Annotated Bibliography

Peter P. Wakker

March 16, 2025

This bibliography subsumes all preceding versions. References to past versions remain effective.

Elucidation on keywords and annotations:

- Annotations are between signs {% and %} above references.
- Use of keywords (are bold): using the FIND function, the keywords below give related references. For example, the keyword
  ambiguity seeking
  gives 116 references on it.

KEYWORDS:

ambiguity seeking:

ambiguity seeking for losses:

ambiguity seeking for unlikely:

ambiguous outcomes vs. ambiguous probabilities: some authors make this distinction although I favor that *by definition* all uncertainty is modeled through the state space.

ambiguity attitude taken to be rational:

Ambiguity = amb.av = source.pref, ignoring insensitivity:

Arrow's voting paradox ==> ordinality does not work:

backward induction/normal form, descriptive:

Best core theory depends on error theory: Starting 2000, many empirical studies in decision theory do not just fit a deterministic decision theory to data with statistics such as t-tests done at the end, but they use a probabilistic choice model with errors in choice incorporated, and have this probabilistic choice model integrated with the deterministic decision model. The latter is then called the core theory.

binary prospects identify U and W: For binary prospects, most nonexpected utilities agree, and are rank-dependent utility. These prospects suffice to identify utility U and the weighting function W.

bisection > matching: Since the 1980s, with a revival in experimental economics starting around 2005, decision theorists have compared choice-based methods such as bisection and the choice list with direct matching. Now (2012) most people prefer choice-based methods.

biseparable utility: the rank-dependent utility (RDU) model for binary prospects;

biseparable utility violated: the models that do not agree with RDU for binary prospects;

calculating RDU: means to calculate RDU and new prospect theory

calculation costs incorporated: incorporating calculation costs into decision making

cancellation axioms: axioms necessary for additively decomposable representations on product sets, studied by Krantz et al. (1971) and many others;

CBDT: case-based decision theory;

CE bias towards EV: certainty equivalent measurements generate biases towards expected value maximization;

Choice enhances noncompensatory heuristics:

coalescing: A prospect written as (1/3:2, 1/3:2, 1/3:0) may be evaluated differently than (2/3:2, 1/3:0). Similar terms are collapsing or event splitting (or outcome splitting);

cognitive ability related to discounting:

cognitive ability related to risk/ambiguity aversion:

cognitive ability related to likelihood insensitivity (= inverse S):

coherentism: Representational view of utility is that all that it should do is represent choice consistently, and this is the only requirement. No external criteria should be imposed. This is like coherentism. See also; paternalism/Humean-view-of-preference; see also search keys starting with "risky utility";

Compare different measurement methods:

confirmatory bias: of new evidence, people select only what reinforce their opinions, leading to divergence of opinions rather than the rational convergence;

completeness criticisms: completeness means requiring a preference between every pair of prospects/choice options;

collapse: see coalescing;

concave utility for gains, convex utility for losses: (see also "risk averse for gains, risk seeking for losses," and please don't confuse risk aversion with concave utility etc. unless expected utility is the explicit working hypothesis!);

consequentialism/pragmatism: putting everything relevant in consequences makes model intractable;

not explained here (see preference for flexibility for future influence);

correlation risk & ambiguity attitude:

criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity: see also the more general: **restrictiveness of monotonicity/weak separability**

criticisms of Savage's basic framework; (see also: R.C. Jeffrey model)

criticizing Knight (1921) for low quality:

criticizing the dangerous role of technical axioms such as continuity:

crowding-out:

deception:

deception when implementing real incentives: (usually done to protect subjects from suffering losses);

decreasing ARA/increasing RRA: ARA = absolute risk aversion, and RRA = relative risk aversion;

decreasing/increasing impatience:

desirable to extend preferences while satisfying/maintaining conditions:

derived concepts in pref. axioms:

DFE-DFD gap but no reversal: Decision from experience usually finds less pronounced inverse S probability weighting than decision from description, but the reversal (S-shape instead of reversed S-shape) claimed in first papers on DFE does not hold. (Or it does?)

discounting normative:

dominance violation by pref. for increasing income: (see also: preferring streams of increasing income);

Dutch book: (see also "ordered vector space" or "reference dependence test");

dynamic consistency:

dynamic consistency. NonEU & dynamic principles by restricting domain of acts:

dynamic consistency: **favors abandoning time consistency, so, favors sophisticated choice**:

dynamic consistency: **favors abandoning forgone-event independence, so, favors resolute choice**:

dynamic consistency: favors abandoning RCLA when time is physical:

DC = stationarity: confusing dynamic consistency (= time consistency) with stationarity (or not):

endogenous midpoints:

extending preference relations using conditions:

equate risk aversion with concave utility under nonEU: Under EU, risk aversion (preferring expected value of prospect to prospect) can be equated with concave utility. Under nonEU this is no longer correct. Unfortunately, many authors, the majority of economists and finance people today, continue to equate risk aversion and concave utility under nonEU. An explanation can be that people want to use a term for concave utility but want to avoid "diminishing marginal utility" because, in the ordinal spirit, they do not want to give empirical meaning to marginal utility. (Thus Arrow, 1951, ECMA, p. 423 wrote: "diminishing marginal utility had lost its meaning.")]Well, it is just incorrect under nonEU, unfortunately.

equity-versus-efficiency:

EU+a*sup+b*inf:

event/outcome driven ambiguity model: event driven: ambiguity primarily modeled through an event function (e.g., Schmeidler's 1989 RDU/CEU). Savage's P4 then usually holds.

event/outcome driven ambiguity model: outcome driven: ambiguity primarily modeled through an outcome function, utility (mostly recursive EU, e.g., KMM's smooth model).

event splitting: see coalescing;

finite additivity:

foundations of probability:

foundations of quantum mechanics:

foundations of statistics:

free will/determinism:

game theory can/cannot be viewed as decision under uncertainty: (see also: game theory as ambiguity):

game theory as ambiguity:

gender differences in risk attitude:

gender differences in ambiguity attitudes:

Harsanyi's aggregation:

homebias:

inconsistency in repeated risky choice:

independence/sure-thing principle due to mutually exclusive events:

information aversion: (see also "value of information"):

insurance frame increases risk aversion:

intertemporal separability criticized:

intuitive versus analytical decisions: (see also "reflective equilibrium");

inverse S: (see also ("risk seeking for small-probability gains")

inverse S (= likelihood insensitivity) related to emotions:

R.C. Jeffrey model:

just noticeable difference: (other terms used in the literature are minimally perceptible threshold/difference or just noticeable increment);

law and decision theory:

linear utility for small stakes:

loss aversion without mixed prospects: people who think to obtain estimates of loss aversion without considering mixed prospect, which is impossible (see also loss aversion: erroneously thinking it is reflection);

loss aversion: erroneously thinking it is reflection: (see also loss aversion without mixed prospects);

losses from prior endowment mechanism: implementing real incentives for losses by first giving subjects prior endowment and then letting them later pay back from that.

losses give more/less noise:

marginal utility is diminishing:

measure of similarity:

Monty Hall's problem: see **three-doors problem**:

Nash equilibrium discussion:

natural-language-ambiguity:

natural sources of ambiguity:

Newcomb's problem:

nonadditive measures are too general:

nonconstant discount = nonlinear time perception: deviations from constant discounting may not so much be nonconstant discounting of well-perceived time, but rather constant discounting of misperceived time.

normal/extensive form:

one-dimensional utility:

optimal scale levels:

ordered vector space:

ordering of subsets: (see also preference for flexibility);

own small expertise = meaning of life: In 2022 this has been renamed as: **ubiquity fallacy**: Many researchers try to suggest that their small expertise can answer all the main questions in life; they confuse ubiquity with explanatory power. There is an explanation at https://www.youtube.com/watch?v=FDvBrcytU7Q&t=52s
1:10 – 3:25 for the special case of ergodic theory.

part-whole bias: (special case for uncertainty: coalescing)**;**

parametric fitting depends on families chosen:

paternalism/Humean-view-of-preference: whether preferences should always be taken as is, or whether one may change them to improve them; see also: coherentism

PE doesn't do well: the probability equivalent, also called standard gamble, does not perform well.

PE higher than CE: (see also "PE higher than others" and "CE bias towards EV"): the standard gamble gives (assuming expected utility) higher utilities than the certainty equivalent method.

PE higher than others: (see also "PE higher than CE"); the standard gamble gives higher utilities than other methods.

preferring streams of increasing income: (see also: dominance violation by pref. for increasing income);

present value:

principle of complete ignorance:

probability elicitation: (see also "proper scoring rules" and "survey on belief measurement");

probability communication:

probability intervals:

probability triangle:

probability weighting depends on outcomes: (other than sign-dependence);

Probability weighting linear in interior:

producing random numbers: (people are not able to produce really random numbers);

proper scoring rules: (see also "probability elicitation");

proper scoring rules-correction:

Prospect theory/Rank-Dependent Utility most popular for risk:

Prospect theory not cited: Many experimental economists do not cite prospect theory. They then have no very good descriptive quantitative theory for risk attitudes, usually using expected utility to fit data. They cannot consider the cognitive insensitivity component of risk attitude (implying the empirically prevailing fourfold pattern and inverse S probability weighting) and instead focus on the risk aversion/seeking component. This tradition, that I regret, was initiated by Holt & Laury (2002)—who did cite prospect theory but in an irrelevant manner. Priority claims can then be problematic. Authors then often suggest that Holt & Laury (2002) invented (or "popularized") the empirical measurement of risk attitudes and/or the use of choice lists, ignoring a preceding half century where this was all done extensively. They sometimes cite the early Binswanger

(1981), but many citations are missing, and only experimental economists are cited. Sometimes Kahneman & Tversky (1979) are cited but only for an irrelevant detail, as did Holt & Laury (2002).

PT, applications:

PT falsified: see also **probability weighting depends on outcomes;**

qualitative probability: see ordering of subsets;

QALY overestimated when ill:

quasi-concave so deliberate randomization:

questionnaire for measuring risk aversion:

questionnaire versus choice utility: see also "coherentism"; compares utility based on revealed preference only with utility measured in different ways, such as using introspection.

random incentive system:

random incentive system between-subjects: (paying only some subjects):

ranking economists:

ratio bias: In a task of an algebraic nature, some people use an additive procedure and others use a multiplicative one. Thus, in tasks where addition is appropriate, a bias is observed in the direction of multiplication, and vice versa. And thus, we usually observe a risk attitude between constant absolute and constant relative risk aversion. A prominent psychologist once told me that this bias was the best kept secret in decision experiments, and that it explained the majority of all empirical findings in the field;

ratio-difference principle: (see also ratio bias)

RCLA: (= reduction of compound lotteries assumption): is called collapse independence when for uncertainty (events instead of probabilities)

real incentives/hypothetical choice: (see also "crowding-out" and "losses from prior endowment mechanism," "stated preference" is a common term for hypothetical choice);

real incentives/hypothetical choice, for time preferences:

real incentives/hypothetical choice, explicitly ignoring hypothetical literature:

reference dependence test: (= asset-integration test: see also losses from prior endowment mechanism);

relative curvature:

reflection at individual level for risk: (positive or negative correlation between risk aversion for gains and losses);

reflection at individual level for ambiguity: (positive or negative correlation between ambiguity aversion for gains and losses);

relation age-risk attitude

restrictiveness of monotonicity/weak separability:

Explanation: Monotonicity w.r.t. money outcomes in the sense of the more money the better is trivial, using the objective ordering on real numbers that everyone agrees on. However, if monotonicity concerns a subjective ordering, as when outcomes are complex multiattribute things, then monotonicity implies weak separability and can be more restrictive than many people are aware of. Btw., many interactions between attributes can be taken as a violation here. See also: **criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**;

revealed preference: violations of the RIS (random incentive system) can also be related to this point.

risk averse for gains, risk seeking for losses: see also "concave utility for gains, convex utility for losses";

risk seeking for small-probability gains:

risk seeking for symmetric fifty-fifty gambles:

risky utility u = strength of preference v (or other riskless cardinal utility, often called value):

risky utility u = transform of strength of preference v:

risky utility u = transform of strength of preference v, latter doesn't exist:

SEU = risk: argue (where I disagree) that Savage (1954) justified considering SEU to be risk;

second-order probabilities:

second-order probabilities to model ambiguity:

SEU = SEU: People, mostly psychologists, who erroneously think that the subjective probabilities of Ramsey (1931)/Savage (1954) are equal to transformed objective probabilities; Ramsey and Savage only provide arguments supporting EU and *against* transforming objective probabilities

SPT instead of OPT: Many authors, seeking to use OPT (original prospect theory of 1979) for nonmixed prospects $(p_1{:}x_1,\ldots,p_n{:}x_n)$ with multiple gains, $x_1 > \cdots > x_n \geq 0$, do not use the formula that Kahneman & Tversky had in mind: $U(x_n) + \sum_{1 \leq j \leq n-1} w(p_j)(U(x_j) - U(x_1))$, but instead use what Camerer & Ho (1994) called separable prospect theory (SPT): $\sum_{1 \leq j \leq n} w(p_j)U(x_j)$. The latter formula is the separate-probability transformation model (separable prospect theory) that psychologists including Edwards often used. That K&T did not have this in mind follows because for n = 2 they use the former formula and not the latter, and because on p. 18 of their 1975 working paper (extending their p. 12) version they use the analog of the former and not of the latter formula. The latter text, as well as their 1981 paper, show that they did have the analog of SPT in mind for mixed prospects. Wakker (2023 Theory and Decision) explains the case.

SIIA/IIIA: comparisons between the condition called independence of irrelevant alternatives in social choice and the different condition of the same name in individual choice;

simple decision analysis cases using EU: nice didactical examples to illustrate expected utility;

small risks overinsured:

small worlds: Savage's (1954) topic;

social risks > nature risks in coordination games:

social sciences cannot measure:

sophisticated choice:

source-dependent utility: this topic concerns not only utility-driven, but also event-driven ambiguity models because there it can still happen empirically that utility is source dependent.

source preference directly tested:

standard-sequence invariance: (see also Tradeoff method);

state-dependent utility:

state space derived endogeously:

strength-of-preference representation:

substitution-derivation of EU:

survey on belief measurement:

survey on nonEU:

suspicion under ambiguity: in Ellsberg-urn type experiments, subjects may fear that the experimentor rigged the urns against them ("suspicion");

testing color symmetry in Ellsberg urn:

time consistency stated ambiguously: of the three relevant time durations (time of decision, time of consumption, and difference between the two) only stating that one changes, without stating which of the other two then also changes

time preference:

time preference: **comparing risky and intertemporal utility**:

time preference, fungibility problem: (money received at some timepoint in an experiment may not be consumed immediately, but instead saved at market interest rate; leading many researchers to prefer consumption outcomes rather than monetary payment outcomes when studying discounting)

three-doors problem: (also known as Monty Hall's three doors problem or three-prisoners problem);

tradeoff method: see also standard-sequence invariance;

tradeoff method's error propagation:

total utility theory:

ubiquity fallacy: (formerly called "own small expertise = meaning of life"): Many researchers try to suggest that their small expertise can answer all the main questions in life. They confuse ubiquity with explanatory power. There is an explanation at
https://www.youtube.com/watch?v=FDvBrcytU7Q&t=52s
(1:10 – 3:25)
for ergodic economics.

uncertainty amplifies risk:

universal ambiguity aversion: authors assuming that people are always averse to ambiguity, modulo noise;

utility concave near ruin:

utility depends on probability:

utility elicitation:

utility elicitation: different EU methods give different curves: (see also: PE higher than CE);

utility families parametric:

utility measurement: **correct for probability distortion**:

utility of gambling:

updating: mistakes in using Bayes' formula:

updating: nonadditive measures: (see also: updating under ambiguity)

updating: testing Bayes' formula:

updating under ambiguity: (see also: updating: nonadditive measures)

updating under ambiguity with sampling: (how ambiguity attitudes are updated after sampling info; not included are: theoretical papers; general papers on updating without explicit mention of ambiguity; general dynamic decisions; decisions from experience; see also: updating: nonadditive measures); studies on decision from experience (DFE) are not always included

updating: discussing conditional probability and/or updating:

value-induced beliefs:

value of information: (see also "information aversion");

(very) small probabilities:

violation of certainty effect: (see also "risk seeking for symmetric fifty-fifty gambles");

violation of risk/objective probability = one source: (see also "PT falsified; probability weighting depends on outcomes")

SLEAPING KEYWORDS: A**HP**: **anonymity protection**; **adaptive utility elicitation**; **PT: data on probability weighting**; **Christiane, Veronika & I**; c**ommon knowledge**; **decision under stress**; **equilibrium under nonEU**: see also game theory for nonexpected utility; **error theory for risky choice**; **game theory for nonexpected utility** (see also equilibrium under nonEU); **games with incomplete information**; **HYE**; **Kirsten&I**; **maths for econ students**; **methoden & technieken**; **Nash bargaining solution**; **preference for flexibility** (since 2000 there is much literature on choice menus); **reflective equilibrium**; **PE gold standard**; **statistics for C/E**; **Z&Z** (on health insurance)

NOTATION AND TERMINOLOGY:

Prospect can refer to choice options in every choice situation. Mostly prospect refers to lotteries (probability distributions over outcomes, which mostly are money amounts), or to acts (mapping states to outcomes, as in Savage 1954).

$\alpha_p\beta$ = (p:α, 1−p: β) denotes a prospect (lottery) giving outcome α with probability p and outcome β with probability 1−p.

$\alpha_E\beta$ = (E:α, E^c: β) denotes a prospect (act) giving outcome α under event E and outcome β under event E^c.

