellaoui (2002), and Abdealloui & Wakker (2005) to PT, providing the most appealing axiomatization of PT presently available.

The paper imposes, first, a common elementary probability shift condition (= sure-thing principle/separability but taken dually, in the probability dimension) to get a general additive rank-dependent representation. Then it adds consistency of endogenous probability midpoints, separately for gains and losses, to axiomatize PT. Remarkable is that no richness of outcomes is used. Only richness in probability is used, which is available anyhow. %}

{% **random incentive system**: discusses that

Oct. 21, 1997: Uses decision cost model, and not nonEU model, to explain deviations from EU, in context of random incentive system. Finds that incentives do not matter much for simple choices but do for complex ones. This result is not surprising, but it is useful to have it demonstrated clearly. I think, actually, that the underlying decision-cost model is not very useful here.

Decision time is taken as index for decision complexity. For low incentives, increased complexity gives less EV maximization (so, less risk seeking I assume); then also more violations of **RCLA.** This shows that incentives do not just reduce noise, but can have systematic effects; a point emphasized much by the author. (**real incentives/hypothetical choice**)

For high incentives, no differences are found.

Pp. 1398-1399 has a good balanced discussion, that the RIS (the author writes RLM) does not really need all of vNM independence, and what is needed may not be violated that much.

P. 1402: Refs that find that EV explains much of decisions. For calculating decision costs, the paper takes EV as the correct model, as first approximation. The discussion on p. 1401-1402 is defensive. True that any other model assumed can be criticized, but so can EV be just as much.

The example on p. 1402 shows that satisfying preference axioms such as independence need not always be better than all else. This can be shown trivially by doing EU minimization (stoch. dom. then needs rediscussion). It is a trivial point rather than a good argument against the pragmatic principle of taking preference-condition optimization as index of goodness of decisions.

Concluding sentence: "The results of this experiment suggest that decision time is a potentially rich explanatory and dependent variable, and so should not be an omitted one." %}

{% **probability elicitation**;

Consider what happens with subjective probabilities when elicited through quadratic scoring rule if utility is nonlinear, but assuming expected utility. As Figure 1 shows, for the convex ("risk-seeking") U(x) = x^2, for subjective p = 0.33 and smaller, it is best to report r = 0.0. Symmetrically, for subjective p = 0.67 and higher, it is optimal to report r = 1. Between p = 0.33 and p = 0.67, the optimal reply is linear, being r = 0.5 at p = 0.5. For the concave ("risk-averse") U(x) = 1 − e^{-x}, the reported optimal probability r is an inverse S-curve of the "true" subjective probability p, illustated in Figure 3 p. 146, that propect-theory advocates will like. {% Cardinal utility is measured by "unit of measurement" method. That is, if x and y are two commodity bundles, then a "unit of measurement," i.e., another commodity bundle u, is chosen, and real numbers s,t, such that su~x, tu~y. Then s/t is a measure for the utility proportion of x and y. Under homotheticity this is independent of the choice of unit of measurement.

First to derive existence of utility function through certainty equivalents in Theorem I, based on a continuity-like axiom V. (Before existence of utility function was simply assumed.)

{% This paper addresses the intriguing question of whether we can have utility over past events (even though we cannot influence them anymore) and, then, how much we discount those. Unfortunately, the model used is out of the blue and not well defined. An interest point is that, although we cannot influence the past, we can still have uncertainty about it. Under nonEU this can probably be used to derive past utility from revealed preference through choices of receiving info about the past or not. Most examples in this paper concern another phenomenon: past events influence current utility instrumentally. But that is a different point. %}

{% **ordering of subsets**: Characterization of qualitative orderings of finite algebras that can be represented by belief functions (complicated proof). Drawback is that the functions are mostly unique only up to an ordinal transformation, given the absence of additivity as probability measures. Roughly, any weak ordering of a finite algebra satisfying monotonicity w.r.t. set inclusion and one more kind of null invariance condition (with >´ denoting strict preference) (A >´ B and A∩C = ∅ then A∪C >´ B∪C) seems to be representable by a belief function if I understand right. Idea is to start with a quantitative representation whatsoever and then apply a sufficiently concave transformation to get all inequalities satisfied.

Main theorem briefly described by Mukerji (1997 *Economic Theory*). %}

{% An original way to measure the interesting differences between **dynamic consistency**, naivity, and sophistication. Students are asked: (a) How much time spent on studying a course to be taken in the future would be optimal; (b) how much time they expect to actually study it; (c) afterwards how much they really studied. (a) = (c) is time consistent. If (a) ≠ (c), then (b) = (a): naïve; (b) = (c): sophisticated. (b) in between is partially sophisticated. My main problem: (a) ≠ (c) can be due to unforeseen circumstances, rather than time inconsistency. The author argues (p. 546 end of 2nd para) that such unforeseen circumstances, if random and exogenous, are only noise and generate no bias, but I disagree: Their average is not 0, but positive. This is typical of time planning, as considered here: They are usually underestimations because unforeseen things are usually bringing extra delays. Would have been interesting had the author asked a question at (c) if there had been unforeseen circumstances, and how big they were. P. 646 3rd para says that it is surprising that predicted delay in one sample has worse general performance than unpredicted delay, but this can be explained by the problem mentioned, that unpredicted delay can be clever students subject to unforeseen extraneous delays.