ABBREVIATIONS:

AA: Anscombe-Aumann

AER: American Economic Review

ARA: absolute risk aversion

AHP = analytical hierarchy process

BDM: Becker-DeGroot-Marschak

C/E = cost-effectiveness

CE = certainty equivalent

CEU = Choquet expected utility

CPT = cumulative prospect theory (I usually write PT)

DC = dynamic consistency

def. = definition

DFD: decision from description

DFE: decision from experience

DUR = decision under risk

DUU = decision under uncertainty

EU = expected utility

EV = expected value

HYE = healthy years equivalent

IIA = independence of irrelevant alternatives

inverse S: inverse S-shaped probability transformation

JRU: Journal of Risk and Uncertainty

KMM: Klibanoff, Marinacci, & Mukerji (2005)

nonEU = nonexpected utility

OPT: original prospect theory of 1979 (if you like: old prospect theory)

PE: probability equivalent method, used to measure utility under EU, and alternative there to the certainty equivalent method (CE). In the health domain, people often use the term standard gamble instead of PE; in other domains standard gamble often refers to both PE and CE.

PT = prospect theory; I prefer to use this term for the new 1992 version of prospect theory, also often called cumulative prospect theory

QALY = quality adjusted life years

RA: risk aversion

RCLA: reduction of compound lotteries

RDU: rank-dependent utility

RIS: random incentive system

RRA: relative risk aversion

SEU = subjective expected utility

TTO = time tradeoff method

WTA: willingness to accept

WTP: willingness to pay

{% **PT: data on probability weighting**;

utility elicitation;

tradeoff method: First, the tradeoff method is used to elicit utility. Then these are used to elicit the probability weighing function. More precisely, first a sequence x_0, ..., x_6 is elicited that is equally spaced in utility units. Then equivalences $x_i \sim (p_i,x_6; 1-p_i,x_0)$ elicit $p_i = w^{-1}(i/6)$ and, thus, the weighting function.

concave utility for gains, convex utility for losses: P. 1506 Finds concave utility for gains (power 0.89), convex utility for losses (power 0.92).

P. 1508 finds more pronounced deviation from linearity of probability weighting for gains than for losses.

inverse S: this is indeed found for 62.5%. 30% had convex prob transformation, rest linear. P. 1507: bounded SA is confirmed.

P. 1510: finds nonlinearity for moderate probabilities, so, not just at the boundaries.

P. 1502: uses real incentives for gains but not for losses.

P. 1504: finds 19% inconsistencies, which is less than usual, but this may be because the consistency questions were asked shortly after the corresponding experimental questions (**inconsistency in repeated risky choice**).

P. 1506: fitting power utilities gives median 0.89 for gains and 0.92 for losses.

P. 1510: no reflection, w^+ (for gains) is different (less elevated) from w^- for losses, also different than dual, so, PT is better than RDU. This goes against complete reflection. It supports the, today commonly believed, partial reflection.

reflection at individual level for risk: correlations at individual level are not reported. Preference patterns not for risk attitude but for utility and probability weighting. For utility found a bit (Table 3; 21 concave for gains is in majority, 13, convex for losses; 8 convex for gains have no convex for losses but mostly mixed). For probability weighting not reported. %}

Abdellaoui, Mohammed (2000) "Parameter-Free Elicitation of Utility and Probability Weighting Functions," *Management Science* 46, 1497–1512. https://doi.org/10.1287/mnsc.46.11.1497.12080

{% **tradeoff method**: is applied theoretically in a dual manner, on probability transformation; %}

Abdellaoui, Mohammed (2002) "A Genuine Rank-Dependent Generalization of the von Neumann-Morgenstern Expected Utility Theorem," *Econometrica* 70, 717–736.

{% Hypothetical choice was used, and discussed on pp. 851 & 862.
tradeoff method: use it in intertemporal context. Now not subjective probabilities, but discount weights, drop from the equations.

P. 847: the asymmetry found between discounting for gains and for losses may have resulted from the assumption, common in the early days, of linear utility, which works out differently for gains (where utility is concave) than for losses (where utility is close to linear and even some convex). This paper corrects for utility but still finds asymmetry (p. 859). They find, though not very clearly, that discounting is less for losses than for gains, but the deviation from constant discounting is the same.

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): Measure intertemporal utility, not going to the unnatural detour of risky choice as for instance Andersen et al. (2008 Econometrica) did, but, more naturally, using only intertemoral choice. Find that it agrees well with utility as commonly measured under risk (p. 860).

P. 855: **convex utility for losses**: Do it in an intertemporal context. With nonparametric analysis, they find linear utility for losses (slightly more convex but insignificant), and concave utility for gains. With parametric analyses, they have no significant deviations from linearity although it is in direction of concavity for gains and convexity for losses. There it agrees with utility as commonly measured under risk.

P. 857: For gains 55 had decreasing impatience and 12 had increasing.

For losses, 47 decr, 18 incr., and 2 constant. They find almost no evidence for the immediacy effect, which drives quasi-hyperbolic discounting.

P. 860: if not correcting for utility curvature, then overly strong discounting, but the deviation is not big at the aggregate level.

Note that this paper measured both utility and discounting using merely intertemporal choice, also with parametric fitting, and is probably the first to do so. It precedes the Andreoni & Sprenger (2012) papers on this point. %}

Abdellaoui, Mohammed, Arthur E. Attema, & Han Bleichrodt (2010) "Intertemporal Tradeoffs for Gains and Losses: An Experimental Measurement of Discounted Utility," *Economic Journal* 120, 845–866. https://doi.org/10.1111/j.1468-0297.2009.02308.x

{% **probability elicitation**; **inverse S; ambiguity seeking for unlikely; natural sources of ambiguity;**

event/outcome driven ambiguity model: event driven

correlation risk & ambiguity attitude: reported in Figures 12 and 13 on p. 715. Correlations between risk aversion on the one hand, and ambiguity aversion and a-insensitivity (ambiguity-generated insensitivity) on the other, are significantly positive and high for all three ambiguity sources (between 0.5-0.86). Figure A3-A4 in the web-appendix do the same for the Ellsberg experiment. The correlations are lower (0.37-0.53) but still significant.

real incentives/hypothetical choice: This paper did the experiment both with hypothetical choice and with real incentives. The main text only reports the incentivized data.

source-dependent utility: Although this paper uses an event-driven ambiguity model, it would still be possible that utility were source dependent. But it is not found empirically here.

testing color symmetry in Ellsberg urn: §III.C confirms it.

random incentive system between-subjects: In a pilot we asked subjects, given the same expected value, if they preferred high payments to some or rather lower payments to all. They clearly indicated a preference for the former. This (+ classroom experiments giving me the same impression) makes me in general, given the same expected value, prefer the between- implementation of high payment for some to the common moderate-payment-for-all. We describe our finding in our Online Appendix (§A.2): "For the second experiment, we asked subjects in a pilot study which form of the random incentive system would motivate them better, the traditional form paying one randomly selected choice for each subject, in which case prizes will be moderate, or one were only one choice of one subject will be played for real but the prize is very large. The subjects expressed a clear preference for the single-large prize system that accordingly was implemented in our experiment."

P. 701 top: "Source functions reflect interactions between beliefs and tastes that are typical of nonexpected utility and that are deemed irrational in the Bayesian normative approach." %}

{% Measure prospect theory, using the well-known method of Abdellaoui, Bleichrodt, & Paraschiv (2007), which can also find loss aversion. The novelty is that they do it for professional managers instead of students. N = 46. They did some tests of prospect theory, and the theory was never violated.

Hypothetical choice. Find, as usual:

concave utility for gains, convex utility for losses: They find this (p. 421). As usual, utility is less convex for losses than it is concave for gains.

risk averse for gains, risk seeking for losses: they find this (p. 420)

Unusual: find less loss aversion, and even quite some of the opposite: gain seeking.

But they find almost no loss aversion (p. 423). The increased rationality of their subjects may have mad this as the first move to EU.

reflection at individual level for risk: they find the opposite, a negative correlation between the powers for gains and those for losses (p. 422).

Pp. 424-425: compares the professional managers to the students of

Abdellaoui, Bleichrodt, & Paraschiv (2007). Utilities for gains are similar, utilities for losses are less convex, and, obviously, loss aversion is much less. %}

Abdellaoui, Mohammed, Han Bleichrodt & Hilda Kammoun (2013) "Do Financial Professionals Behave According to Prospect Theory? An Experimental Study," *Theory and Decision* 74, 411–429.

{% **natural sources of ambiguity;**

This paper considers the source method of Abdellaoui et al. (2011 American Economic Review). It considers New York & Rotterdam temperature. Unlike the 2011 paper, it does not measure subjective probabilities on a continuum in a parameter-free way, but it uses parametric fitting. Beta-distributions fit best, better than normal or others. Given that cross-checks in the 2011 paper revealed no violations of probabilistic sophistication under real incentives, this paper does not do such cross-checks. It interprets the subjective (so, choice-based; I prefer the term a-neutral) probabilities as beliefs.

The paper also fits the smooth ambiguity model (= recursive expected utility). They use a finite mixture model with the smooth model and PT (the latter done for binary-gain prospects so that it is biseparable utility and captures Choquet expected utility, multiple priors, and most event-driven ambiguity models). 80% of subjects did PT and 20% did smooth. Utilities did not change across sources (such changes is what the smooth model does, having different U for first and second stage and combining it using backward induction), but the source function did, showing source dependence of that. Calibration of choice-based probabilities was good.

The authors obtain inverse S source functions, with Rotterdam (where the experiment was done) slightly but still significantly more elevated than New York. %}

Abdellaoui, Mohammed, Han Bleichrodt, Emmanuel Kemel, & Olivier L'Haridon (2021) "Measuring Beliefs under Ambiguity," *Operations Research* 69, 599–612. https://doi.org/10.1287/opre.2020.1980

{% N = 48;

Discuss pros and cons of parametric fitting.

First paper to use the method to elicit PT as follows: First consider a subset of prospects with one fixed probability and fit PT with some parametric utility (usually log-power), where the probability weight is just one parameter. This gives reliable estimates of probability weighting. Then this parameter is used to estimate utilities of other outcomes.

random incentive system between-subjects: One subject is paid. They used very large outcomes, such as 10,000 euros, in the experiment, but for real incentives scaled down by a factor 10 (oh well). For losses they found slightly concave utility, but yet risk seeking.

concave utility for gains, convex utility for losses: find concave utility for gains, and slightly concave utility for losses.

risk averse for gains, risk seeking for losses: they find this.

reflection at individual level for risk: Table 4 p. 256 gives weak counterevidence, not counting mixed or neutral: of 25 risk averse for gains, 15 are risk averse for losses and only 10 are risk seeking; of 3 risk seeking for gains, all 3 are risk seeking for losses.

They also estimated power of utility (under PT) but do not report correlations.

The finding of concave utility for losses, but risk seeking, is a nice empirical counterpart to Chateauneuf & Cohen (1994).

inverse S: find it, both for gains and losses, fully in agreement with the predictions of PT.

Use a measurement method where utility is measured through parametric fitting, assuming power utility. %}

{% Exemplary study into intertemporal choice, providing the first complete quantification. One good thing is that they derive both discounting and utility from intertemporal choice, which is the obvious natural way to go and first thing to try for anyone who thinks about it. Abdellaoui, Attema, & Bleichrodt (2010) and Andreoni & Sprenger (2012 AER, "Estimating Time Preference from Convex Budgets") also did such a thing, only using intertemporal choice, but less completely than this paper. In retrospect it is hard to understand why papers such as Andersen et al. (2008 Econometrica) detoured to risky choice to get utility from there.

First, in Rotterdam, intertemporal choices were measured with both gains and losses, and then this is best done hypothetically, as the authors argue on p. 229 bottom and I agree. Use only two nonzero payoffs, one always at present, and for gains and losses measure present values. For mixed they match a loss outcome; always done by bisection-choice (p. 230 last para). Use linear-exponential utility. P. 235 Table 3 lists the other discount families tested, besides generalized hyperbolic: its special cases of constant discounting, proportional, and power; further families that are no special cases: quasi-hyperbolic, fixed cost, constant sensitivity, and constant absolute.

P. 236: For gains utility is close to linear. Moderate loss aversion, of 1.3 or so.

P. 237: moderate discounting. §2.1.7: Data fitting much better with sign-dependent discounting. The (rational) discount factors for gains and losses were strongly correlated (0.7 corelation), but the (irrational) deviation from constant discounting not at all, with more deviation for losses (p. 238)

P. 238 (footnote 6 cites personal communication with Prelec on it) generalized hyprbolic fits the data poorly, with especially the α parameter (deviating from constant discounting) unstable.

P. 238 §2.1.8: Mixed model gives ¾ subjects linear U for gains, concave for losses (**concave utility for gains, convex utility for losses**), modest discounting and loss aversion. ¼ had concave U for both gains and losses, and much discounting and loss aversion.

P. 239-240, §2.1.9 (with Table 7 on p. 241): Constant sensitivity fitted the data best, although its superiority over quasi-hyperbolic and fixed-costs was not significant. The authors corrected for number of parameters using AIC.

Given present value, it can only be constant sensitivity and not the extension by Bleichrodt, Rohde, & Wakker (2009).

P. 239, here in hypothetical, only one subject had increasing impatience.

reflection at individual level for risk (positive or negative correlation between risk aversion for gains and losses): Find positive correlation between concavity of utility for gains and convexity for losses (0.32; p = 0.007), but this is utility for intertemporal choice, and not for risky choice. They also find positive correlation (0.70; $p < 0.001$) for discounting for gains and losses.

P. 240 ff.: 2nd experiment in Paris, repeated only gains, but now with real incentives and individual interviews. (Details of future payment: p. 242 top, before §2.2.1. Every subject had a 1/20 chance of real play (**random incentive system between-subjects**).

P. 244 §2.2.3: data similar to hypothetical, except for two differences: way higher discount parameter β (so, less discounting), and now more (26%) subjects had increasing impatience.

P. 246 §2.2.6 (Table 11): again constant sensitivity fitted best, now ex aequo with generalized hyperbolic, and superiority over fixed-cost was not significant.

P. 247 §3 (discussion) and §4 (conclusion, p. 248): sign-dependence, and possibility to accommodate increasing impatience, are desirable. %}

https://doi.org/10.1007/s11166-013-9181-9

{% The first disseminated and citable working paper version of this was in March 2010.

Most choices were done hypothetically. The authors considered losses and intertemporal choices, and for those hypothetical is best I think. In the Rotterdam half of the experiment (N = 65), all was done hypothetically (p. 2157), also for gain-risks (here real incentives could have been implemented with no problem), so as to have ceteris paribus in comparisons. In the Paris half of the experiment (N = 50), real incentives were used for gain-risks, paying 1/20 subjects stakes up to €200. (**random incentive system between-subjects**)

risky utility u = transform of strength of preference v: this paper investigates the question empirically, with mature interpretations and discussions.

§2, p. 2154 last para, suggests separability over states of nature, but they mean so in a rank-dependent (comonotonic) manner, as eplained a few lines below.

They use the method of Abdellaoui et al. (2008) to measure utility and probability weighting. The same method can obviously be used in intertemporal choice, with the discount value of a timepoint rather than the decision weight of a probability as unknown parameter. It is strange that until recently people never treated time just the same as risk before in the literature when doing parametric fitting to get utility, but here it is done. Abdellaoui, Attema, & Bleichrodt (2010) and Andreoni & Sprenger (2012 AER) preceded them in this regard.

P. 2156, Eq 3 seems to assume that a future payoff automatically involves uncertainty, captured by a decision weight, but unlike most works in the literature this decision weight is not taken as part of the discount weight, but is taken as a separate parameter, which may be hard to identify. In the Kreps-Porteus (1978) model, the authors interpret the late utility function as purely capturing risk attitude, and the early one to capture intertemporal attitude.

The authors use exponential U to fit data with loss aversion so as to avoid the mathematical problems of power utility when estimating loss aversion.

Find more noise for risk than for time (p. 2159). Paris experiment, unlike Rotterdam, did personal interviewing, leading to less noise (p. 2159).

Rotterdam results:

P. 2159: Utility was different for risk than for time. For risk it was usual S-shape, but for time it was linear for gains and concave (instead of convex) for losses. An explanation of the latter could be an underestimation of the discount factor of the future time (always 1 year), because the authors always considered a larger gain/loss at the later timepoint (Table B.2 in appendix). This can make utility extra convex for gains and extra concave for losses, so as to amplify the effects of extreme outcomes.

P. 2160: Loss aversion might be the same for risk and time. Utilities and loss aversion for risk and time were not significantly correlated, which is a negative result, suggesting much noise.

P. 2160: Paris results did not find significant convexity for loss-utility. More loss aversion for risk than for time.

P. 2162: violation of time separability can distort results.

P. 2163 footnote 6 proposes how to measure utility unaffected by probability weighting for risk, or, in general, to measure one parameter unaffectedly by another. It elaborates the point if one probability p is used, as is the case here. The idea is as follows: (1) Take any indifference, and use it to express w(p) in terms of utilities. (2) Next, replace every appearance of w(p) by that expression. What results is equalities with only utilities, giving utility without speculation on w(p). A difference with the tradeoff method is that the authors' method does not disentangle probability weighting and utility, but is a general method for solving equalities. In the tradeoff method, if one makes a mistake in probability weighting w(p) and, for instance, erroneously assumes expected utility (w(p) = p) whereas the subject does prospect theory with nonlinear probability weighting, then mistakes in utility assessment might slip in when deriving the utilities of what is called the gauge outcomes. However, utility inferences of the gauge outcomes are simply not used in the tradeoff method. In the authors' method, if one erroneously assumes expected utility, whereas the subject perfectly well satisfies PT, then one erroneously thinks that there are inconsistencies in the utility measurements, which one will try to capture by partly changing the estimated utility values and partly capturing the deviations through an error term.

The conclusion (p. 2163) nicely summarizes the paper, and here it is:

"Utility under risk and utility over time were different and uncorrelated with utility curvature more pronounced for risk than for time. Utility under risk was concave for gains and convex to linear for losses. Utility for losses was closer to linear than utility for gains. Intertemporal utility was close to linear. Our subjects were loss averse both in decision under risk and in decision over time, but it was stronger for risk. Loss aversion for risk and time were uncorrelated, suggesting that even though loss aversion is important in both domains, it is volatile and affected by framing." %}

Abdellaoui, Mohammed, Han Bleichrodt, Olivier L'Haridon, & Corina Paraschiv (2013) "Is there One Unifying Concept of Utility? An Experimental Comparison of Utility under Risk and Utility over Time," *Management Science* 59, 2153–2169.
https://doi.org/10.1287/mnsc.1120.1690

{% This paper measures utility for different sources that should give the right utility for all models considered. It does so by using the Wakker-Deneffe TO method (**tradeoff method**), using only two-outcome prospects where all theories agree, being bisparable. More precisely, it uses a sign-dependent generalization that also covers PT.

Loss aversion is measured by taking the kink of the overall utility at the reference point, or $-U(-\alpha)/U(\alpha)$ for several α's > 0. More precisely, they get $\alpha_E\beta \sim 0$ for $\alpha > 0 > \beta$, then $\gamma \sim \alpha_E 0$ and $\delta \sim o_E\beta$, from which it follows that $U(\gamma) =$

–U(δ). Then γ/δ is an approximation of loss aversion, under the reasonable assumption of locally linear utility at either side of 0 (but kink at 0).

So, it can see whether utility is really different for different sources. (I take loss aversion as part of utility here. This is debatable and it can also be taken as a separate component, besides basic utility.) The most sensitive point of utility curvature is loss aversion, and the paper develops a special technique for measuring it. It finds that utility does not depend on the source. As sources it uses the classical Ellsberg known/unknown urn. The paper does find ambiguity aversion, so, the utility-based theories are really falsified here. (**event/outcome driven ambiguity model: event driven**)

Find same loss aversion for risk as for ambiguity.

They test sign-comonotonic tradeoff consistency, a necessary and (under richness assumptions) sufficient preference condition for PT. Find it satisfied. %}

{% **concave utility for gains, convex utility for losses**: find concave utility for gains, convex for losses

reflection at individual level for risk: p. 1667 Table 3: Of people with concave utility for gains, by far most (26) have convex utility for losses and only 1 has concave. Of people with convex utility for losses, still quite some (6) have convex utility for losses, but now 3 have concave utility. They also fitted power utility and, nicely, report correlation between gains and losses (p. 1669), being 0.389 (which means reflection at the individual level).

Table 1 gives a nice summary of the various definitions of loss aversion used in the literature.

They first measure some utilities for gains and losses through the **tradeoff method**, getting some utility midpoints. Using that, they measure $w^{-1}(0.5)$ for both gains and losses. Then they know so much that from indifferences between mixed prospects they can measure loss aversion efficiently. %}

Abdellaoui, Mohammed, Han Bleichrodt, & Corina Paraschiv (2007) "Loss Aversion under Prospect Theory: A Parameter-Free Measurement," *Management Science* 53, 1659–1674.

{% **probability intervals**: Hill (2019) showed that α in the α maxmin model can be identified if one adds events with objective probability intervals. This paper reports an experiment using this result. For every subjective event E one can specify an objective "matching probability-interval," bringing all the same preferences and, hence, the same probability interval. It is the probability-interval analog of matching probabilities. It takes quite some effort to implement this way in an incentive compatible manner in an experiment, but this paper does it. The paper finds plausible results, supporting the method. It should be noted though that the paper only does it for (many) partitions {E,E^c}, so that it in fact elicits probability intervals and not sets of priors.

I often argued that the multiple priors model in its generality is too general to be elicited. An exception is the very simple case of two states of nature, with an event E and its complement E^c. Then multiple priors models are biseparable utility models, and can be elicited. This paper considers this very simple case, but for several events. Put differently, it elicits upper and lower probabilities of some events. This is different than multiple priors, which involves entire probability distributions. %}

{% Matching probabilities of lotteries that pay either now or at some fixed future time. Probability weighting better fits/predicts than utility curvature. Insensitivity and pessimism increase as the time of payment gets later (**violation of risk/objective probability = one source**:). Here the timing of resolution of uncertainty varies, not of outcome. %}

Abdellaoui, Mohammed, Enrico Diecidue, Emmanuel Kemel, & Ayse Onculer (2022) “Temporal Risk Resolution: Utility versus Probability Weighting Approaches,” *Management Science* 68, 5162–5186.

{% N = 39. Do choice list, matching on outcomes rather than on probability, with always one prospect riskles, and fit **biseparable utility.** They use the method used in many papers by Abdellaoui, where the probability p is kept fixed, and then w(p) is derived from data fitting as the only parameter of probability weighting needed, and is then used to obtain the utility function. The main contribution of this paper is to demonstrate, using data, that their method is less dependent on assumptions about probability weighting than methods that use different probabilities.

The paper has some strange claims. For example, the paper writes, 3rd page penultimate para: “A major strength of the HL probability scale method is that it allows a direct estimation of individual degrees of relative risk aversion on the basis of a specific utility function.” However, as far as I can judge, for ANY data set and method one can fit power utility just as well as for the HL method.

3rd-4th page writes, again about HL: “probability scale ... First, the method is highly tractable: only one table has to be used to obtain an indicator of risk aversion, and this can be implemented either through a computer-based questionnaire or through a simple pencil and paper questionnaire.” Again, cannot any indifference obtained by any measurement method be used the same way?

The third main drawback at the end of §2.3 (that "it uses a the probability scale to measure risk attitudes under expected utility." The authors have put forward that their novelty relative to HL is that they use "the outcome scale rather than the probability scale" (abstract; beginning of §2.3 calls this the main difference between what the authors do and what HL does): doesn't this same drawback hold for any method assuming EU, also if, as in the case of this paper, matching is in the outcome scale? So, it is assuming that EU, and not matching in the probability scale, matters. Later the paper explains that they use only one fixed probability p, implying that only that one w(p) has to be estimated and in that sense the paper relies less on matching in the probability scale.

The results show that HL type measurements with PE have the resulting utility function depend much on the parametric probability weighting function assumed, but the authors' method does not. (**PE doesn't do well**) %}

Abdellaoui, Mohammed, Ahmed Driouchi, & Olivier l'Haridon (2011) "Risk Aversion Elicitation: Reconciling Tractability and Bias Minimization," *Theory and Decision* 71, 63–80.

{% N = 61. Losses and mixed were only hypothetical. For gains, half did hypothetical and for the other half two subjects could play one gain-choice for real (= **random incentive system between-subjects**). This paper never finds differences between real incentives and hypothetical. (**real incentives/hypothetical choice**)

Paper assumes PT, with binary prospects. It first uses Abdellaoui's semi-parametric method to measure utility, where one and the same probability/event is always used for the most extreme nonzero outcome, impying that its weight is the only parameter beyond utility to be fit. Then power utility is fit. With utility available, decision weights for all kinds of events/probabilities are elicited. All up to this is based on measured certainty equivalents. Loss aversion is measured using power utility with the T&K'92 assumption that u(1) = u(−1) = 1, where € is unit of payment.

One difference with usual studies of decision from experience (DFE) is that the subjects are informed beforehand about what the set of possible outcomes is.

concave utility for gains, convex utility for losses: find concave U for gains, close to linear (bit convex) utility for losses, both for DFE and for description

(DFD).

reflection at individual level for risk: They have the data within-subject but do not report it. §5.1 writes that of the subjects with concave utility for gains, about as many had convex as concave utility for losses. This to some extent suggests independence of gain/loss utility shape. Great majority was loss averse.

inverse S: Find it for DFD. Note that no parametric family was assumed to determine the decision weights. Intersects diagonal at about $p = 0.25$. Not really different for gains and losses, though some more elevation and some higher sensitivity to losses (§5.2).

For DFE one can take objective probabilities of events, or observed frequencies from sampling, in the analysis of decision weights. Doing the first, most results are the same as with DFD. The only differences are: Utility is more concave for losses (slight majority concave here), but still close to linear. Probability is less elevated for gains than with DFD, although still overweighting $p = 0.05$. For losses probability weighting is equally elevated as for DFD, so, it is less elevated than for gains with DFE. Doing the second, sampled frequencies, gives no clear differences.

The abstract summarizes the main comparisons between DFD and DFE: decision weights for gains are lower with DFE, and no big differences otherwise.

The paper claims, in some places, to show that DFE and DFD are different, but it mostly shows that there are almost no differences. Most remarkable is that this study does not find the opposite of inverse S-shaped weighting that most studies on DFE do. The paper does not discuss this point much (**DFE-DFD gap but no reversal**). This point is probably generated by the methodological difference of telling subjects what the possible outcomes are. The paper cites Erev, Glozman, & Hertwig (2008) on this in §7.2, but not in a very explicit manner. If I understand well, Erev, G&H found this also. %}

Abdellaoui, Mohammed, Olivier L'Haridon, & Corina Paraschiv (2011) "Experienced versus Described Uncertainty: Do We Need Two Prospect Theory Specifications?," *Management Science* 57, 1879–1895.

{% PT fits well for married couples, as for individuals. The attitudes for couples are usually a mix of the individuals, with more weight for the female attitude, especially for unlikely events. Use two-stage data-fit method of Abdellaoui, Bleichrodt, & l'Haridon (2008). %}

Abdellaoui, Mohammed, Olivier L'Haridon, & Corina Paraschiv (2013) "Individual vs. Couple Behavior: An Experimental Investigation of Risk Preferences," *Theory and Decision* 75, 157–191.

{% Propose a parametric probability weighting function family of the form

$w(p) = \delta^{1-\gamma}p^{\gamma}$ if $0 \le p \le \delta$ and

$w(p) = 1 - (1-\delta)^{1-\gamma}(1-p)^{\gamma}$ if $p > \delta$

with $0 \le \delta \le 1$, $0 < \gamma$.

The function is **inverse S**, has many nice properties, is given a preference foundation, and fits data well. It intersects the diagonal at δ. To get pessimism or optimism, δ should be chosen 0 or 1 after which the power family results. It seems that $\delta = 0$ and $\delta = 1$ give about the same curves.

Under inverse S, δ reflects elevation (anti-index of pessimism, because w is concave and above diagonal up to δ) and γ reflects sensitivity (curvature; anti-index of inverse S).

For gains the neo-additive weighting function (called linear by the authors) fitted data better, but for losses their function did. %}

{% **updating under ambiguity with sampling** %}

Abdellaoui, Mohammed, Brian Hill, Emmanuel Kemel, & Hela Maafi (2020) "The Evolution of Ambiguity Attitudes through Learning," working paper.

{% **real incentives/hypothetical choice**: find no difference in patterns, but less error for real incentives.

Do decision under risk both with monetary outcomes and with time as outcome. For time, subjects were told beforehand that the experiment would last approximately 2 hours, where it might be 1 or 3. The time unit designated a time to wait in the lab with no amusing/useful things like computers or mobile phones available. They were anchored to think 2 hours, but then it could become more (gains) or less (losses).

concave utility for gains, convex utility for losses: (§5.1) They find pronounced concavity for gains, and moderate concavity, and not convexity, for losses. For time less concavity for gains than for money. Loss aversion lower for time than for money (end of §5.1).

inverse S: (§5.2) confirmed for time and money, and for gains and losses.

On average more inverse S for time than for money, both for gains and for losses. For time, probability weighting has more elevation for both gains (optimism) and losses (pessimism). Which is not very nice for PT. Probability weighting depending on outcomes can be taken as a violation of PT (**PT falsified; probability weighting depends on outcomes**). The symmetry for gains and losses is nice for reflection. Would be interesting to see if at the individual level there is much difference between probability weighting for time and for money, but the paper does not report it. (Statistics may not be easy.)

losses from prior endowment mechanism: this they do. For money there is the usual problem that subjects may integrate the prior endowment with the loss and, hence, not perceive losses, which is why they do money only hypothetically, something that I agree with. For time such integration is less likely because time loss is not so easily integrated with the prior endowment OF MONEY (they are paid for the time loss). This makes this paper the most convincing implementation of real incentives for losses that I have seen in the literature (in 2022). Abdellaoui, Gutierrez, & Kemel (2018) will use similar incentives. Casari & Dragone (2015) do a similar thing. %}

Abdellaoui, Mohammed & Emmanuel Kemel (2014) "Eliciting Prospect Theory when Consequences Are Measured in Time Units: "Time Is not Money"," *Management Science* 60, 1844–1859.

{% Subjects choose between lotteries paid at different times. The resolution of uncertainty always is immediate. They find the usual inverse S probability weighting, even while they chose a design where random errors go against inverse S; see, e.g., p. 468 middle para. (**inverse S**) This is useful to show that inverse S is not (just) noise. They also do find present bias in the presence of risk.

Some may have suggested that it disappears under risk, but this study finds it doesn't. They fit power utility to the data, but assume it to be the same for risk and time, an assumption that I like. They discuss this on p. 468 3rd para. They use Prelec's two-parameter family.

Every subject had 1/10 probability of real incentive, but stakes were up to €500. (**random incentive system between-subjects**) The authors explain on p. 463 bottom that this is necessary to get real curvature of utility, and I fully agree.

P. 468 2nd para explains that the EU-utility correction of Andersen et al. (2008) may do more harm than good.

P. 468: "Together, these studies underline the importance of explicitly designing experimental stimuli in a way that allows the different dimensions to be identified. Estimating complex models on data that are not especially designed for that purpose is bound to generate biased inferences if the resulting estimations are accepted without question." This is a good observation, relevant for many data fittings. The conclusion (p. 463), 1st para, explains that they took their stimuli with plenty variations in outcomes and probabilities to properly estimate probability weighting and utility curvature separately.

P. 463 last para: if doing the EU correction for utility, then discounting is 6% per year. Bringing in probability weighting increases it to 14%.

The authors considered hyperbolic, quasi-hyperbolic, but also the constant-sensitivity family of Ebert & Prelec (2007) for discounting, but do not report which fitted better. %}

{% Halevy (2007) found an almost perfect relation between ambiguity aversion and violation of RCLA. This paper finds some relation, but only weak, with much else going on. They find that compound risk aversion is increasing in the winning probability, nice in harmony with likelihood insensitivity, as they point out on pp. 1306-1307. %}

Abdellaoui, Mohammed, Peter Klibanoff, & Laetitia Placido (2015) "Experiments on Compound Risk in Relation to Simple Risk and to Ambiguity," *Management Science* 61, 1306–1322.

{% This paper criticizes Bernheim & Sprenger (2020, Econometrica) (BS). I list five major problems below, as explained extensively in my annotations to the paper in this file and more concisely in Wakker (2023, *Journal of Behavioral and Experimental Economics* 107, 101950). I here write only about something else: how our paper here was rejected by Econometrica.

Five problems of BS:

1. The experiments were poor, with overly complex stimuli and too low incentives.
2. BS ignored much preceding literature that showed their found violations of rank dependence in better experiments, and BS ignored much preceding literature with positive evidence of rank dependence. They incorrectly criticize preceding literature by erroneously arguing that commonly used counting tests are invalid.
3. SB used a wrong formula of 1979 prospect theory.
4. Their remedy of complexity aversion does not work, with the prevailing (existing! but not cited) empirical evidence opposite to their claims.
5. Their §3.2 & §4.1 use only prospects with one nonzero outcome to identify both probability weighting and utility, but this is a well-known mistake (unidentifiable joint power).

This paper was submitted to Econometrica, but was rejected with four unanimously negative referees. I think, if a paper should clearly be accepted, then providing four negative referees is a bit overdoing it. One referee said no more than that our paper was too negative. The other three referees all, remarkably, used the same linguistic tric to downplay our paper. They all wrote that they focus on our main criticism, for which they all chose Problem 1 above. Thus, they ignored the other four problems, which I think cannot be done for problems that serious. Then they criticized us for not having provided new evidence on that Problem 1 but only citing existing literature, arguing that we should have provided new experimental evidence and should have shown how the experiment could have been done properly. That is, we should have investigated in detail what happens if one only makes the mistakes of Problems 2-5, but not of Problem 1. The editor sided with these judgments, reiterating them in his decision letter. We were not invited to provide such evidence in a resubmission, but our paper was just rejected. Looks like, to criticize a claim 2 + 2 = 5, one has to provide new experimental evidence! %}

{% N = 101 student-subjects. **random incentive system between-subjects**: described in §3.4.1.

losses from prior endowment mechanism: they use the same good system as Abdellaoui & Kemel (2014)

Consider discounted utility when the outcomes refer to time duration, which is time to work, and also when it is money. A reference point is framed and then gains or losses are considered. It is a contract specifying that one is supposed to work for four hours, but then it can reduced or increased. It can concern 4 work hours on an early date, or on a late date. They allow for nonconstant discounting and nonlinear utility. They use the tau-discounting of Bleichrodt, Potter van Loon, & Prelec (2022), and also constant sensitivity of Ebert & Prelec (2007). Bleichrodt, Kothiyal, Prelec, & Wakker (2013 p. 69) preferred the term unit invariance for this family. P. 17 writes that all parametric families performed similarly well, but that the authors prefer the constant sensitivity family because it is the only one that allows for both insensitivity and over-sensitivity.

For losses, they find many violtions of impatience, preferring an early to a late loss. There is more heterogeneity for utility and discounting for time duration than for money. %}

natural sources of ambiguity;

real incentives/hypothetical choice: used flat payment and hypothetical choice, because utility measurement is only interesting for large amounts that cannot easily be implemented.

inverse S & **uncertainty amplifies risk**: confirm less sensitivity to uncertainty than to risk. This implies: **ambiguity seeking for unlikely**

tradeoff method to elicit utility, (**concave utility for gains, convex utility for losses**) gives concave utility for gains (power-fitting gives power of about 0.88 on average) and some convex, but close to linear, utility for losses. They use mixed prospects, and thus can let the standard sequence start at 0 and they get utility over a domain $[0, x_6]$, including 0 (see just before §3.1, p. 1387). They use an uncertain event E, not given probability, to measure the standard sequence. They measure matching probabilities, $x_p0 \sim x_E0$.