(b) – (c) is an index of lack of self-control.

Question is also to what extent the subjects have an interest in truthfully responding, but I cannot easily think of biases.

DC = stationarity: p. 646 3rd l of §2.1 writes that time consistency iff exponential discounting. %}

{% real incentives: not used; instead, flat payment

PT falsified through **coalescing**;

inverse S: taking PT violations as they are, probability weighting seems to be inverse S.

Finds violations of PT (= 1992 prospect theory; the author writes CPT) due to canceling of common outcomes, which original 1979 prospect theory (OPT) can account for. I did not find definitions of the theories in the paper, and am not sure which version of OPT the author uses. P. 57 writes “whether or not the editing stage is formalized”

Structure on p. 42, with r = q´-q, and s remaining probability.

R				S				
p	q	r	s	p	q	r	s	
$\underline{x}$	y	0	0	$\underline{x}$	y´	y´	0	A question
$\underline{y}$	y	0	0	$\underline{y}$	y´	y´	0	B question

The A question concerns choosing between

(p:x, q:y, r:0, s:0) and (p:x, q:y´, r:y´, s:0). In the B question, the underlined common outcome $\underline{x}$ has been replaced by a common outcome $\underline{y}$.

Cancellation here does not work to enhance the sure-thing principle, but differently: Consider, with majority preferences indicated in percentages

0.32	0.01	0.01	0.66		0.32	0.01	0.01	0.66		
3600	3500	0	0	[60%]	**3600**	2000	2000	0		Question A
3500	3500	0	0		**3500**	2000	2000	0	[78%]	Question A´

This violates the comonotonic sure-thing principle, and even Green & Jullien's ordinal independence. Explanation: in Question A, the common 3600 is ignored, and then the longshot effect gives overweighting of the best (of what remains) outcome 3500. In reality, the prospects are presented in collapsed form with outcome 0 not written. Then Question A´ becomes

(0.33: 3500) versus (0.32: 3500, 0.2: 2000) and there is no longshot perception for the best outcome 3500.

P. 42, ℓℓ. 7-8: "we believe that subjects are using this editing operation to simplify the gamble, thus reducing the complexity of the decision-making task."

P. 56, §3.2, discusses between versus within prospect heuristics.

P. 56 has nice balanced writing: "Although the results are not completely clean" %}

{% **PT: data on probability weighting**; **inverse S** of weighting function;

P. 1679: I rewrite their concavity condition, boldprinting the common outcome that changes, ordering outcomes from good (left) to bad (right), and writing z for the worst outcome (so, x > y > z), to show that it is the kind of test of the sure-thing that can be used to test for optimism/pessimism:

If

	p	q´	q–p	q´´–q´	r
R	x	y´	z	**z**	z
			~		
R	y	y	y	**z**	z

then R becomes preferred if we change the common outcome from z to y. So,

	p	q´	q´´–q´	q–p	r
R	x	y´	**y**	z	z
			$\succcurlyeq$		
R	y	y	**y**	y	z

Their convexity condition is similar.

§5 does estimations; use preference ladders, which means choices that differ only regarding their common outcome (common consequence), but in a very particular way, so that it fits into the probability triangle. Assume $\gamma \succ \beta \succ \alpha$:

$(\mathbf{p_1+\varepsilon:\gamma}, p_2:\gamma, p_3:\alpha, \mathbf{p_4-\varepsilon:\alpha})$ vs. $(\mathbf{p_1+\varepsilon:\gamma}, p_2:\beta, p_3:\beta, \mathbf{p_4-\varepsilon:\alpha})$.

The bold-printed parts reflect common consequences. By manipulating ε, we can compare degrees of convexity of probability weighting w throughout the unit interval.

real incentives: they used flat payments

decreasing ARA/increasing RRA: use power utility;

$x^{0.55}$ comes out as utility function for gains. %}

{% Test OPT ('79 version of prospect theory) versus PT (or CPT; '92 version of prospect theory). Overall, OPT does some better.

§1.12, pp. 109-110, define PT and OPT. Their Eq. 1.3 is OPT. They describe it as "OPT with an editing operation," but it is OPT and nothing but OPT. (Their Eq. 1.4 is an earlier version of OPT that was used in the working paper Kahneman & Tversky (1975).) Their Eq. 1.2 is not OPT, but what has sometimes been called separable prospect theory (Camerer & Ho 1994), and that has often erroneously been taken as OPT. The authors do not make clear which formula they use for OPT. It does not matter for what they do. For OPT tradeoff consistency (p. 116) they only consider prospects that assign a positive probability to 0. Then Eqs. 1.2 and 1.3 coincide. (EQ. 1.4 is somewhat different but also implies OPT tradeoff consistency.