Test two-stage model of PT with $W(E) = w(B(E))$, axiomatized by Wakker (2004). Here W is measured from PT by first measuring utility using the tradeoff method (§3.1), and then extending Abdellaoui's (2000) and Bleichrodt & Pinto's (2000) method for measuring probability weighting to uncertainty: $1_E0 \sim x$ then $W(E) = U(x)$, assuming $U(0) = 0$ and $U(1) = 1$ (§3.2). B, called choice-based probability by the authors, is measured through matching probabilities: $1_E0 \sim 1_p0$ then $B(E) = p$ (§3.3). (That is, they do this only for gains.) They then derive w as $w(p) = W(B^{-1}(p))$.

W satisfies bounded SA (= inverse S extended to uncertainty) for almost all subjects. Bounded SA is similar for gains and losses, but elevation is larger for losses. Bounded SA also holds for the factor B (p. 1395 bottom of first column), and for w. Hence, all common hypotheses of diminishing sensitivity of Fox & Tversky (1998), Tversky & Fox (1995), Wakker (2004), and others are confirmed. One small deviation is that for losses they find overweighting of unlikely events but no significant underweighting of likely events (§5.4, p. 1394).

ambiguity seeking for unlikely gains and **ambiguity seeking for losses**are confirmed by bounded SA

tradeoff method's error propagation: do so on p. 1394, §5.3 end.

reflection at individual level for ambiguity: Although they have the data at the individual level, they do not report these. They do it neither for utility (§5.2), where they even fitted power and exponential utility, so could (but do not) correlate parameters, nor for ("overall") decision weights (§5.3), nor for the estimations of the risky probability weighting functions in §5.5.

For example, p. 1397 2nd para (about the function carrying matching probabilities into decision weights, which should be the probability weighting function under risk) mentions "at the level of individual subjects," but it is paired t-tests. Those, while corrected for errors at the individual level, only test hypotheses about group averages. No correlations between gain-loss parameters are given, for instance, and nothing in their results suggests that these would be positive or negative.

For group averages, they find the same insensitivity (inverse S, called bounded subadditivity by the authors) for gains as for losses, both for overall decision weights W^+ and W^- and for the risky probability weighting functions w^+ and w^- derived from $W^+(E) = w^+(B(E))$ and $W^-(E) = w^-(B(E))$ with B the matching probabilities. But elevations are higher for losses than for gains.

Although the beginning of the paper takes matching probabilities B as beliefs (so that ambiguity attitude is entirely belief), as commonly done in the Tversky et al. two-stage approach, the paper later points out that it will also incorporate source preference (p. 1386 2nd column middle) and said more firmly at bottom of p. 1398, where it nicely follows on p. 1399 with Tversky's view that source preference may not be central for transitive individual preference but rather a contrast effect.

P. 1398: "The similarity of the properties of judged probabilities and choice-based probabilities comes as good news for the link between the psychological concept of judged probabilities and the more standard economic concept of choice-based probabilities." %}

{% This paper presents source- and rank-dependent utility (SRU), a convenient joint generalization of the smooth ambiguity model and rank-dependent utility for ambiguity, axiomatizing it as well as all of its specifications. It thus serves well to compare the various approaches.

The authors consider a two-stage model of uncertainty as do Anscombe-Aumann (1963). The first-stage events (whose uncertainty is resolved first; left in the decision tree) are uncertain, for the second-stage events probabilities are given, as in Anscombe-Aumann, although the results of this paper could readily be extended to the case where second-stage events also have no given probabilities. The authors use a tradeoff-consistency-type preference tool (**tradeoff method**) to provide, at one end of the spectrum, a new axiomatization of Anscombe-Aumann expected utility that does not use probability mixing. At the other end of the spectrum, they provide a recursive RDU model that generalizes recursive EU (the smooth model) and Schmeidler's (1989) RDU by allowing nonEU (rank-dependent utility) not only for the first-stage events but also for the second-stage events. Every intermediate model, covering almost the whole domain of recursive models, can be characterized by turning on or off the corresponding tradeoff consistenty condition. The paper shows how to incorporate sign dependence and how to do comparative concavity of utility.

A central question in current (2023) ambiguity theory is whether models are better outcome driven, as is the smooth model, or better even driven, as rank-dependent utility and multiple priors. This paper provides good tools to address the central question. %}

{% **PE doesn't do well**: surely not if evaluated using EU;

Typical of decision analysis is that simple choices are used to (derive utilities and other subjective parameters and then) predict more complex decisions. This paper performs this task in an exemplary explicit manner. The authors first use simple choice questions (PE with risk for chronic health states and TTO with time tradeoffs for chronic health states; if I rememer right, they use the term standard gamble and SG instead of my PE) to get basic utility assessments. For PE they calculate utility both assuming EU and assuming PT. Then they use the findings to predict preferences between more complex risky prospects (involving no real intertemporal tradeoffs), and between more complex (nonchronic) health profiles (involving no real risk). For decisions under risk, PT better predicts future choices than EU. It does so both when PE-PT utilities are used as inputs, and when TTO-based ("riskless"!) utility measurements are used as inputs. Bleichrodt (08Jan10, personal communication) told that TTO utility inputs and then PT work as well as PE inputs (no significant differences), which supports **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)** with intertemporal utility instead of strength of pr. But if I understand well, for intertemporal decisions TTO utilities did somewhat better than PE utilities, although with one exception the differences were not significant. %}

{% **ubiquity fallacy**: opening sentence: “If this is the age of information, then privacy is the issue of our times.” The closing sentence of the paper is in the same style: “should be sufficiently flexible to evolve with the emerging unpredictable complexities of the information age.” So are expressions such as “seismic nature” (p. 509 1st column last line). It is a style that, apparently, impresses average researchers and attracts many citations from them.

P. 509 3rd column middle para gives as example of privacy intrusion (physical privacy): “such as when a stranger encroaches in one’s personal space.” But I think that then there are more important concerns (safety, health, wealth) than privacy.

The paper distinguishes between social sciences and behavioral sciences (abstract: “connect insights from social and behavioral sciences”):, but I would think that the second is a small subset of the first, and this writing overestimates the role of behavioral sciences.

The paper organizes studies around three themes: (1) that people are uncertain about privacy threats, and their preferences over them; (2) that people's concerns are context dependent (psychologists' favorite conclusion); (3) malleability of privacy concerns.

The paper uses the, overly broad, term privacy paradox for the apparent findings that people's verbal expressions of their concerns about privacy deviate much from their actual behavior. This finding will not be surprising to economists, especially given the vagueness of privacy risks.

Several reported findings may be due to experimenter demand. %}

Aczel, Amir D. (2004) "*Chance. A Guide to Gambling, Love, The Stock Market and just about Everything Else*." Thunder's Mouth Press, New York.

{% Theorem 2.1.1.1 (on p. 34) and top of p. 35: Cauchy equation implies that f is linear as soon as f is continuous at one point or bounded from one side on a set of positive measure. Only stated there for functions on $\mathbb{R}$. Stated for functions on $\mathbb{R}^n$ in Theorem 5.1.1.1 on p. 215.

P. 151 (also 240, with f^{-1} instead of f): Quasi-linear mean is CE (certainty equivalent) under EU of 2-outcome prospects with fixed probabilities. Translativity is constant absolute risk aversion and homogeneity is constant relative risk aversion (both only of CEs but then it follows for preference). Theorem 3.1.3.2 then gives linear-exponential (CARA) and log-power (CRRA).

Section 5.3.1 gives functional equations characterizing arithmetic means. That is, they characterize subjective expected value as in Ch.1 of my 2010 book in terms of properties of certainty equivalents.

§5.3.2 (Theorem on p. 242) characterizes quasilinear weighted means, which are the CEs of EU for all binary probability-contingent prospects. The main axiom used is bisymmetry.

§6.2 studies associativity, F(Fx,y),z) = F(x,F(y,z)) and the like. They usually give additive representation $F(x,y) = f^{-1}(f(x) + f(y))$ and the like. Readers who know Gorman's (1968) theorem may recognize separability of (x,y) and of (y,z) in (z,y,z), and then the result comes as no surprise.

§6.4 uses bisymmetry to get $f^{-1}\big(qf(x)+(1-q)f(y)\big)$ (Theorem on p. 287) and nonsymmetric generalizations (Theorem 1 on p. 287).

§6.5 has the autodistributivity property $F[x,F(y,z)] = F[F(x,y), F(x,z)]$ as a nice alternative to bisymmetry, still axiomatizing $f^{-1}\big(qf(x)+(1-q)f(y)\big)$ (Theorem on p. 298).

§7.1, 7.2 have many equations such as $F(G(x,y),z) = H(x,K(y,z))$, with many different functions involved, giving additively decomposable solutions with many different functions involved (Theorem on p. 329). Often differentiability is used.

Ch. 8 considers vectors and matrices but, unfortunately, generalizes the preceding results as binary operations on vectors rather than as n-ary operations on reals. The latter, and not the former, would have given extensions to more than two states of nature. Pity for me. %}

{% **quasi-concave so deliberate randomization**: find evidence for quasi-convexity w.r.t. probabilistic mixing, supporting concave probability weighting in RDU.

In one treatment (Part I), subjects get repeated choice, as usually done, separated by other stimuli so they don't notice. But in another treatment (Part III) the repeated choices are put together so subjects see it and it is explicitly told to subjects that it is repeated choice. Use RIS for implementation of Parts I & III, but in addition also pay all choices in Parts II and IV, arguing that portfolio (income) effects in these parts are not likely to happen. Also in Part III, subjects have many inconsistencies, well here it is deliberate randomization (71% of subjects had it sometimes). It is probably rather that subjects want to avoid responsibility for the choice made, something also nicely illustrated by Cettolin & Riedl (2019 JET). When asked, most subjects gave hedging and diversification as reasons.

In Part IV, subjects had an extra option: Not they choose, but the computer chooses randomly; they had to pay a very small amount for choosing this option. It is like avoiding responsibility as in Cettolin & Riedl (2019 JET). 29% sometimes chose this option.

There may be a confound of experimenter demand: Subjects will figure that the experimenters want them to change choice because, why else ask? Same way as if you put a big orange button on the keyboard then subjects will sometimes push it because, why else would it be there? But experimenter demand is often hard to avoid.

P. 56 3rd para, on probabilistic choice: They find that utility difference (as in Luce's 1959 model) does not predict random choice very well because dominance-or-not, being salient, is important. Rather, questions being easy because of (almost) stochastic dominance or not matters.

Inconsistent choice is correlated with violating EU, but not with risk aversion or violations of RCLA. %}

{% **R.C. Jeffrey model**; **ordering of subsets**: This paper axiomatizes a model of maximization of average expected utility over sets, similar to Jeffrey (1965). The objects are interpreted as probability distributions over outcomes where the set reflects ambiguity over which is the right probability distribution. In this axiomatization, both probability μ and utility u are subjective/endogenous, implying that the model is essentially the same as Jeffrey (1965) and Bolker (1966, 1967) in a mathematical sense. There are some technical differences

regarding continuity and Ahn's model having singletons present in the domain and JBB not.

The model can be considered to be a modification of maxmin EU or it's α-maxmin generalization. The usual Pratt-Arrow characterization of φ^* being more concave than φ is given in Proposition 4 and is now taken as more ambiguity averse. %}

Ahn, David S. (2008) "Ambiguity without a State Space," *Review of Economic Studies* 75, 3–28.

{% Consider three states of nature denoted x, y, z. The subjects are told that y has probability 1/3, and are told that x and z have unknown probability. Subjects were not told more. In reality, x and z also have objective probability 1/3. (The authors generated event x by first letting a number p_x be selected at random (uniform distribution) from [0,2/3], and then let x be chosen with probability p_x, and z with probability $2/3 - p_x$; see footnote 3 on p. 201). However, this is only a roundabout manner for generating probability 1/3. Given that this procedure was not told to the subjects, so it does not matter for them, and given that any researcher who knows probability calculus knows that it is just objective probability 1/3, no use doing this two-stage procedure.)

Let subjects choose prospects organized similarly as budget sets. The axiom of revealed preference is reasonably well satisfied. (**revealed preference**)

Consider the following models:

(1) "Kinked," being RDU (for uncertainty; also known as CEU) with fixed decision weight 1/3 for state y (amounting to EU for known probabilities). Thus, RDU for the remaining states is like **biseparable utility**, and comprises most other models such as Gilboa & Schmeidler's (1989) maxmin EU, Schmeidler's (1989) RDU, α-maxmin, and Gajdos et al.'s (2008) contraction expected utility. The authors, fortunately, do combine it with RDU for risk (§8) and not just with EU for risk.

(2) Recursive EU, where as second-order distribution they take the uniform prior over [0,2/3], and where the two utility functions are exponential with possibly different exponents. It is useful to note that the rho parameter of utility for risk can be identified from bets on s_2, and then the parameter for ambiguity

can be identified from bets on s_1 and s_3 while keeping the payment under s_2 equal 0.

§7, e.g. footnote 11 on p. 212: they favor least-squares data fitting without probabilistic error theory.

The find that RDU (“kinked”) fits better than recursive.

The do not reject the H_0 of SEU for 64% of the subjects. Problem with such within-subject tests is that it assumes stochastic independence of within-subject choices, and needs many choices per individual to get statistical power. %}

Ahn, David S., Syngjoo Choi, Douglas Gale, & Shachar Kariv (2014) “Estimating Ambiguity Aversion in a Portfolio Choice Experiment,” *Quantitative Economics* 5, 195–223.

{% Their model is called partition-dependent SEU.

Consider decision under uncertainty in an Anscombe-Aumann framework, with partition-dependent SEU, as follows. They do not take an act as a function from S to outcomes, as Savage did, but (as did Luce) as a 2n-tuple, so that the act and its preference value can depend on the partition chosen. Thus, they can accommodate event splitting (**coalescing**) and so on. In their model there exists a utility function u and a nonadditive measure ν. For a partition $(E_1,\ldots E_n)$ of S, SEU is maximized w.r.t. u and $P(E_j) = \nu(E_j)/(\nu(E_1) + \cdots + \nu(E_n))$, so, with ν for single events but normalized.

They present axiomatizations. First, they assume usual axioms giving SEU within each partition. They use Anscombe-Aumann axioms. (I would have preferred tradeoff consistency; oh well …) This within-partition representation does not yet relate between-partition representations in any sense. A monotonicity condition implies the same u for all partitions. For the rest (for the role of ν), they consider two special cases:

CASE 1. The collection of partitions considered is nested: For all two partitions, one is a refinement of the other. Then an extra sure-thing principle characterizes the model with ν: if acts f and g agree on event E, then the preference between f and g is not changed if the common outcomes on E are replaced by other common outcomes, but also not if the partition outside of E is changed (so, refined or coarsened). This axiom ensures the consistent conditioning in $P(E_j) = \nu(E_j)/(\nu(E_1) + \cdots + \nu(E_n))$, from always the same ν.

CASE 2. The collection of partitions considered is the collection of all partitions. Then besides the version of the s.th.pr. of Case 1, also an acyclicity axiom is imposed.

P. 656: To the authors' knowledge, they are the first to incorporate framing and partition-dependence in a formal model. However, Luce preceded here. A brief but not very accessible account of his ideas is in Luce (1990, Psychological Science 1). A complete account is in the book Luce (2000). Luce also worked on such models in the 1970s, such as in Ch. 8 of Krantz et al. (1971). Luce used the term experiment instead of the term partition, and the elements of Luce's experiment need not always give the same union (so, they are conditional on their union). Ahn & Ergin always have S as the total union.

The topic of partition dependence is even more central in Birnbaum's work. He does write formal models but does not do formal work with them such as axiomatizations (although he does give derivations of logical relations between preference conditions). He does comprehensive empirical work, testing every empirical detail of framing. Birnbaum, Michael H. (2008, *Psychological Review* 115, 463–501) provides a comprehensive summary. He usually (always?) assumes known probabilities. There is also much empirical evidence on event splitting by Loomes, Sugden, Humphrey, and others.

The authors relate their work to support theory. ν is indeed an analog of the support function. A difference pointed out by the authors is that support theory focuses on probability judgment (Tversky and I started working on a decision theory but he died too soon) whereas they have preferences between acts. A difference not pointed out by the authors is that in support theory there are not only the (partitions of) hypotheses but also there is another layer, of events, and there is a distinction between implicit and explicit unions. Mainly this distinction between hypotheses and events drives why support theory deviates from classical models. Thus, I disagree with the claim on p 663 that this paper provide an extension of support theory to decision theory, or that they provide a decision foundation.

P. 657: The authors relate their model to unforeseen contingencies. A big difference is that in this paper the union of events in a partition is always S, whereas with unforeseen contingencies there are typically events outside of S.

A topic for future research is to what extent the particular partition-dependence proposed here, with consistent conditioning on one nonadditive measure, is of interest empirically or normatively.

The EU assumed within given partitions of course runs into empirical violations of EU, although there is empirical evidence that using the same partition for describing all acts reduces the violations.

The model of this paper is also reminiscent of the source method by Abdellaoui, Baillon, Placido, & Wakker (2011 American Economic Review), where different sources are different partitions. One difference is that the source method does not give up extensionality, and acts are functions from states to outcomes. Another is that the source method allows for violations of EU throughout, also within a source/partition. In the source method, there can be subjective probabilities within each source but they can be transformed differently for different sources. %}

Ahn, David & Haluk Ergin (2010) "Framing Contingencies," *Econometrica* 78, 655–695.