They assume at most three outcomes, the domain where OPT is defined only, but which gives an advantage to OPT because its natural extension to more outcomes does not work at all.

no real incentives but flat payment.

They derive a tradeoff consistency condition for PT, based on Abdellaoui (2002), and one for OPT, and find data in the **probability triangle** where these two give contradictory predictions.

violation of certainty effect: p. 120 reports that Simplex IV gives, strangely enough, a violation of the certainty effect.

P. 126 writes that PT (their CPT) has several advantages so that

"Thus, our tests should not be seen as reason to abandon CPT." %}

https://doi.org/10.1007/s11166-005-6561-9

{% A focused history of decision under risk and uncertainty. It puts many subtle nuances that many people don't know exactly right.

P. 401 middle writes: "Indeed, in its abstract form, the independence axiom [vNM independence characterizing EU] is intuitively compelling." This is exactly how it is. The problems of the axiom are only recognized in concrete examples such as the Allais and Ellsberg paradoxes, when plausible interactions between disjoint events become conceivable. Luce (2000) p. 55, opening sentence of §2.4.2 is similarly nice: "Although this line of rational argument seems fairly compelling in the abstract, it loses its force in some concrete situations."

P. 401 ℓ. -4 writes: "The critical axiom is Savage's "Sure Thing Principle." The sure thing principle shares the same basic intuition as the Independence Axiom." Again, I fully agree. The s.th.pr. is way more critical than his other intuitive axiom, his P4. Here the authors, as commonly accepted today, let the sure-thing principle only refer to Savage's P2. (Savage took the term s.th.pr. broader and less formal.)

P. 402, Section "The Pre-prospect Theory Area" gives a central role to Edwards (1954), and I again agree.

P. 403 first half explains how between 1954-1980, many "modern" empirical

findings were already known, (e.g., described by Edwards 1954), but that theory was lacking in that period: "Looking back, it is surprising how much was already known both empirically and theoretically by 1954. It is also surprising how far away researchers and theoreticians were from a comprehensive model of decision making under risk and uncertainty. Many of the major empirical results that characterized research in the 1980s were already known, but the lack of a proper theoretical framework kept researchers from fully understanding these results. ... Edwards [1954] identified the fundamental problem of decision making research, "[the] development of a satisfactory scale of utility of money and of subjective probability" (p. 403). Indeed, Edwards also anticipated the theoretical problem that would characterize much research in the last 15 years: the composition rule that combines utility with distorted probabilities. In Edwards' words, "it seems very difficult to design an experiment to discover that law of combination" (p. 400)." The point is reiterated more or less on p. 404: "Although the Allais Paradox was now 25 years old, very little data existed challenging expected utility, and there were no theoretical alternatives to the classic model.
" P. 404: "Kahneman and Tversky's (1979) ... The paper's success is probably due to its unique combination of simplicity and depth." This is, indeed, a big feature of Kahneman and Tversky's work in general: they have deep understandings but present them accessibly. They can put everything so right and have everything working so well because of their deep understandings. Luce had similar deep understandings, but could not make things tractable and accessible.

P. 407: "prospect theory ... The paper took ideas that had been around, some for as long as 30 years, scattered in different literatures and thought to be unrelated, and constructed a formal model in which all the elements worked together."

Prospect theory/Rank-Dependent Utility most popular for risk: P. 407: "the reputation of prospect theory as one of the most important papers in social science is nevertheless completely deserved.". P. 408: "At the end of these 25 years of research, prospect theory stands out as the best descriptive model.". P. 410: "Rank-dependent utility (RDU) was an ingenious way of allowing probability distortions"

P. 407, as a contribution of prospect theory: "Most importantly, the view that the Allais Paradox was an isolated problem for expected utility was no longer tenable."

P. 407: "In general, economists strove for a descriptive theory of decision under risk that was elegant, general, and mathematically tractable. P. 408: … In contrast, psychologists were generally more concerned with explaining the underlying psychological process. ... These models tended to have more free parameters than prospect theory, and therefore were more flexible but less tractable and parsimonious."

P. 413: "The new theory unified the basic shape of the value and weighting function according to one psychophysical principle ... diminishing sensitivity" … The authors properly let diminishing sensitivity apply as well to utility as to probability weighting. For utility the reference point, the outcome denoted 0, is salient, and for probability two points are, p = 0 and p = 1. Diminshing sensitivity, however, does not speak to loss aversion. %}

{% **natural sources of ambiguity; second-order probabilities to model ambiguity**.

Many papers have discussed the relation between ambiguity aversion and violation of reduction of compound lotteries (RCLA), with aversion to compound lotteries (ACL), propagated by Halevy (2007) who argued that ambiguity aversion is mostly generated by ACL, assuming that people perceive of ambiguity as 2nd stage uncertainty, uncertainty about what probabilities are. I think that such 2nd stage perception may occur for Ellsberg urns, but not for natural ambiguity. This paper nicely reverses the direction, finding that ambiguity aversion generates ACL, not the other way around. It does so by having a control group just exhibiting the usual ACL and ambiguity aversion, with the usual strong correlation. However, in the experimental treatment subjects are taught how to reduce compound lotteries. The idea is that this directly reduces ACL, but doed not DIRECTLY impact ambiguity aversion. Then, if ACL generates ambiguity aversion, and this is the causal direction, then one should also find reduced ambiguity aversion. However, ambiguity aversion is not reduced if ambiguity aversion impacts ACL and this is the causal direction, or if there is another cause impacting both the same way. The latter is found: ambiguity aversion is not reduced at all. This finding suggests that ambiguity aversion impacts ACL and not the other way around (or they have a common cause).

They find much and much higher correlation between ambiguity aversion and compound risk aversion when the former is from Ellsberg urns (what I qualify as artificial ambiguity) than from natural ambiguity, cnfirming opinions that I have. %}

SPT instead of OPT: Their p. 209, Eq. 3. Propose a numerical method to fit data, using fitting with Prelec's family as intermediate step. An experiment confirms all common properties. %}

Wu, Sheng, Hong-Wei Huang, Yan-Lai Li, Haodong Chen, & Yong Pan (2021) "A Novel Probability Weighting Function Model with Empirical Studies," *International Journal of Computational Intelligence Systems* 14, 208–227. https://doi.org/10.2991/ijcis.d.201120.001

{% **inverse S:** in a motor task, subjects had to quickly hit a spot on a screen and then got prizes if they succeeded. After some learning, their hit probabilities stabilized (the subjects were not told what these were but could experience so). Then they were given choices between different games, which amounts to choices between different lotteries. They also answered traditional risky decision questions.

In motor decision tasks people are closer to EU than in usual decision tasks (several further references are given). The utility functions elicited were the same (**source-dependent utility**: not the case here), but the probability weighting functions were different, with motor tasks giving the opposite of inverse S. The motor task is very similar to the experienced decision tasks (DFE) studied by Erev, Hertwig, and others, involving some ambiguity, be it that now motoric skills come in. Note here that a crucial assumption in Savage's (1954) expected utility is that the agent has no influence at all on the states of nature (no moral hazard). This assumption is violated if agents vary their efforts, but is satisfied if agents are assumed to maximize their effort. An explanation may be that subjects dislike a task where they fail with high probability. Another difference with classical decisions under risk is that the motoric task has repeated payments, so, perceptions of laws of large numbers come in. %}

{% Review of decision from experience (DFE) using non-rewarded sampling. Typical of the overselling in DFE: "When people decide whether to start a business or contemplate the success of a first date, there are no written records of risks to consult. Instead, they need to rely on their experience— if existent—with these options, and make decisions from experience rather than decisions from description (Hertwig, Barron, Weber, & Erev, 2004)." They first claim that many everyday decisions are different than decision from description (DFD), but then, out of the blue, claim that it must be DFE. I think DFE is as rare to happen in practice as DFD, and that most practical decisions are neither. Some lines below it is more nuanced "which we understand as poles on a continuum." But I still disagree. Most everyday decisions are not somewhere between DFD and DFE, but are just different.

P. 157 reviews whether there is a reversal of the overweighting of rare events into actual underweighting and concludes that the evidence is completely mixed, unclear, and hard to assess. (**DFE-DFD gap but no reversal**) The main problem is that it is hard to say which probability is being underweighted. The evidence is clearly that in DFE there is less overweighting than in DFD (p. 159 2nd para). %}

{% A remarkable paper that contains many of the ideas basic to prospect theory! **utility elicitation**: one of the few empirical papers actually trying to find out whether gambles for money show risk aversion through an experiment.

Takes DUU with finite state space and monetary outcomes. Explains that in SEU the probabilities are not objectively given and therefore traditional risk aversion cannot be defined. Then tests convexity of prefs. Does not show formally that that is equivalent to risk aversion in DUU. The tests of convexity are such that they involve, by modern views, loss aversion, which may explain the extensive risk aversion = convexity found there.

inverse S: End of §IV finds longshot effect, and explains it by overestimation of small probability rather than by EU. P. 278 says that coexistence of gambling and insurance can both be explained by overestimation of small probabilities.

real incentives: it seems that he used that. He discusses an auction and the **random incentive system** to do so, and suggests that these were done, but is not 100% clear on it.