{% The authors consider time inconsistencies, and then naïve choice making. They propose two indexes of naivity. Naivity shows up if an agent strictly disprefers an a-priori-strictly-beneficial commitment, not for wanting to be sophisticated, but for mispredicting future choice. One comparative notion for being more naïve is if dispreferring more of such commitments. The second is by how much money is lost because of naivity (via indirect utility). These are two preference conditions that do not assume any model. The authors emphasize this point much. They extend the indexes to probabilistic future choice. The two indexes of this paper are equivalent for deterministic choice if two conditions hold: (1) only monetary outcomes matter; (2) choice sets are determined only by how much money one has to spend. The authors on p. 2325 mention the equivalence without mentioning the restrictions.

Footnote 2 explains that the authors consider single-choice choice functions, so that a selection has to be made if there are several optimal, mutually indifferent, choice alternatives. I did not try to find out how the authors then can rule out complete indifference. Probably using some strong monotonicity in money.

The authors see what their conditions mean for some models, primarily quasi-hyperbolic discounting.

In general, different indexes have different pros and cons, and which is most relevant depends on the particular decision situation. To illustrate an alternative index, consider Prelec's (2004 Scandinavian Journal of Economics). His index concerns time inconsistency. He considers the set of all future timepoints at which a decision is taken deviating from the present decision. The total duration of this set is Prelec's index. The authors, unfortunately, do not cite Prelec, probably because they consider time inconsistency to be different than naivity. But Prelec's index can readily be restricted to only naïve choice and, thus, can serve as an index alternative to the ones of this paper. It is also preference-based with no commitment to any model and in this sense precedes this paper. (Prelec, personal communication, explained to me that in the quasi-hyperbolic, also called beta-delta, model, then $\tau = \ln \beta / \ln \tau$ is the relevant index.) Imagine that someone can pay a controler for controlling the future agent and preventing her from time inconsistency, and imagine that this is imperative to be done. Further imagine that the controler is to be paid per time unit. Then Prelec's index is the relevant one, and not the indexes of this paper. In the same spirit, in some decisions under risk the relative index of risk aversion is the relevant one, and in others the absolute index is.

The writing of this paper is narrow in the sense that the authors consider alternative definitions, consider examples where those alternatives give different results than those of this paper, but then blame the alternatives for being counterintuitive (p. 2321, p. 2323) or erroneous (p. 2325), just because they deviate from the ones of this paper. Their own approach is called "most reasonable" (p. 2321). Similarly, someone using an absolute index of risk aversion could blame the relative index just for deviating. %}

{% §3.4 correctly cites de Finetti on his arguments against countable additivity. Unfortunately, it also suggests that Savage disliked countable additivity but Savage (1954, §3.4) did not have such an opinion. For Savage it was not central and only a pragmatic matter of convenience. He used all subsets of the state space and not a sigma-algebra only for expositional purposes, actually preferring sigma-algebra other than for exposition. Savage did express a slight preference for not committing to countable additivity but, again, not out of principle but only pragmatically, and not committing clearly. (Probably to quite some extent so as not to get in conflict with de Finetti who was in a less refined league than Savage.)

The paper considers to what extent infinitely many observations necessarily lead to unique probabilities of all events through the law of large numbers. If the set of events considered is complex and large, and way more so than the number of observations, and if probability is finitely additive, then probabilities may not get uniquely determined. This is of course a mathematical result in the sense that it really builds on finite additivity and complexity degrees of infinity.

§4: this paper derives a set of priors from learning, and only then derives decisions from that. %}

{% **ambiguity attitude taken to be rational**: This paper criticizes the normatively motivated modern ambiguity aversion literature. I, as Bayesian, only and purely study ambiguity for descriptive reasons, and fully agree that the nonEU models (including ambiguity) are not rational. Empirically, though, there is considerable ambiguity seeking (**ambiguity seeking**). The paper, appropriately, writes on p. 252 2nd para that its arguments have been known before by specialists. The paper is written with enthusiasm of a kind that will especially appeal to young readers, but it is informal and not very sophisticated. I disagree with many nuances.

Central to the paper are the rationality problems of ambiguity models in dynamic decision making and **updating** (**dynamic consistency**). However, these are general problems of nonexpected utility and not particularly of ambiguity. Because the paper assumes expected utility for risk (and then can assume payment in utils so that it is risk neutrality), a debate of ambiguity (which is about *differences between* unknown and known probabilities) is the same as the debate about nonexpected utility. It has been widely known since Hammond (1988), and was explained more clearly before in the impressive Burks (1977, Ch. 5), that nonEU violates convincing principles in dynamic decision making. The best paper to start on this debate is Machina (1989). Ghirardato (2002) is also good. He appropriately used the term folk theorems for the results, because they were widely known. I wrote
Wakker (1999) http://personal.eur.nl/Wakker//pdf/alias.pdf.
The debates are often hard to pin down because the relevant assumptions discussed are so self-evident (surely I as Bayesian think so) that people often assume some of those critical conditions implicitly, and verbal descriptions often can equally well refer to one condition as to the other.

In the resolute choice approach one gives up what Machina (1989) called consequentialism so as to maintain dynamic consistency. Then one's decisions depend on risks borne in the past; i.e., on events that could have happened at some stage in the past but are now known to be counterfactual and nonexistent. In Wakker (1999) I described this as believing in ghosts. This was Machina's preferred way to go, and also McClennen's who coined the term resolute for it, and also Jaffray's.

In **sophisticated choice** one gives up dynamic consistency, so as to maintain consequentialism. Then prior and posterior preferences are not the same, and from a prior perspective one may violate dominance (one is willing to pay for precommitment). This was preferred by Karni & Safra and is the least unconvincing for nonEU in my opinion. In Wakker (1999) I called this split personality.

A third approach is to give up RCLA, which for uncertainty is something like event invariance. These are models about not being indifferent to the timing of the resolution of uncertainty. I will not discuss them further.

Footnote 1, p. 250 suggests that probabilistic sophistication (Machina &

Schmeidler's P4*) is a special case of the sure-thing principle but this is not so. P4* implies Savage's P4 which is logically and conceptually different from the sure-thing principle (Savage's P2).

P. 251 $\ell\ell$. 1-2: "The all-consuming concern of the ambiguity aversion literature is the Ellsberg "paradox."" expresses well my impression: the field is too much focused on the Ellsberg paradox.

P.254 4th para and elsewhere: It is not true that capacities (weighting functions) are interpreted as indexes of belief in nonEU. Some people, especially novices, do so, but experienced people know that this need not be. Abdellaoui et al. (2011 American Economic Review, p. 701 top) wrote, where source functions capture the nonadditivity of capacities/weighting functions: "Source functions reflect interactions between beliefs and tastes that are typical of nonexpected utility and that are deemed irrational in the Bayesian normative approach." They reference preceding contributions by Winkler (1991), Vernon Smith (1969), and others. Wakker (2004, Psychological Review) suggested that inverse S/source-sensitivity could be a belief component but pessimism/source-preference/ambiguity-aversion not so. Also in maxmin EU many are aware of the difference. It is explicit in contraction expected utility by Gajdos, Hayashi, Tallon, & Vergnaud (2008, JET), for instance. KMM's smooth model also has it explicitly.

The paper then assumes risk neutrality, or, in other words, EU plus payment in utils.

P. 259 discusses what the authors call irrelevance of sunk costs but what amounts to the additivity axiom (discussed in Wakker, 2010, Ch. 1) restricted to constant acts in combination with some updating. It is well known that nonEU can depend on counterfactual risks and costs (see above on resolute choice).

What the authors call fact-based on p. 261 is like **sophisticated choice**. The informal presentation does not allow for an exact pinning down.

P. 267, on dynamic inconsistency à la Strotz, takes it purely as externally-imposed (say ingrained in your genes) and not as decision based, thus ducking the central questions there. The dynamic inconsistency resulting under ambiguity is not taken that way in this paper. Hence the difference ...

P. 275 criticizes multiple priors for the concept of unknown true probability, with which I agree. They then go to self-references, referring to previous technical work by themselves with limiting theorems on identifying better-knowing experts versus pretending-phony-experts.

§5 (announced before on p. 255) argues that ambiguity aversion may be a mis-applied social instinct. In some places it is suggested that it then could be rational, but misapplications do not seem to be rational I would think. This instinct-misapplication-interpretation does not invalidate attempts to model things using ambiguity models. Note also that the considerable ambiguity seeking found empirically shows that more is going on. Another problem in this explanation is that most interactions with other human beings can be expected to be favorable rather than unfavorable, because human beings have more common interests than conflicting interests. So, I think that the misapplied social instincts should generate more ambiguity seeking than ambiguity aversion. In the conclusion section, pp. 280-281, the authors will argue that their mis-applied heuristics model is descriptively superior to existing models. Such a claim, with almost no knowledge of the empirical literature, based mostly on theoretical examples on updating (see their first problem there), is naïve. The second problem on p. 281 has a strange and incomprehensible mix of rational and descriptive requirements. The third problem seems to be unaware that descriptively working people know well that not only fit but also parsimony are important, a standard fact in statistics in all empirical fields. %}

{% **risky utility u = transform of strength of preference v, latter doesn't exist**: writes on p. 50: "In effect the utility whose measurement is discussed in this paper has literally nothing to do with individual, social or group welfare, whatever the latter may be supposed to mean."

Paper gives nice account, didactical with numerical examples etc., of the difference between ordinal utility and cardinal vNM utility. Nice for students with little mathematical background.

P. 31: "Whether or not utility is some kind of glow or warmth, or happiness, is here irrelevant;". Footnote 4 on that page is pessimistic about the step, called psychological, philosophical, of relating utility to satisfaction, happiness, etc.

P. 34 ℓℓ. 2-3 does the naive "expected utilitycism" of saying that all of life is decision under uncertainty.

independence/sure-thing principle due to mutually exclusive events: p. 37 2nd para gives the nice separability argument for vNM independence that goods contingent upon mutually exclusive events are never consumed jointly, which was first put forward by Marschak (see Moscati 2016).

P. 37 last para states that different ways of generating same probability distribution should be equivalent.

Paper makes clear that whether a function is ordinal/cardinal etc. depends on what we want the function to do, such as on p. 40 middle. P. 43 bottom states the **utility of gambling**.

P. 42 already has the **probability triangle**.

P. 44 clearly states the prospect theory/Markowitz idea that outcomes are taken as changes with respect to a reference point, and not as final wealth. He later refers to Markowitz for it.

P. 45 shows this weird past convention of calling convex what is nowadays (1980-2023) called concave.

P. 46: on difficult observability status of reference point theories in absence of theory about location of reference point: "Markowitz recognizes that until an unambiguous procedure is discovered for determining when and to what extent current income deviates from customary income, the hypothesis will remain essentially nonverifiable because it is not capable of denying any observable behavior." %}

{% **EU+a*sup+b*inf**: A special case of neo-additive RDU for uncertainty. The agent, for every act, adds an "unforeseen" state, which she endows with the worst outcome of the act. It means that the worst outcome is overweighted. The author uses tradeoff consistency and thus escapes from drawbacks of the Anscombe-Aumann framework. (**tradeoff method**) %}

Alon, Shiri (2015) "Worst-Case Expected Utility," *Journal of Mathematical Economics* 60, 43–48.

{% An important improvement of Alon & Schmeidler's (2014) axiomatization of maxmin EU. They had one problematic axiom, Axiom 7. This paper shows that it can be removed. Now a clean preference axiomatization of maxmin EU results, with simply all the natural analogs in terms of the, tractable, endogenous midpoint operation, of the mixture axioms used by Gilboa & Schmeidler (1989). Thus, Theorem 1 provides the most appealing preference axiomatization of maxmin EU existing today (2022). %}

Alon, Shiri (2022) "A Comment on the Axiomatics of the Maxmin Expected Utility Model," *Theory and Decision* 92, 445–453.
https://doi.org/10.1007/s11238-022-09879-8

{% Every individual in society satisfies Savage's axioms and does SEU, and society is assumed to do maxmin EU. Society's preferences are maxmin EU with utility an average of the individual utilities and the set of priors the convex hull of the individual priors (Theorem 2), or a subset of it (Theorem 1) if and only if the following two Pareto conditions: The authors impose Pareto only if there is agreement on the probabilities or on the utilities and, thus, avoid impossibility results by Mongin and others on aggregating SEU. Agreement on probabilities is only needed for exchangeable partitions where all agents agree on this exchangeability, so, it is observable (socially unambiguous partition). Note that these are not subject to source preference because agents do SEU.

They assume at least one such twofold partition to exist, referring to, say, a coin toss. Agreement on utility is ordinal in the sense of ordering the relevant outcomes the same way. P. 1182 middle para suggests that it makes sense that society more than individuals are not ambiguity neutral. My opinion is opposite: it is natural that aggregation at society planning level will be more rational. %}

Alon, Shiri & Gabrielle Gayer (2016) "Utilitarian Preferences with Multiple Priors," *Econometrica* 84, 1181–1201.

{% Do the Bewley (1986, 2002) model but now for qualitative probability. %}

Alon, Shiri & Ehud Lehrer (2014) "Subjective Multi-Prior Probability: A Representation of a Partial Likelihood Relation," *Journal of Economic Theory* 151, 476–492.

{% **tradeoff method**: Is used to obtain the first axiomatization of maxmin EU that I consider to be satisfactory, not needing Anscombe-Aumann. Thus, it does not need EU for risk, and, more importantly, does not need the dynamic backward induction assumption of the Anscombe-Aumann framework (p. 384 3rd para). Alon (2022) provided a significant improvement, showing that their most complex Axiom 7 is implied by the other axioms and can be removed. Thus, Alon (2022) provided the nicest axiomatization of maxmin EU that I know (April 2022).

I agree much with the discussion of axioms on pp. 385-386. P. 393 penultimate para explains that the axiomatization in Ghirardato et al. [12] uses an operation which implies that their axioms involve infinitely many variables and in this sense are intractable. This paper avoids this problem by only using, roughly, 50-50 subjective mitures.

P. 392 Axiom A0* suggests that for the biseparable approach topological separability would be needed. However, Köbberling & Wakker (2003, §7) provide several generalizations for this approach, obtained as corollaries of their results using the tradeoff technique. Their Observation 18 shows that topological separability can be dropped, as they point out on p. 407 last line. Hence Axiom A0* is redundant. %}

{% Repeated choice. %}

Aloysius, John (2002) "A Behavioral Model of Intertemporal Decision Making under Risk," University of Arkansas.

{% Discusses Samuelson's colleague, much literature about it, and the extent to which it entails a violation of expected utility. Presents the analysis of Tversky & Bar-Hillel, which shows that the behavior of Samuelson's colleague is precluded by the following three conditions:

A1 ($200_{0.5}(-100)$) is not liked under all levels of wealth possible for the 100 times repeated Samuelson game, i.e., [−10000, 20000]),

A2 ("dominance") if prospect X is not liked conditional on each outcome of prospect Y, then X should not be liked under Y), and

A3 (transitivity).

Axiom A2 is called dominance, which is misleading because A2 is pactically as strong as independence (especially in the version of standard gamble

consistency as I call it). The author argues that the behavior of Samuelson's colleague can be reconciled with expected utility more than thought before. If I understood well, he does so by taking what is sometimes called utility of income; i.e., at every choice of accepting or not accepting the prospect the reference point is the status quo of that moment, and probably abandoning axiom A1. I did not understand the role of Samuelson's citation on pp. 65-66. One can of course complicate by bringing in dynamic models such as distinguishing between conditional preference and preference if the event actually happens. %}

{% Comments for version of 29 Nov 2018.

This paper measures the ambiguity indexes of Baillon et al. (2018, ECMA) in a sample of almost 300 people in the Dutch population of the Dutch bank household survey. The sample is representative, however, with the restriction that subjects did financial investments. The paper also measures risk attitudes and has all kinds of demographic info. The indexes are measured for four sources: familiar individual stock (chosen by the subjects themselves), the local stock market index, a foreign stock market index, and the crypto-currency Bitcoinn. What Baillon et al. take as insensitivity index, these authors take as perception of ambiguity. I will continue to use the term insensitivity.

65% of subjects is ambiguity averse, 5% is ambiguity neutral, and 30% is ambiguity seeking. The four aversion indexes are highly correlated for the different sources, with 1 factor explaining 70% of their variance. The insensitivity indexes for the different sources are much less related to each other. It suggests that aversion for financial stocks is only person-dependent but source-independent, whereas insensitivity is also source dependent.

Insensitivity is lower for financial literacy and better education, supporting its cognitive interpretation. (**cognitive ability related to likelihood insensitivity**)

correlation risk & ambiguity attitude: ambiguity aversion is positively related to risk aversion.

Aversion and insensitivity are almost unrelated, supporting their orthogonality.

For a 0.50 gain probability, 65% of subjects is risk averse. For a 0.33

probability, 56% is risk seeking.

Many subjects are ambiguity seeking for domestic stocks (**ambiguity seeking**) but ambiguity averse for foreign stocks, showing the desirability of source dependence of ambiguity attitudes, as also shown by Tversky & Fox (1995). %}

{% Consider risky experimental choices from a large representative sample from the Danish population also used in other papers, with varying prior endowments in the lab. They here use a 2009 sample. They also have data on wealth of the subjects, which is possible in Denmark, which they now for the first time bring in and this is a novelty of this paper. This Danish data set is very valuable because it can have such information. Using it, the authors can investigate dependence of risk attitude on wealth. For wealth dependence, they assume homogenous preferences, i.e., a representative agent. Their (claimed) finding is between complete asset integration and none at all, i.e., partial asset integration. Unsurprisingly, they find asset integration for the prior endowment in the lab, but not for bank account.

With w denoting wealth and y denoting experimental money won, they take a two-variate utility function U(w,y), and do not assume asset integration (which would give U(w+y)) but use another 3 parameter family

$$U(w,y) = \left((\omega w^{\rho} + y^{\rho})^{1/\rho}\right)^{1-r}$$

where ρ is taken to reflect nonlinear asset integration, ω reflects importance of w, and r would be risk aversion if there were perfect asset integration (otherwise ρ

and ω also influence risk attitude). For $\omega = 0$ the functional has complete asset independence (“nonintegration”), depending only on y. For $\omega = 1$ and $\rho = 1$, it has perfect asset integration, depending on $w + y$. I find ρ, elasticity between w and y, hard to interpret behaviorally. Given that w will greatly exceed y, a large ρ means more weight to w and, hence, ω and ρ interact. ω and ρ will also interact with risk attitude.