P. 278: "because utility and probability are two purely theoretical components of an integral decision process."

P. 281, 2/3, in criticism of Friedman & Savage (1948), Yaari confuses risky and cardinal riskless utility, or, at least, equates them without further ado. (**risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**)

P. 282: "writing P ... for preference or indifference, and agreeing to call the wealth level to which the relation corresponds the zero wealth level. In other words, let us agree to measure wealth in terms of deviations from the level which corresponds to P."

P. 285 2nd para: Discusses that each choice should be in isolation, and in fact proposes RIS, where unfortunately he also suggests that maybe a few, so, more than one, choices will be implemented. The description of the experiment does not make clear how the incentives were actually implemented.

End of §IV finds that several subjects (seven out of seventeen) exhibited risk seeking for small probability

inverse S: Yaari posits this on p. 290: "one finds that some subjects tend to overstate low probabilities and to understate high probabilities" and refers to Preston & Baratta (1948) and Mosteller & Nogee (1951) for related findings.

Yaari argues that convexity of preference w.r.t. outcome mixing and the overestimation of small probabilities, and also coexistence of gambling and insurance, can be reconciled. However, under Quiggin's (1982) rank-dependent utility and modern 1992 prospect theory, convexity w.r.t. outcome mixing is equivalent to concave utility AND convex probability weighting=pessimism (Wakker & Yang 2021), so then small probabilities of good outcomes are UNDERweighted and gambling cannot be accommodated. But Yaari did not commit to any such theory here. %}

{% Introduced comonotonicity on p. 328 $\ell\ell$. 3-5 ("bets on the same event," also stated for n events) but did not foresee its role in nonadditive theories. When Yaari worked on his (1987, Econometrica) paper on rank-dependent theories, he first was not aware of the role of comonotonicity. He learned it from Schmeidler. Hence, I still think it is fair to say that Schmeidler invented comonotonicity for rank-dependent theories.

He introduced the MRA relation for subjective EU. It implies that agents must have the same subjective probabilities. One can, of course, take more flexible definitions of MRA that, under EU, allow for comparisons of concave utility also if decision makers have different beliefs, e.g., in Baillon, Driesen, & Wakker (2012).

P. 328 last para argues that the analysis requires state-independence of utility. %}

{% **proper scoring rules**

It is well known that the only strictly proper scoring rule that is local (payoff conditional on event depends only on probability assigned to that event) is the logarithmic family. However, virtually all proofs in the literature assume differentiability. For applications, one should also answer the question without assuming differentiability. This paper provides the answer, and some generalizations: it shows that, also without presupposed differentiability, the logarithmic family is the only one that satisfies weak properness and locality,

where it also generalizes the domain considered. Before, Savage (1972) had also provided a proof without differentiability assumed for properness and on full domain, but it was complex and contained some steps that I never understood. The present paper considerably simplifies Savage's proof. %}

{% **PT falsified**: This paper re-analyzes classical evidence favoring loss aversion, such as Fishburn & Kochenberger (1979), showing many weak points in that evidence. It argues that loss aversion was found for high stakes, but not for small ones.

I imagine that for high stakes, concavity of utility for gains and fear of ruin for losses, rather than loss aversion, can be doing much. For small stakes, joy of gambling and peanut effect can distort. For intermediate outcomes, loss aversion is more manifest. The distinction between what is small and what is moderate in the author’s terminology and in mine plays a big role here. I am more positive about loss aversion than the author. I think that loss aversion is strong and frequent, but, it is very volatile and can double or entirely disappear just by small changes in the stimuli. As components of decision attitudes become more volatile as they are more irrational. Loss aversion in the strict sense as I take it (only what results from reframing effects on reference point, and not “genuine” utility) is very volatile.

In the penultimate para, p. 1337, the author seems to argue that increased attention for losses is not loss aversion, and is not cognitive. I do not understand this para, and disagree. It can still be cognitive, and is as much part of loss aversion as strengthened feelings. Peeters & Czapinski (1990) give a good discussion of these two together comprising loss aversion. %}

{% Present a model and evidence that loss aversion is driven more by overattention to losses than by extremer utility (for which the authors use the term weight) for losses. P. 213 first para cites preceding findings.

losses give more/less noise: Several studies have found that choices under losses are more difficult and, hence, noisier than choices under gains (de Lara Resende, Guilherme, & Wu 2010 p. 129; Gonzalez, Dana, Koshino, & Just 2005 JEΨ; Lopes 1987). Somewhat different in spirit but not contradictory is that rewarding in terms of imposing losses to punish mistakes can work more effectively than imposing gains for good acts in making people make right choices. The presence of losses can make people pay more attention, improving decision quality.