The authors fit assuming RDU (with power weighting, unfortunately) or EU as they call it, with utility function U(w,y). As explained in §8.5 of my 2010 book, I regret this terminology because giving up asset integration is giving up EU. w plays a similar role as reference point in prospect theory. Thus, what they do theoretically is in fact prospect theory with a particular form of reference dependence. They find a bit of wealth dependence of the curvature of U, but weakly so.

The authors interpret dependence of U’s curvature on w (wealth dependence) as reference dependence. However, this cannot be inferred from the data, bit is only the interpretation of the authors. It could also be wealth dependence of a reference-independent (terminal-wealth) utility function. Their finding of weak reference dependence may also be weakly nonconstant absolute risk aversion. They should more carefully compare different pairs w,y with the same sum $w + y$, rather than brute-force data fitting with interacting parameters. In the terminology of Bleichrodt, Doctor, Gao, Li, & Meeker (2020 JRU), they should distinguish reference dependence and outcome dependence as in Figs. 1d1 and 1d2 of Bleichrodt et al., so, situations that are identical in terminal wealth but different in reference points/outcomes.

The authors suggest that their data shed new light on Rabin’s (2000) paradox. Well, Rabin himself already pointed out that loss aversion explains much of his paradox, which entails reference dependence, as (possibly) comprised by using U(w,y), and their claims are consistent with that.

They measure probability weighting but use the RIS, something strongly criticized by Harrison & Swarthout (2014). %}

Andersen, Steffen, James C. Cox, Glenn W. Harrison, Morten I. Lau, E. Elisabet Rutström, & Vjollca Sadiraj (2018) “Asset Integration and Attitudes toward Risk: Theory and Evidence,” *Review of Economics and Statistics* 100, 816–830.

{% Considers SEU, with, however, **second-order probabilities** (interpreted as ambiguity), with bingo cages. The introduction suggests that virtually all ambiguity models model it as second-order probabilities or at least sets of probabilities (multiple priors). Does not mention the other theories that use nonadditive measures. Uses meta-population assumptions about distributions and then fits this to data. Some extreme results are found. P. 179: For probability that experimenter knows to be 20%, the subjective probabilities are about 40%. Assume same utility for risk as for uncertainty. %}

Andersen, Steffen, John Fountain, Glenn W. Harrison, Arne Risa Hole, & E. Elisabet Rutström (2012) "Inferring Beliefs as Subjectively Imprecise Probabilities," *Theory and Decision* 73, 161–184.

{% **probability elicitation**; elicit choices between prospects with known probabilities, to elicit risk attitudes (probability weighting and utility), and then use those to infer subjective probabilities from **proper scoring rules** (do QSR, and also the nonproper linear scoring rule). Use error models and econometrically fit all parameters in one blow, with the usual technique of this team (that cannot handle indifferences and) that takes different choices of the same individual as stochastically independent (given individual characteristics), with subjects only distinguished by their characteristics. Thus, for each combination of characteristics they get a global agent. Restrictive is that they assume global probabilistic sophistication, so that they can´t handle ambiguity aversion and the Ellsberg paradox.

They claim repeatedly that with slight risk aversion already an interior solution will result for the linear scoring rule, but this is not so. It is only so for subjective probability 0.5 (and then 0.5 as interior solution). If subjective probability is 0.9, for instance, then under considerable risk aversion still $p = 1$ is optimal under linear scoring. Rather can the many interior solutions found be explained by the compromise effect.

decreasing ARA/increasing RRA: Find strongly increasing RRA. Strangely enough, they find optimistic concave probability weighting (they fitted power weighting and not inverse S).

Problem of this paper is that scoring rules serve to quickly get beliefs and to circumvent extensive measurements. If the whole uncertainty attitude including subjective probabilities is measured anyhow, then it is not belief measurement but entire uncertainty attitude measurement, and the typical feature of scoring rules is lost. It is interesting to study scoring rules and to also know about entire risk attitudes to know more about scoring rules, which makes this paper valuable, but it cannot go as an improved way to do proper scoring rules.

They measure probability weighting but use the RIS, something strongly criticized by Harrison & Swarthout (2014). %}

{% **time preference**; **error theory for risky choice**; **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**

In discounted utility, there are two unknowns, being the subjective discount function and the subjective utility function. This is much like prospect theory that has subjective probability weighting and subjective utility (let us focus on gains, so, no loss aversion) as two unknowns. Estimating the two subjective functions jointly can be done but takes some work in both cases. In intertemporal choice, people have mostly simply assumed linear utility to simplify the task, but some studies sought to generalize and reckon with nonlinear utility.

A big controversial issue has been, since the ordinal revolution of the 1930s, what the status of cardinal utility is, and also if cardinal utility used within expected utility can be equated with that in intertemporal choice. The history is presented in Abdellaoui, Barrios, & Wakker (2007, §2-3). Early allusions to such differences of cardinal utility are in Samuelson (1937 last paragraph of paper, on p. 161) who from the beginning understood this issue, and Baumol (1958). There have been many debates on the issue using a risky-riskless utility distinction (I do not like here the lumping of all nonrisky versions of cardinal utility into one "riskless" class, something like non-elephant zoology). I favored equating all cardinal utilities in Wakker (1994, Theory and Decision), but not to be done naively. It may be done after work, such as handling differences between risk attitude and marginal utility using, for instance, prospect theory. Epper, Fehr-Duda, & Bruhin (2011) do this in a sophisticated manner.

This paper by Andersen et al. is unaware of the mentioned history. It assumes, without any discussion or justification, that cardinal utility is to be measured from risky choice only and take this as almost by definition (why not directly from intertemporal choice by many observations and data fitting, for instance; Abdellaoui, Attema, & Bleichrodt (2010) give a nonparametric method for deriving intertemporal utility from intertemporal preferences, and Bleichrodt, Rohde, & Wakker (2009) give yet another). It further assumes that cardinal utility then is to be used for intertemporal choice. Thus, it falls victim to a version of what Luce & Raiffa (1957, p. 32) called "Fallacy 3." Comes to it that this paper uses expected utility to measure risky utility, having utility distorted by the other components of risk attitude. Those other components have even less to do with intertemporal. The authors' position appears for instance from pp. 589-590, or from p. 603: "Although the basic insight that one *should* elicit risk and time preference jointly seems simple enough" [italics added]. P. 614: "Our results have direct implications for future efforts to elicit time preference. The obvious one is to jointly elicit risk and time preferences, or at least to elicit risk preferences from a sample drawn from the same population, so that inferences about time preferences can be conditioned appropriately."

In earlier separate papers the authors elicited time preference and risk attitudes separately, for time preference apparently assuming linear utility. In this paper they combine the two, using the risky-utility function that they estimated from risky choice, assuming expected utility (EU), to estimate time preference. This correction for nonlinearity of utility leads to less discounting (because the large late payment now is less valued because of concave utility rather than because of strong discounting) and less deviation from constant discounting. They use power utilities. Using risky choices and expected utility to measure discounting (or, equivalently, its integral, being utility of life duration), and then using this correction of linearity in intertemporal choice, has been done before in the health domain in QALY calculations. Two references are:

Redelmeier, Donald A. & Daniel N. Heller (1993) "Time Preference in Medical Decision Making and Cost Effectiveness Analysis," *Medical Decision Making* 13, 212–217.

Stiggelbout, Anne M., Gwendoline M. Kiebert, Job Kievit, Jan-Willem H. Leer, Gerrit Stoter, & Hanneke C.J.M. de Haes (1994) "Utility Assesment in Cancer Patients: Adjustment of Time Tradeoff Scores for the Utility of Life Years and Comparison with Standard Gamble Scores," *Medical Decision Making* 14, 82–90.

Utility functions for risk and time are not taken completely identical in this paper. Risky choice gives instant payments, which is taken to be emotional and driven by temptation. Long-term intertemporal choice is not subject to such emotions. Hence, the authors take power (= CRRA) utility, but with initial wealth terms added as extra utility parameters, which may be different for risky choice than for intertemporal (p. 584 3rd para; p. 592 2nd para). The power is taken the same for both. Why the initial-wealth parameter would be good to capture the difference is not clear to me. The authors argue that the difference between immediate emotional choosing or long-term lies in different ways of integrating payments with initial wealth, but I can imagine many other effects and consider it a question to be tested empirically. The difference between risky and intertemporal utility that they use here is that emotions can generate extra initial wealth for time, and not as it should be that these can be different concepts.

The various parameters are derived from fitting data over the whole group, taking all choices (both within and between subjects; p. 586 2nd para) as independent observations and assuming a representative agent. They later do regressions where demographic variables (gender (**gender differences in risk attitude**), age, and so on; p. 604) are added as regressors, which gives some individualization, but still within-subject choices are then taken as statistically independent within same subgroups. (**relation age-risk attitude**)

P. 585 footnote 4 on the history of the price list (the authors use the inefficient term multiple price list): Cohen, Jaffray, & Said (1987) preceded Holt & Laury (2002) by 15 years here, and still were not the first. (**Prospect theory not cited**) (**risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**)

The paper takes a simple position regarding aggregation. The opening sentence says that there are [only?] three ways of aggregation for utility, being over goods, time, and uncertainty. The authors do not consider other types of aggregation such as over different persons as in welfare and utilitarianism, for instance, or over different locations, and so on. Different body locations to do radiotherapy, to mention yet one more.

real incentives/hypothetical choice, explicitly ignoring hypothetical literature: p. 585 top writes: "There are only a few studies that address the joint elicitation of risk and time preferences directly using monetary incentives and procedures familiar to experimental economists." (**Prospect theory not cited**) §4 cites two hypothetical-task studies but they are not as close as studies mentioned above.

random incentive system between-subjects (paying only some subjects): p. 586 bottom: one of 10 subjects was paid for real.

equate risk aversion with concave utility under nonEU: As do so many economists, the authors equate risk aversion with concave utility. Unlike most economists, they are aware of the problematic nature of this equating and mention it in footnote 11 (p. 589). Yet, the confusions continue in their writings. If one uses the term risk aversion for concave utility as they do, then what term to use for what others call risk aversion? P. 591 2nd para claims evidence for risk aversion, which is solid if risk aversion concerns the empirical phenomenon of preference for expected value but less clear (because rarely properly separated and, therefore, concavity of utility usually overestimated) if it concerns concave utility. The confusion is aggravated because the authors cite Holt & Laury (2002) for it, who do not separate risk aversion from concave utility, and then spend 10 lines on their own work, but not on the ocean of other literature reviewed for instance by Starmer (2000). The beginning of §C shows that the authors do need the evidence for the claim of concave utility because they contrast the above with arguments for linear utility for small stakes.

linear utility for small stakes: They state it on p. 591, beginning of §C. Selten, Sadrieh, & Abbink (1999) found that the deviations from expected utility are stronger than those from linear utility, which for this context suggests that the approach of this paper generates bigger new deviations than the original deviations that it avoids.

My opinion summarized: Assuming linear utility for measuring discounting is better than the utility correction of this paper because EU utility captures more nonEU risk factors than true utility curvature for risk, let be for intertemporal.

P. 602: more error in risky questions than in intertemporal. %}

{% Yet another analysis of a Denmark data set, which they continue to call field study. This sampling was done in 2009 (p. 685). This time they focus on the magnitude effect, whose estimation is the contribution of this paper, and they allow for individual heterogeneity.

The abstract writes: "If the magnitude effect is quantitatively significant, it is not appropriate to use one discount rate that is independent of the scale of the project for cost–benefit analysis and capital budgeting." I do not understand here why a descriptive finding can fully determine a prescriptive procedure.

real incentives/hypothetical choice, explicitly ignoring hypothetical literature: they explicitly ignore studies using hypothetical choice except some early ones, writing on pp. 671 bottom (& p. 678): "We concentrate our review on studies with real monetary rewards, but also discuss the earliest papers on magnitude effects that rely on hypothetical questions, and studies that allow for nonlinear utility functions." They explicitly use the words "statistically significant" for every result of that kind.

P. 671 writes: "We carefully review the most important contributions here, and every other paper in Appendix A (available from the authors on request)." From that appendix we can learn what are unimportant contributions!

Pp. 684-685 again equates risky utility with utility for discounted utility, as the authors do in other papers.

P. 685 writes: "This design does not assume that behaviour is better characterized by expected utility theory (EUT) or some other model." suggesting full generality for their utility measurement, independent of whatever decision model is used. However, they simply use EUT to derive utility on pp. 686-687. P. 689 reiterates the claim: "Nothing in this inferential procedure relies on the use of EUT, or the CRRA functional form."

P. 685 writes that there were 40 intertemporal choices and 40 risky choices, where each subject had a 1/10 probability to play one for real for each of these two 40 tuples.

They measure probability weighting but use the RIS, something strongly criticized by Harrison & Swarthout (2014). %}

Andersen, Steffen, Glenn W. Harrison, Morten I. Lau, & E. Elisabet Rutström (2013) "Discounting Behaviour and the Magnitude Effect: Evidence from a Field Experiment in Denmark," *Economica* 80, 670–679.

{% For N = 413 subjects, representative for Denmark, measure discounting, finding average of 9% annually. Find little evidence of nonconstant discounting. The introductory §2 assumes that the cardinal utility function for intertemporal choice must be the same as for risky choice, via EU or other risk models. Although footnote 6 cites some of the several papers that elicit utility, to be used in intertemporal choice, directly from intertemporal choice, the rest of the paper continues to assume that it must be derived from risky choice. P. 20 seems to take the issue up, writing: "We also assume that the same utility function that governs decisions over risky alternatives is the one that is used to evaluate time-discounted choices. This assumption has been criticized recently, and we take up those issues in Section 7." However, Section 7 does not discuss this issue. It does discuss risk and time, but not the issue of cardinal utility.

real incentives/hypothetical choice, explicitly ignoring hypothetical literature: p. 27 on hypothetical choice: "We ignored all hypothetical survey studies, on the grounds that the evidence is overwhelming that there can be huge and systematic hypothetical biases. It is simply inefficient to take the evidence from hypothetical survey studies seriously."

{% They consider choice under time and risk. Seems that they find that conditioning on timepoints fits better than conditioning on states but that the evidence is thin. %}
Andreoni, James, Paul Feldman, & Charles Sprenger (2017) "A Stream of Prospects or a Prospect of Streams: On the Evaluation of Intertemporal Risks," NBER Working Paper,

{% The authors compare the convex-set method for measuring discounting of Andreoni & Sprenger (2012 American Economic Review) with the measurement of Andersen et al. (2008, *Econometrica*). The latter measured utility using risky choice and EU and then used this to measure discounting. That is, they used risky utility to serve as intertemporal utility. The former method fitted intertemporal utility to intertemporal choice, which is the more natural way to go, as in Abdellaoui, Attema, & Bleichrodt (2010, EJ) or Abdellaoui, Bleichrodt, & L'Haridon (2013 JRU), works not cited by the authors. They use power utility and quasi-hyperbolic discounting to fit. Unsurprisingly, the risky EU utility function is way more concave than the intertemporal utility function. The latter is close to linear. (**linear utility for small stakes**) As many studies on prospect theory have shown, the EU utility function is too concave because it also captures the risk aversion generated by probability weighting. The authors show no awareness of this literature, nor of the Nobel-awarded prospect theory, following a tradition in experimental economics as in Holt & Laury (2002) and others.

(**Prospect theory not cited**)

To define their intellectual position and level, the authors side with Andersen, Harrison, Lau, & Rutstrom (2008), as appears from many parts in their paper:

- P. 452: "However, in an important recent contribution, Andersen et al. (2008) …"
- P. 452: "This observation has reset the investigation of new elicitation tools. …"
- P. 452: "Andersen[,] et al. (2008) (henceforth AHLR) offer the clever use of …"
- P. 463, §4, 1st line describes the two methods as "two recent innovations"

P. 1 footnote 2 gives a nice discussion of the outside-market arbitrage problem in intertemporal experiments. (**time preference, fungibility problem**)

Nicely, this paper also does a predictive exercise, where their convex method fares better than the Andersen et al. method.

P. 459: Taking linear utility in binary choice, they estimate an annual discount rate of 102%. This is absurdly high of course. Bringing in the (overly) concave utility reduces it to 47%, which still is extreme. Their convex method instead, gives annual discounting of 74%, which again is very very high.

Section 3.2.3 explains why the authors used no probabilistic model: They considered Luce's error model but take it up on its weakest point: that it predicts violations of dominance (through irrational switchings), which are not found much in the data.

When justifying a new model by comparing with an existing model in a horse race, one of several difficulties usually is that there is no existing gold standard. So, whatever existing model one takes, many readers will think that it is not interesting because they think that the existing model chosen is not the best one. This happens with me reader here. %}

decreasing/increasing impatience: Find counter-evidence against the commonly assumed decreasing impatience and/or present effect. This may be because they have a front-end delay, as they point out. They give theoretical arguments (p. 3347) but cite no empirical evidence. Attema, Bleichrodt, Rohde, & Wakker (2010, Management Science) find it too and on p. 2026 cite a dozen other studies finding it. The above keyword (**decreasing/increasing impatience**) gives literature in this annotated bibliography.

SUMMARY

Subjects can do weighted allocations of tokens over one timepoint near (some hours) and one some months (1, 2, or 3) ahead. The authors assume time-separable discounted utility, and fit the discounted utility model with power utility with a time-dependent transfer parameter that may reflect background consumption (Stone-Geary utility functions). They find utility close to linear (power 0.921), but still significantly different from linear.

NOVELTIES

Until Jan. 2022 I thought that one novelty of this paper for intertemporal choice is that it simultaneously fits discounting and utility to data. January 2022 I realized that Abdellaoui, Attema, & Bleichrodt (2010) had done that before. (They give both parametric and nonparametric estimates.) So, then only remains as novelty that it has subjects choose from continua of stimuli.

Regarding the simultaneous measuring of discounting and utility, discounted utility, and prospect theory alike, face the difficulty that there are two subjective functions to be estimated, where to estimate one function one would like to know the other. Thus, nonparametric estimations are not so easy to conceive, but have still been found (Abdellaoui 2000 and others for risk; Abdellaoui, Attema, & Bleichrodt 2010 for time; Attema, Bleichrodt, Rohde, & Wakker (2010, Management Science), also for time, writing on p. 2016, on Method 2: “The latter approach is the first one available in the literature that measures the discount function in an entirely utility-free manner.”). Parametric econometric fitting in one blow is of course possible with no problem, and for risk and prospect theory this has often been done. Why it was for a long time not done before for intertemporal choice is puzzling. This paper does it. But Abdellaoui, Attema, & Bleichrodt (2010) did it also with parametric fitting, before.

As regards the only remaining novelty, not letting subjects choose from pairs but from multiple objects, even continua, has often been done in risky/uncertainty choice. Examples are proper scoring rules, and many experiments that ask subjects to divide money over different risky investments. Choi, Fisman, Gale, & Kariv (2007 American Economic Review) nicely did so with choices from budget sets. Again, this had not yet been done in intertemporal choice, and this paper may be the first to do it. A useful move. A drawback is that this approach has biases of its own, such as the compromise effect, of subjects, partly driven by experimenter demand, too much choosing middle answers and no corner solutions. Thus, I expect the number of corner solutions reported on p. 3344 to be an underestimation, and the curvature of utility an overestimation (even if it is already close to linear). I also conjecture that simulations with most models will show that for these stimuli it should nearly always be corner solution.

Thus, the paper is a routine contribution, extending an idea from risk to intertemporal, but it is useful. The implementation of real incentives (p. 3339) is careful, so much that the self-praising “unique steps” (p. 3337 middle) is justified.

PROBLEMS WITH INTERPRETING UTILITY

A difficulty in the writing is that the paper takes Andersen et al. (2008, Econometrica) as the state of the art, probably misled by the prominence of the journal Econometrica (p. 3334 ℓ. 10 ff. “An important step”), and guided by Andersen et al. being experimental economists as are the authors here. I conjectured this difficulty in my comments on this paper in versions of this annotated bibliography before 2015. A confirmation is available since 2015, from Andreoni & Sprenger (2015) "Risk Preferences Are not Time Preferences: Reply (#14)," *American Economic Review*, p. 2287 2nd para: "the work that we saw as the best and most impressive was that by Andersen et al. (2008)." Andersen et al. "solve" the problem of two unknown intertemporal functions (utility and discounting) by measuring utility from risky choices, assuming expected utility uncritically. This was an unfortunate move. Most people had not done this before because they knew it does not work. Thus, Cohen, Jaffray, & Said (1987, p. 11), preceding Holt & Laury (2002) by 15 years, wrote: "The reason why subjects' risk attitudes are not correctly conveyed by the conventional definitions may simply be that these definitions, despite their intrinsic character, take their origins in the EU [expected utility] model, and therefore share in its deficiencies." An advanced study separating out intertemporal utility by measuring, yes, intertemporal utility rather than risky utility, is Abdellaoui, Attema, & Bleichrodt (2010, EJ, not cited by Andreoni & Sprenger). See also Epper et al. (2011), cited below.

Utility from EU captures risk attitude (and does not do so very well) and therefore is not suited to be used in other contexts. A number of keywords in this annotated bibliography starting with "**risky utility u =**" give over 100 references on this topic, dating back to the 1950s. Sentences such as

"the two elicitation methodologies ostensibly measure the same utility concept" (p. 3353)

and

"require further research on the relationship between risk and time preferences. This work is *begun* in Andreoni & Sprenger (2012b)." [p. 3349 italics added here]

suggest that the authors are not really aware of these ideas (despite some literature added on p. 3335 end of 3rd para, with Allais 1953 not fitting there). Their conclusion

"These findings suggest that the *practice* of using HL risk experiments to identify and correct for curvature in discounting may be problematic" [p. 3353; italics added]

therefore will not surprise many people, and again shows their focus on Andersen et al. (2008). P. 3354 writes that there is no correlation between risky HL utility and intertemporal utility.

Epper, Fehr-Duda, & Bruhin (2011 JRU; not cited by Andreoni & Sprenger) use utility, inferred from risky decisions, to measure discounting, but use the better prospect theory instead of Andersen et al.'s (2008) expected utility to measure utility, and so as to have the separation of marginal utility and risk attitude more plausible.

They mostly use CRRA utility with time-dependent location shifts (Stone-Geary) as extra parameter. %}

Andreoni, James & Charles Sprenger (2012) "Estimating Time Preference from Convex Budgets," *American Economic Review* 102, 3333–3356. https://doi.org/10.1257/aer.102.7.3333

{% **time preference: comparing risky and intertemporal utility**. Earlier versions of this paper put central that a utility function measured for intertemporal choice can be different than a utility function measured for risky choice. The naïve title (and some cross references in the accompanying paper Andreoni & Sprenger 2012, *American Economic Review* 3333–3356) still refer to that idea, and it is reiterated by Andreoni & Sprenger (2015 "Risk Preferences Are not Time Preferences: Reply (#14)," *American Economic Review* p. 2292). However, this point has been too well known (see keywords with "**risky utility u =**" in this annotated bibliography, giving over 100 references). Fortunately, in this published version the authors removed such claims. Nevertheless, quite some novices to the field have been misled, probably by early versions of the paper, to cite Andreoni & Sprenger for the "discovery" that risky utility need not be the same as intertemporal utility. A mature paper with good empirical tests and mature interpretations of the relevant issues is Abdellaoui, Bleichrodt, L'Haridon, & Paraschiv (2013, Management Science).

The contribution that remains is as follows.

The authors use the same, impressive, design as Andreoni & Sprenger (2012, *American Economic Review* 3333–3356). Subjects invest part of money received in a, possibly risky, soon payment (in some hours) and the rest in a, possibly risky, late payment (in some months), with the late return per invested unit exceeding the soon return so as to make up for impatience/discounting. The risk is always resolved immediately, also for later payments. Subjects' choices are used to infer their risk/time attitude. The classical model for these risky intertemporal stimuli is discounted expected utility, with no interactions between risk and time attitude.

The authors focus on three phenomena in this paper. The first is the common ratio effect but with no riskless prospects involved. There they find no violations of classical discounted expected utility, in agreement with most of the literature.

The second phenomenon focused upon is the common ratio with one riskless prospect involved, as in the Allais paradox. For instance, for a sure outcome α and a risky prospect x, $\alpha \succ x$ but $(\alpha_{0.25}0) \prec (x_{0.25}0)$ is the common ratio paradox, violating expected utility. They find this for α an intertemporal outcome and x a lottery over intertemporal outcomes. This phenomenon has often been observed before. The authors point out that this, of course, need not entail a violation of prospect theory. It was one of the main motivations for developing prospect theory.

[Added July 2014: My analysis below follows the theoretical assumptions of this Andreoni & Sprenger paper. Cheung (2015), Epper & Fehr-Duda (2015), and Miao & Zhong (2015), all in AER, pointed out another problem: In the experiment, there was not one joint probability over early-late payments, but those probabilities were always independent. This invalidates the theoretical analysis of A&S. I nevertheless keep the analysis below, showing that there are more problems in A&S's analysis even if they had done the above right.]

restrictiveness of monotonicity/weak separability: The third phenomenon is interpreted as a special kind of common ratio by the authors, but I prefer to interpret it as a generalized stochastic dominance. Now there are two riskless outcomes. If, for two riskless outcomes, we have $\alpha \succ \beta$, then by generalized stochastic dominance we should have $\alpha_{0.25}0 \succ \beta_{0.25}0$. (More generally, in every lottery we should prefer replacing β by α under generalized stochastic dominance.) The authors call this common ratio with the two probabilities 1 in the first choice but both reduced by the same factor 0.25 for the second choice, and also group it under "direct preference for certainty." As said, I prefer to relate it to generalized stochastic dominance. The violation does not reflect direct preference for certainty, but instead a changed evaluation of outcomes under certainty than under risk. For monetary outcomes α,β, generalized stochastic dominance is regular stochastic dominance and is obvious and trivial. For general multiattribute outcomes, generalized stochastic dominance, even if rational, may easily be violated empirically. Diecidue, Schmidt, & Wakker (2004) use the term ordinal equivalence for what I called generalized stochastic dominance here, and describe the phenomenon as follows (their p. 248), giving references that find empirical violations of it:

> "For general outcomes, e.g. multiattribute outcomes or commodity bundles, ordinal equivalence is not self-evident because the tradeoffs made between commodities may be different under risk than under certainty. For example, chronic health states are two-dimensional outcomes, with one dimension specifying a health state and the other the duration of that health state. Subjects may prefer (blind, 25 years) to (full health, 20 years) but may prefer the riskless gamble (1/2: (full health, 20 years); 1/2: (full health, 20 years)) to the more complex gamble (1/2: (full health, 20 years); 1/2: (blind, 25 years)). Such discrepancies have often been found when measuring quality of life through the "time-tradeoff method," a method that uses riskless preferences of the former kind, and the "standard-gamble method," which uses risky preference of the latter kind (Miyamoto & Eraker, 1988, pp. 17–18; Lenert et al., 1997).
> Bleichrodt and Pinto (2002) observed a direct violation of ordinal equivalence. Participants preferred death to a severely impaired health state following stroke. However, if these outcomes resulted with probability .25 (.75 probability of full recovery), then the preferences reversed." [Death and stroke are not explicitly modeled as multiattribute here but are similar.]

I add here that Bleichrodt & Pinto (2009) found, with FH denoting full health and X some health state, $(FH_{0.75}\text{death}) > (FH_{0.75}X)$ but death < X, which can be taken as yet another violation of generalized stochastic dominance. A special case arises if multiattribute outcomes are intertemporal (streams of) money. It is well known that the presence of risk affects the present bias (also called immediacy effect), weakening it. For example,

(now, \$100) $\succ$ (delay, \$110)

but

(now, \$100)$_{0.25}$0 $\prec$ (delay, \$110)$_{0.25}$0

is a typical finding. Andreoni & Sprenger find this phenomenon also. They point out that it entails a violation of prospect theory. However, it entails a violation of all theories with generalized stochastic dominance, which is virtually all presently existing, and not just prospect theory. In its quantitative form (proportion of investment in presence versus future) it is a strict test of generalized stochastic dominance because any distorting factor affecting the tradeoff between time and outcome for

(now, \$100)$_{0.25}$0 versus (delay, \$110)$_{0.25}$0

differently than

(now, \$100) versus (delay, \$110)

will generate violations. That is, noise goes against the hypothesis here, and it would be statistically better to have a consistency check to assess noise and then do ANOVA type testing. Anyway, the only theory in the literature that can accommodate this finding, cited by the authors for this purpose, is the theory of the utility of gambling (**utility of gambling**), where riskless outcomes are evaluated by an entirely different utility function than risky outcomes, which is the topic of Diecidue, Schmidt, & Wakker (2004), and several other earlier and later papers.

The above violations of generalized stochastic dominance for the context of intertemporal choice have been known before. The earliest paper that I know, showing that the presence of risk moderates the present bias, is Keren & Roelofsma (1995; see my annotations there). Fudenberg & Levine (2011) predicted it in a theoretical model. Similarly, other papers have shown that delaying risks moderates the certainty effect. Anderson & Stafford (2009) find the opposite, with risk increasing impatience. Bommier (2006) presents a theoretical model on it.

If we let the multiattribute outcomes be lotteries themselves (why not?), then, with RCLA, generalized stochastic dominance becomes vNM independence, clearly showing the nontrivial nature of the condition, and that it is not surprising to have it violated for multiattribute outcomes.

Not the same phenomenon, but related, is that risk attitudes for future risks can be different than for present risks, with often less risk aversion for future risks. This was found in empirical studies by Abdellaoui, Diecidue, & Öncüler (2011), Baucells & Heukamp (2010), and Noussair & Wu (2006). Advanced theoretical models capturing interactions between risk and time are in Baucells & Heukamp (2012) and Halevy (2008).

Andreoni & Sprenger cite some of the above literature in the published version of their paper, but did not digest it enough to articulate the novelty of their contribution relative to it. For instance, the sentence in the intro (p. 3558) "The question for this research is whether the common ratio property holds both on and off this boundary of certainty in choices over time." suggests that they are just redoing the well-known tests of common ratio. Their contribution is, as I see it, not that they found new phenomena, because they only reconfirm preceding findings from behavioral economics on common ratios and generalized stochastic dominance known before. Their contribution is that they do so in a very good experiment with good stimuli (multiple choice) and a good implementation of real incentives, bringing in the bigger experimental rigor of experimental economics. For the attenuation of the present bias due to the presence of risk, their paper is probably the best demonstration presently (2013) available.

The authors conclude their paper enthusiastically: "This intuition … may help researchers to understand the origins of dynamic inconsistency, build sharper theoretical models, provide richer experimental tests, and form more careful policy prescriptions regarding intertemporal choice." %}

{% P. 2287 2nd para: the authors reveal their intellectual level and position by writing: "the work that we saw as the best and most impressive was that by Andersen et al. (2008)." [Andersen, Harrison, Lau, & Rutstrom (2008) "Eliciting Risk and Time Preferences," *Econometrica*.]
Whereas the empirical contribution of the authors is valuable, p. 2292 shows once again that the authors did not yet properly digest that the difference between risky and intertemporal utility has been understood in the economic literature since Samuelson (1937), and has been discussed in 100s of papers (see my keyword "**risky utility u =** "), because they still put it forward as their "primary conclusion" when writing: "None of these challenges the primary conclusion of or study: that risk preferences and time preferences are not the same." %}

{% Comments are on the working paper of Feb. 17, 2024. They interview 4,500 mothers in a rural area in India, on finding partners, grooms, for their daughters. They use hypothetical vignets, not about their own daughters but about hypothetical other daughters of other people (to avoid social desirability bias). They vary five attributes of daughters and grooms, such as level of education and whether or not job with government, and see how the mothers choose between different options of desirability of getting groom for daughter. In their sample, marriages are usually arranged, determined by parents. They first do “ex-post” questions, meaning choices between grooms, obtained with certainty. From this they derive utilities, I presume. (Note that this paper uses the term “preference”, or “taste”, for wat I would call utility, where subjective beliefs/probabilities are no part of it, differently than I use the term preference, where it comprises beliefs.) Then they ask “ex ante” questions, where the mothers choose between taking a groom now with certainty or waiting for, say, five years to get a better groom, so with uncertainty involved. Given that they have utilities, they can derive subjective probabilities from the latter questions of getting a good groom in, say, five years. I guess that this is what they did, although I did not do very detailed reading and did not find it easily explained in the paper. To get utilities from the ex post questions, they will have had to make many assumptions. One of them must address the issue that those ex post questions only give the ordinal level of utility, and it then is not clear which cardinal level to use as needed in SEU. They did the main study in 2017, but re-interviewed the subjects five years later, in 2022, finding that the real choices made corresponded well with the hypothetical preferences measured five years before. This is a good way to validate hypothetical questions.

The authors emphasize much their novelty claims on them introducing a new methodology for measuring subjective beliefs. However, I don’t see novelty. Using hypothetical vignets with variations of attributes is widely used in marketing, health, psychology, and other fields, often analyzed using multiattribute utility theory or conjoint analysis. Measuring subjective beliefs/probabilities, not by direct asking which may be difficult for people who don’t understand the concept of probability, but by revealing choices and using as-if models, was first done by de Finetti (1931) and Ramsey (1931), and has since been done in 1000s of papers. Ambiguity theories are popular today, to generalize SEU there and get better measurements of beliefs. The authors suggest to be new on doing the above things. Thus p. 3 writes, naively: “The identification approach is based on the *novel* insight that by varying the amount of information on future realizations of stochastic variables, discrete choice experiments can identify not only preferences, but also subjective beliefs." [italics added] **Prospect theory not cited:** the authors, without one word on it, implicitly assume expected utility. On their claimed novelty of deriving subjective beliefs from observed choices, Footnote 34 on p. 17 writes, strangely, that papers on learning are related. They then do a within-clan citation of Charness & Levin (2005), a paper that only investigates one paradoxical finding on updating that has little to do with learning and very little with measuring subjective beliefs from revealed preferences. Then, even more weirdly, they cite Nash (1951). That citation may look fancy to novices, but the paper has absolutely nothing to do with measuring subjective beliefs. Nash (1951) gives an improved proof, and applications, of his Nobel-awarded 1950 paper on the existence of equilibria.

Situations of once choosing a terminal outcome and deciding when to go for that, which is the marriage problem studied here, is often studied under the name secretary problem, a term not mentioned here.

The findings of this beautiful data set may speak to decisions to give more school education to daughters, and this may be relevant. I regret that the authors did not elaborate on this point. %}

{% Use a data set of betters on football games and fit PT (they write CPT). As objective probabities they take the betting odds of the bookmakers, which are well calibrated. They confirm all findings of PT, with concave utility for gains, convex utility for losses, probability weighting inverse S for gains and losses, and loss aversion, although less strong than traditionally thought. A restriction for these results is that they fit parametric families that do not really allow for different patterns. For instance, utility is logpower (CRRA) with the same power for gains and for losses and, hence concave utility for gains must be accompanied by convex utility for losses. Probability weighting for losses is taken the same as for gains. Thus, both utility and probability weighing do not permit deviations from reflection.