PT falsified: This paper has an interesting experiment: People can choose between safe 35 and risky $200_{0.5}1$, and also between safe 35 and risky $200_{0.5}(-1)$. (Unit of outcome is points converted into small money amounts at the end of the experiment, with repeated payments, so income effects.) They more often choose risky in the second case, amounting to a violation of transitivity or stochastic dominance! The explanation is that the loss makes people pay more attention and, thus, they more rationally choose the highest expected value. This goes against the spirit of loss aversion. Interesting finding. They show that it is increased attention rather than contrast effect, because if the risky option has lower expected value then the loss makes people more often choose against the, now inferior, risky prospect. (**cognitive ability related to risk/ambiguity aversion**)

Note that, in general, loss aversion can be generated by increased attention for losses (rather than losses having lower utility), but the above increased attention is of a different kind.

This indirect violation of montonicity is comparable to the zero-outcome effect paradox of Slovic-Birnbaum ((.95, $96; .05, $24) receives lower CE than (.95, $96; .05, $0); Birnbaum, Coffey, Mellers, & Weiss (1992)) but now without outcome 0 involved.

The conclusion writes: "losses may be treated as signals of attention and not only as signals of avoidance. … Our findings demonstrate that the attentional effect of losses is indeed distinct from loss aversion," %}

{% **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**: Considers tax schedules in some countries, such as US. Assumes equal sacrifice principle of John Stuart Mill: All people paying tax should lose the same amount of utility (leading to flat tax rate under logarithmic utility). Then from the amounts that the authorities let be paid by the various levels of income, we can derive the marginal utility that the authorities assume there, and then the cardinal utility. For 1957 US tax data, CRRA 1.61 fits the data well. This could be interpreted as cardinal welfare utility and be left as that. The author, however, does not shy away from relating this to utility measured from risky choice. On p. 255 2nd column the author very explicitly relates the utility found to risky utility, writing for instance: "The equal sacrifice hypothesis will be plausible if: (i) the estimated utility function is reasonably consistent with utility theory; … In the modern theory of risk bearing, …" %}

{%Was lecture at D-TEA conference 2019, Paris.

This paper reports on personal letter communication between Savage and others regarding the issue of unknown/imprecise probabilities and ambiguity. I want to distinguish between two different reasons for having imprecise probabilities:

(1) You are fully Bayesian, but for your decisions to be made you need not

specify your probabilities precisely. For example, you have to choose between 100_E0 and 40, and have linear utility. Then it suffices to know that P(E) < 0.4 to know that you choose the sure 40. In this sense your probability can be imprecise while being fully Bayesian. Your preference relation over some usual rich set of acts is incomplete only because it is irrelevant, not because it would be "intrinsically" incomplete.

(2) You are not ambiguity neutral and go by some multiple prior model such as maxmin EU.

In papers published and in public presentations Savage never stated that deviations from his axioms can be rational. I conjecture that in his letters Savage was open to imprecise probabilities only because of (1) and not because of (2), so that it was not really a deviation from Bayesianism, and I here deviate from the opinions expressed in this paper.

de Finetti writes to Savage: "Have you read D. Ellsberg's note (Quarterly J. of Econ., 75,4, Nov. 1961) that claims that you were 'inconsistent' in answering to one of his questions concerning issue such as Smith's?"

B. de Finetti to L. J. Savage, March 8, 1962, LJS Papers, 8, 194, (Zappia's translation from the original Italian)

Savage replies in a letter: "I have not only read Ellsberg's paper but had a very thorough visit with him here in Ann Arbor. He is intelligent, steeped in the material, but quite blind about certain aspects of it. I feel that there may be a grain of truth in what he is trying to say, but find it very difficult to clear my own head on the subject." (L. J. Savage to B. de Finetti, March 16, 1962, LJS Papers, Box 8, 194)

Here Savage may be close to accepting Ellsberg's violation of his model as rational, by not explicitly negating what de Finetti writes, but there can be many explanations for why Savage wrote this.

In later writings Savage says that there may be unsatisfactory aspects to his theory, and that alternative theories are welcome if they get laid down, but this may as well be ADDING axioms to his own as removing some.

Savage wrote to de Finetti: "If upper and lower probabilities are taken seriously, they at least double the vagueness that they intended to alleviate … Nevertheless, I agree that there is practical importance in exploring the implication of a set of probabilities that might be designed as "acceptable" … I would expect convexity to be an innocuous assumption about a set of acceptable probabilities, and a convex set of probabilities can be well described by inequalities on expectations" (L. J. Savage to B. de Finetti, (February 23, 1962, LJS Papers, 8, 194)

This can all fit with (1) above. It can also be that one precise probability is desired at the end, to be a convex combination of a set considered.

Zappia's paper ends with:

> It can then be concluded that Savage's reluctance to endorse the critical viewpoint underlying the Ellsberg Paradox was related to methodological caution rather than to rejection of its content. The new notion of mathematical rigor he had endorsed as part of the group of mathematical economists and statisticians he had worked with in the 1950s was crucial to him. His doubts were mostly based on the inability of his critics to provide an alternative theoretical set-up rather than on a clear-cut denial of the normative relevance of their argument. He may have been ready to endorse it had a consistent theoretical corpus and the appropriate axioms been made available by his critics. He died at the age of fifty-four, far too early to see such analytical progress come into reality.

In Zappia's interpretation, Savage would accept later-axiomatized multiple prior models of ambiguity and violations of his sure-thing principle P2. But I do not share this interpretation. My reading of Savage is that he only doubted completeness. That he would never abandon the sure-thing principle. With which I agree.%}

{% A modification of a model of Diecidue & van de Ven (2008), where the evaluation of a lottery has extra terms being the probability of gaining and the probability of losing. It can be modeled by letting utility have jumps at outcome 0. This paper does it for prospect theory. If finds that people pay more attention to the probability of a loss than of a gain.

PT falsified: the paper qualifies its model and finding as a violation of prospect theory but it is no more than jumps of utility at 0, i.e., prospect theory with utility jumps at 0. %}

Zeisberger, Stefan (2022) “Do People Care about Loss Probabilities?,” *Journal of Risk and Uncertainty* 65, 185–213.
https://doi.org/10.1007/s11166-022-09391-y

{% Section 2 nicely reviews stability across domains, tasks, and time.

Fit the same parametric family as T&K’92 to CE (certainty equivalent) measurements. Do measurements month apart, to test time stability. If I remember right, Cohen, Jaffray, & Said (1987) did two measurements a week apart.

random incentive system between-subjects (paying only some subjects): paid 1 of every 10 subjects.

losses from prior endowment mechanism: did that.

risk averse for gains, risk seeking for losses: find it.

concave utility for gains, convex utility for losses: Find linear utility for gains (power 0.98), somewhat convex for losses (power 0.88). The probability weighting parameter is 0.865 for gains and 0.79 for losses, so, somewhat stronger for the latter. Loss aversion is 1.41.

Abstract and p. 360 point out that for CE measurements of PT parameters there can be considerable collinearities (they do not use this term). This is further

analyzed on p. 366-369. Figure 1 concerns gain prospects with only one nonzero outcome. Then the joint power of utility and probability weighting is unidentifiable. Because the parametric family chosen for w has no free power, it leads to implications for the w parameter.

They show nice figures of maximum likelihood tests, showing that for CE measurements the parameters of PT strongly interact, with much collinearity. Show that there is a wide set of parameter combinations that fits the data almost as well as the optimal parameters. Figure 3b shows it for the Tversky & Kahneman (1992) data.

They find PT parameters similar to other studies, confirming **inverse S** (although their one-parameter T&K'92 family enhances it).

P. 374: They test for stability at the individual level by using statistics that take within-subject choices as independent. It gives 1/3 of instable subjects (significant changes according to the statistic just mentionend. %}

{% They measure risk attitudes by fitting preference functionals, EU and RDU with CRRA and CARA utility and, for RDU, the Tversky & Kahneman (1992) 1-parameter probability weighting family. They do so for four elicitation methods: Choice list (called Holt-Laury), pairwise choice, BDM (Becker-DeGroot-Marschak), and allocation. They equate risk aversion with utility curvature. (I criticized this on many occasions.) The main finding is that utility curvature depends more on elicitation method than on functional assumed. The paper presents a new visual implementation of BDM in Figure 4: The CE chosen leads to a lottery that is a mixture of a uniform distribution over [CE, max] and the original lottery. Reducing the CE a bit means adding a lower part to the uniform distribution while reducing the probability of getting the lottery. This works under EU but depends much on conditional thinking and may not be easy under nonEU theories. I suggest a different visual representation in Figure 4c: Put the uniform distribution all to the right, so that the subject clearly sees that reducing the CE means reducing the conditioning probability so as to add the lower part of the uniform distribution. Even nicer would be 100 little lines with each either containing the lottery or part of the uniform distribution, and the subject could choose how many of the 100 parts with lotteries to replace by the uniform distributions.

P. 737: “We choose the most popular [preference functionals] in the literature, namely Expected Utility (EU) and Rank Dependent expected utility (RD).” %}

{% **relation age-risk attitude**: see title;

Several studies reported that risk aversion increases with age. This is usually done in experiments on choices between safe and risky options. This paper investigates whether complexity of the choice options is a confounding factor. To do so, it manipulates complexity by expressing outcomes through more or less complex mathematical formulas. This can, of course bring many confounds on its own, such as formulations not being more complex but rather more artificial. They also investigate/find that probability weighting becomes less pronounced when all options are complex. %}

Zilker, Veronika, Ralph Hertwig, & Thorsten Pachur (2020) "Age Differences in Risk Attitude Are Shaped by Option Complexity," *Journal of Experimental Psychology: General*, 149, 1644–1683. https://doi.org/10.1037/xge0000741

{% The paper argues that the probability weighting found in prospect theory (inverse S) may be explained by the attentional Drift Diffusion Model (aDDM). This model, widely used in psychology, uses attention paid to all kinds of aspects to explain many things. The authors argue that aDDM can replace, refute, the interpretations of inverse S probability weighting through insensitivity and liking/disliking. I did no read enough to know: to what extent aDDM may explain, rather than refute, prospect theory's concepts, to what extent it is "simply" assuming different stimuli, and to what extent it can accommodate just anything.

Prospect theory/Rank-Dependent Utility most popular for risk: p. 949: "cumulative prospect theory (CPT; Tversky & Kahneman, 1992), arguably the most influential theory of decision making under risk." %}

{% Consider infinite sequences of outcomes (interpreted as intertemporal), and rank-dependent representation + exchangeability, so, temporal ordering plays no role (rank-discounted utilitarian approach). Provide preference foundation for it, mostly by a comonotonic stationarity. Mathematical problem is how to do for infinite sequences, where symmetry can generate impossibility results. Results on inequality aversion, dictatorship.

Here is a detailed explanation:

It is easiest to understand this model first for finitely many timepoints/generations. In fact, let us first do decision under uncertainty, where RDU (often called CEU (Choquet expected utility)) is better understood, and then extend it to the case of this paper. Assume that there are n states of nature in S =

$\{s_1,\ldots,s_n\}$, and

$x = (x_1, \ldots, x_n)$ is the prospect

yielding $\$x_j$ if state of nature s_j occurs.

We consider a rank-dependent evaluation, as in Wakker (2010). We will do reversed rank-ordering to stay close to the paper. Wakker (2010 §7.6) explains, for risk, that reversed or not reversed ranking does not matter, and the same holds for uncertainty. I strongly advise everyone to do nonreversed ranking, but for clarifying this paper consider reversed ranking still. We take a weighting function W with $W(\varnothing) = 0$ and $W(S) = 1$ (the latter relaxed soon). If $x_1 \leq \cdots \leq x_n$, then

$$\mathrm{RDU}(x_1,\ldots,x_n) = \sum_{j=1}^{n} \pi_j U(x_j)$$

where the weight π_j is

$W\{(s_j,\ldots,s_1\} - W\{s_{j-1},\ldots,s_1\}$. (My book does it for non-reversed ranking $x_1 \geq \ldots \geq x_n$, but this is an arbitrary convention as just explained.)

If not $x_1 \leq \cdots \leq x_n$, then we have to reorder the outcomes into

$x_{[1]}, \ldots, x_{[n]}$ with $x_{[1]} \leq \cdots \leq x_{[n]. \text{The}}$n

$$\mathrm{RDU}(x_1,\ldots,x_n) = \sum_{j=1}^{n} \pi_{[j]} U(x_{[j]})$$

where $\pi_{[j]} = W\{(s_{[j]},\ldots,s_{[1]}\} - W\{s_{[j-1]},\ldots,s_{[1]}\}$.

For example, if $n = 3$, $(x_1,x_2,x_3) = (5,7,1)$, then

$x_{[1]} = x_3 = 1$, $x_{[2]} = x_1 = 5$, and $x_{[3]} = x_2 = 7$.

The convention is that $W(S) = 1$, but this is not important and is just normalization. We can allow it to be any value > 0, and will do so. Only point to keep in mind is that a constant act $\alpha = (\alpha,\ldots,\alpha)$ is evaluated by $W(S)(U\alpha)$ rather than by $U(\alpha)$.

Now assume

$W(E) = 1 + \beta^1 + \ldots + \beta^{j-1}$ whenever E contains j states, such as

$E = \{s_1, \ldots, s_j\}$ or $E = \{s_{n-j+1}, \ldots, s_n\}$. Here $\beta \geq 0$.

If $x_1 \leq \cdots \leq x_n$, then $\mathrm{RDU}(x_1,\ldots,x_n) =$

$U(x_1) + \beta^1 U(x_2) + \cdots + \beta^{j-1} U(x_j)$.

Rank dependence allows dependence of the weights on the rank, with different weighting for the best outcome than for the worst outcome for instance. This happens here. For $\beta < 1$, outcomes are weighted more as they are ranked worse.

Such pessimism can be seen to be equivalent to W being concave for this reversed rank-ordering.

Now assume that s_j does not refer to a state of nature, but to a generation. Then we can use the same evaluation as above. Now overweighting the lowest outcome does not reflect pessimism, but preference for equity: The poorer a person is, the more weight is given to this person. It reflects a desire for fairness. That rank dependence can be used this way to capture fairness in welfare (if s_j is a person instead of a state of nature) has been long known, and has been used in several papers. Wakker (2010, Appendix D, Interpretation D.2) discusses it. This is what Zuber & Asheim do, for generations. A generation is not weighted more as it is nearer to the present, but as it is poorer, for fairness reasons. So, β has nothing to do with discounting, but reflects fairness. The smaller β, the more fairness concern. The authors extend the model to the case of infinite generations, which brings some mathematical complications but does not affect the concepts. %}