They consider mixture models where subjects can turn either of probability weighting or loss aversion on or off. 2/3 of subjects have loss aversion, but all have probability weighting. So, they conclude that probability weighting is more important than loss aversion. Their subjects are mostly risk averse. They are of course not a representative sample, but people attracted to gambling. The authors write that subjects are not risk seeking but skewness seeking, and this is why they gamble even though being risk averse. %}

{% Theorem 3 of this paper is, actually, more general than Schmeidler's (1986) characterization of the Choquet integral.

Theorem 3 as stated does not state the characterization of the Choquet integral explicitly. But the displayed equality in the proof shows that the functional is indeed identical to the Choquet integral, so that we have a characterization of the Choquet integal after all.

The topological assumptions of Anger may seem to be complex, but a simple way out is: If E (the state space) is finite, R is the collection of all subsets of E, and H is the set of functions from S to Re^+, then all topological assumptions of Anger (see, for instance, the top of p. 246) are satisfied, and readers not knowing these can restrict attention to the finite case as mentioned. Definition 2 gives a condition weaker than comonotonic additivity. It amounts to imposing additivity only for functions f, g such that g takes its minimal value whenever f is not maximal. The latter restriction implies comonotonicity of f and g. (The author only states the condition for normalized functions, and assumes positive homogeneity separately. Schmeidler (1986) stated his comonotonic additivity in general, in which case it, together with other natural conditions, implies positive homogeneity.) In Wakker (1990, *Fuzzy Sets and Systems*) I used the term minmax-relatedness for the condition for f and g mentioned above. Chateauneuf (1991, JME, Axiom 5) also used this weakening. Schmeidler's comonotonic additivity immediately implies Anger's Definition 2, and quickly implies positive homogeneity, after which Schmeidler's theorem follows from Anger's. %}

{% What is called the Anscombe-Aumann framework "these days" (1990-2022 etc.) is described in §13.1 of Fishburn (1970). It is two-stage with first horses and then roulette, and leaves out the first stage that Anscombe-Aumann have.

Results similar to this paper had been around and probably people knew this before, but no one stated it as nicely as Anscombe-Aumann. Arrow (1951, Econometrica, p. 431/432) describes a state-dependent version, citing unpublished papers by Rubin (1949) and Chernoff (1949), and oral contributions by Savage. The Chernoff paper was published in Econometrica in 1954, so, after Arrow's paper; see comments there.

What is usually called monotonicity in the Anscombe-Aumann framework (replacing a roulette-lottery conditional on a horse by a preferred roulette-lottery improves the act) would better be called (weak) separability. Monotonicity w.r.t. an objectively given predefined ordering such as the natural ordering on the reals can, indeed, be called monotonicity. Increasing a monetary payoff in a lottery, or one of the commodities in a commodity bundle, concerns monotonicity. In the Anscombe-Aumann framework, however, it concerns a subjective preference relation over lotteries to be derived from preferences, and then it is a kind of separability. Here it is more conceivable that the subjective ordering of lotteries conditional on one horse is affected by the lottery received conditional on another horse, entailing a violation of monotonicity or, rather, separability. It underlies the backward induction optimization of the Anscombe-Aumann framework. In the modern applications of the Anscombe-Aumann framework under nonEU such as ambiguity about the horse-events such violations are VERY conceivable, and almost by definition are what ambiguity entails. My book Wakker (2010 Figure 10.7.1) gives an example. This is a big drawback of the use of the Anscombe-Aumann framework to study ambiguity. Because of this reason, some people including me have argued that the order of events in the Anscombe-Aumann framework is unfortunate for studying nonEU for horse events and then better the roulette events PRECEDE the horse events (Wakker 2010 §10.7.3; Wakker 2011 Theory and Decision p. 19 penultimate para).

Anscombe-Aumann monotonicity can be called weak separability because it only concerns single horse states and not composite (overlapping) horse events. The theorem can be obtained as a corollary of Harsanyi (1955), as pointed out by De Meyer & Mongin (1995). %}

{% **updating under ambiguity with sampling**: An interesting point of this paper is that ambiguity is generated through missing information, with an incomplete data set.

The first part of the paper is theoretical, discussing a number of attempts to define ambiguity aversion endogenously (Epstein & Zhang 2001; Ghirardato & Marinacci 2002; Nehring 1999). The theoretical analysis considers only convex or concave weighting functions, with 1 – W(A) – W(A^c) type measures of ambiguity aversion. (**Ambiguity = amb.av = source.pref, ignoring insensitivity**)

The second part presents two experiments. Subjects could gamble on the color of a ball drawn from an urn with yellow and white balls. (Pity they did not take Ellsberg’s colors red and black; they also had signs O and X not discussed here.) Experiment 2 was the main one, discussed here first. It had two treatments. In the first (precise info), they told subjects that 8 drawings with replacement from the urn gave 3 yellow balls and 5 white balls. A difficulty in ambiguity experiments with real incentives is always how to generate the ambiguity. Here the authors did it using deception (**deception when implementing real incentives**): They told results of samples that had not really taken place (especially regarding the missing information). 3-5 was not the result of a real drawing, but instead was the real composition. In the second treatment (imprecise info) subjects were told that of 8 drawings, 4 were yellow, 2 white, and 2 unknown color. (Again, this drawing had not really taken place.) Some subjects were asked the CE (certainty equivalent) of gambling NIS 150 on yellow, and others were asked the CE of gambling NIS 150 on white. Because subjects did not know what was offered to the others, and could not choose the color, there was no control for suspicion (**suspicion under ambiguity**). (The authors assume that ambiguity neutral subjects with imprecise info will treat it as if 3-5, but I find 2-4 more plausible there.) The CE for imprecise info (average 50.9) is lower than for precise info (average 65.3), suggesting ambiguity aversion. Note that the CE of precise info is high, suggesting risk seeking (or subjective probability close to a prior 0.5 rather than observed relative frequency of 3-8). Experiment 1, reported below, will suggest risk seeking rather than subjective belief. They did a similar experiment with more unlikely events, and found the same ambiguity aversion.

For completeness, here is the first experiment, which served as a kind of control. Experiment 1 has two treatments. The first treatment did not consider the main research question but was preparatory, and considered no imprecise info. They told subjects that 8 drawings with replacement from an urn gave 3 yellow balls and 5 white balls (precise info). Again, this drawing had not really taken place, so, it is a form of deception. In the second, control, treatment, subjects were told the true composition 3-5. Then they were offered the gamble of winning NIS 150 (≈ $40) if a color drawn would be yellow, and a choicelist was used to measure the certainty equivalents (CE). Thus, there was again no control for suspicion. In the precise-drawing info subjects could conjecture that despite this drawing the number of yellow balls still was low. The average CEs were 67.37 and 69.52 for the two treatments, suggesting that they were the same, and suggesting that precise info is treated like objective probabilities. Btw., the CEs are remarkably high, with risk seeking. %}

{% **paternalism/Humean-view-of-preference** ?

Considers three kinds of errors:

(1) Strategy-based errors occur when the cost of extra effort outweighs the potential benefit of additional accuracy.

(2) Association-based errors (semantic memory) are costs caused by wrong associations due to special words etc.

(3) Psychophysically based errors are due to nonlinear perception of linear things.

At first I found the division ad hoc. Ad (3) for instance, what about stimuli that do not constitute a continuum, or are not even numerical, or are nonlinear? Ad (2), is all our knowledge memory and/or association? Then I took them as the author's way of indicating broader categories: Maybe (3) concerns perception, (2) cognition, and (1) how we turn the other two into actions? As often with psychologists, each single example is not convincing and may have many other explanations, but together they do bring the picture. Weak is that the author confuses reflection and framing, as pointed out by Fagley (1993). (**loss aversion: erroneously thinking it is reflection**)

P. 492 ff. on debiasing is interesting. Giving examples of innate mistakes that are not reduced by incentives, but by clarifications. P. 494 1st para: "To diminish an association-based judgment error, neither the introduction of incentives nor entreaties to perform well will necessarily cause subjects to shift to a new judgment behavior. Instead, it will be more helpful to instruct the subjects in the use of a behavior that will add or alter associations." %}

{% **probability elicitation**: applied to experimental economics.

Measure beliefs through subjective probabilities in first-price auctions. Measure it by introspective judgment, quadratic scoring rule, and prediction (rewarding those whose probability estimates are closest to true objective probability). Argue that the third method is a good compromise between being incentive compatible (which it is only partly) and understandable.

inverse S: They find that subjects throughout underestimate their probability of winning, going some against inverse S. They find that probability weighting better explains data than utility curvature (which they call risk aversion: **equate risk aversion with concave utility under nonEU**), which supports the importance of probability weighting and prospect theory. %}

Armantier, Olivier & Nicolas Treich (2009) "Subjective Probabilities in Games: An Application to the Overbidding Puzzle," *International Economic Review* 50, 1013–1041.

{% Investigate **proper scoring rules**, assuming EU. They investigate, both theoretically and empirically, how proper scoring rules are distorted by risk aversion, and what the effect is of increasing stakes or adding event-contingent stakes, depending on risk attitudes.

In the instructions, they explain the payments using a table, but they do not give instructions on what is good or bad. They emphasize much that their instructions do not use the concept of belief or probability. %}

Armantier, Olivier & Nicolas Treich (2013) “Proper Scoring Rules: Incentives, Stakes and Hedging,” *European Economic Review* 62, 17–40.

{% P.1956: The paper nicely rewrites the parameters of the two-parameter family of Prelec (1998). The authors write

$w(p) = \exp\big(\ln(a)[\ln(p)/\ln(a)]^b\big).$ (*)

(The family is an affine transformation at the level $-\ln(-\ln(p))$.)

Prelec uses $\alpha = b$, $\beta = (-\mathit{ln}\,a)^{1-b}$.

Now a is the fixpoint, which may serve as an index of optimism, and b, the derivative of w at the fixpoint a, is an index of insensitivity. It has been pointed out in the literature, and also in my annotations below at Prelec’s (1998) paper, that his insensitivity parameter also impacts optimism/pressimism. This also happens with the parametrization in Eq. (*), be it to a lesser extent. Set the optimism parameter a at the neutral value $a = 0.50$. Set $b = 0.65$, say. The $1 - w(p) - w(1-p)$ is always negative for $p = j/1000$, with most extreme value 0.051 at $p = 0.018$, showing optimism.

They pay by RIS.

violation of risk/objective probability = one source: Show that the source of risk (known probabilities) is not always weighted the same, but one can generate negative emotions, e.g., by making the events complex. Such a finding had been obtained before, as can be found through my keyword above. For instance, Chew, Li, Chark, & Zhong (2008) had it.

I agree with the main message of the paper, that many things besides probabilities being unknown-versus-known or multi-stage-versus-single-stage play a role. The paper shows that complexity may be just as important. Uncertainty is a rich domain, and Ellsberg’s paradox has led most of the field—Ellsberg (2011) himself not included fortunately— to overfocus on probabilities being unknown, as much of the recent literature overfocuses on RCLA.

One thing I learn from this paper is that in the definition of ambiguity as uncertainty minus risk, one has to specify that risk is to be taken as neutral risk, without special emotions aroused. Fox, Rogers, & Tversky (1996) and Tversky & Fox (1995) also state this; see my related annotation there, added in 2022. I don’t end as negative as the authors do on p. 1960, end of §5.3: “Experimental measures of ambiguity aversion are thus contingent on the source of risk considered." Here pragmatism and parsimony should prevail. I still like to take risk as one source, adding "emotion-neutral." Tversky (personal communication) argued that risk ("chance" as he liked to call it) best be taken as one source.

Another limitation that I see is not that often there are more than one risk attitude, but rather that, let me say imprecisely first, there is less than one risk attitude. What I mean is that for uncertainty the thought experiment of all the same except that probabilities are known, is often too unrealistic to even consider. Then ambiguity attitude in the narrow sense of only difference between unknown-known probability is too uninteresting to consider. Then we should only look at an all encompassing uncertainty attitude. But for now the word "ambiguity" is the magic popular term in the field, so, for a decade or so to come (2017-2027) we will be dealing with this often meaningless concept.

This paper has nice ways of generating complexity other than through multistage. In Experiment 1, there are the known and unknown Ellsberg urns, but there is, in addition, a third treatment, a complex one, where draws from two known urns are combined but this is of course more complex than simply the one urn. They find that subjects treat the unknown and complex urns quite similarly, strongly correlated (p. 1958). I find this agreeing with my opinion that Ellsberg's unknown urn is not about unknown probability but about weird silly urns. In experiment 2, two dice are thrown, each giving one of 10 numbers, numbered 0 … 9. In one treatment, simple risk, they just compose two-digit nos. 00 … 99 and ask probabilities of number between 1 (included) and 25 (included), which has probability 1/4. In the other treatment, complex risk, they take the sum of the two throws. The event that the sum is between 2 (included) and 6 (included) also has probability 1/4 (the authors claim so and I trust them) but this is a complex risk. They find, in proper scoring rules, that people treat multistage and complex probabilities quite similarly, strongly correlated.

A difficulty is that the complex probabilities are simply too complex for subjects to get, so that for them it is not risk but ambiguity. The authors seem to discuss this somewhere but I don't know where.

source-dependent utility: Experiment 1 & 2 find the same utility for different sources (p. 1956 & 1959).

The authors take (their versions of) the parameters of the Prelec family as indexes of pessimism and insensitivity. Both pessimism and insensitivity are larger for unknown and complex than for known (so, ambiguity aversion) in Experiment 1 (p. 1957). In Experiment 2, insensitivity is larger for two-stage/complex than for simple, but pessimism is the same (p. 1959).

ambiguity seeking for unlikely: they confirm ambiguity seeking for unlikely and aversion for likely.

P. 1961, §5.5, is more pessimistic on the source method than I am. The following sentence is their sentence in §5.5 but with everywhere "the source method" replaced by "utility theory," "source function" by "utility function," and "source (of uncertainty)" by "commodity":

"Indeed, because it is context dependent, utility theory has an infinite number of degrees of freedom (i.e., a different utility function for each commodity). As a result, utility theory does not lend itself to out of sample prediction: knowing an agent's attitude toward one commodity does not provide guidance as to the attitudes of that agent toward a different commodity." Note that Abdellaoui et al. (2011) call the DOMAIN rich, not their model. Every ambiguity theory has to deal with source dependence. Multiple prior models will have to have different sets of priors for the Dow Jones index than for the Amsterdam index, and the smooth model will have to have different two-stage decompositions there. (And, what I empirically predict, deviating from KMM's views, also different φ functions.)

P. 1963, Appendix C, suggests improvements of the statistics of Abdellaoui et al. I agree with this appendix. The authors write: "First, the t-tests conducted in Step 3 to compare the distributions of $w_{it}(j/8)$ across treatments are valid if one treats the $w_{it}(j/8)$ as (recoded) data, but they are not valid if one treats the $w_{it}(j/8)$ as econometric estimates, i.e., random variables whose standard deviations depend on the sampling error from the estimation of …" This puts things exactly right. Outside econometrics, the first approach is common and we followed it.

The reason that Abdellaoui et al. used a two-step parametric approach, with an extra parameter w(1/2) estimated, is that such a procedure can be interesting for interactive decision analysis sessions where w(1/2) is a once-and-for-all correction factor. %}

Arrow, Kenneth J. (1951) "*Social Choice and Individual Values.*" Wiley, New York. (9th edn. 1972, Yale University Press, New Haven.)

{% P. 404, opening para, writes that uncertainty is present in all our decisions and that uncertainty theory can answer all questions in life, but the author is not subject to

the ubiquity fallacy because he carefully lets others say this (not **ubiquity fallacy**). This paper immediately starts with a first signal of the depth and subtleness of the author! At least at the age he had then.

P. 405 in this preSavage (1954) paper writes "the distinction between the two will be carefully maintained." where "the two" means consequences versus acts. But he never clearly states how acts, consequences, and events are formally related.

P. 405/406 give some nice words on **free will/determinism**:

> I do not wish to face here the question whether or not there is any "objective" uncertainty in the economic universe, in the sense that a supremely intelligent mind knowing completely all the available data could know the future with certainty. The tangled web of the problem of human free will does not really have to be unraveled for our purposes; surely, in any case, our ignorance of the world is so much greater than the "true" limits to possible knowledge that we can disregard such metaphysical questions.

P. 406: "In view of the general tradition of economics, which tends to regard rational behavior as a first approximation to actual, I feel justified in lumping the two classes of theory together." That this was view in economics up to 1980s is stated also in opening para of McQuillin & Sugden (2012 p. 553). A nice accompanying citation is from Newton (1687): "I can calculate the motion of heavenly bodies, but not the madness of people."

P. 407, on coexistence of gambling and insurance, mentions, as a class of economic phenomena that by their definition are concerned with uncertainty, insurance and gambling. Then writes, "A theory of uncertainty must account for the presence of both."

P. 410 middle: statistical hypothesis are uncertainty but not risk (I mean, no probabilities)

Pp. 410-411 describes various views on probability

P. 411, footnote 4, describes the idea of matching probability.

End of §3.1.1 seems to criticize Lange incorrectly for assuming cardinal probabilities if only ordinal info. Ordinal info about probabilities easily gives cardinal info because of additivity, if A,B,C are three mutually exclusive and exhaustive events, then A ~ B ~ C immediately implies that their probabilities are 1/3.

P. 412: Jacob Bernoulli first formulated the principle of insufficient reason in the 17th century. P. 413 2nd para will discuss its problem.

P. 416: Keynes essentially abandons completeness of preference when handling subjective probabilities. (P.s.: Keynes likes logical interpretation of probability)

P. 418 etc. is on **foundations of statistics**, its early history, origin of Neyman-Pearson.

P. 419 defines, for potential surprise, the max and min operations for union and intersection, which will later underly fuzzy sets.

P. 421 writes "With the development of the utility theory of value in the 1870's, Bernoulli's proposal was found to fit in very well, especially in view of the common assumption of diminishing marginal utility of income." Arrow gives no references from that period, unfortunately.

P. 422 mentions nonEU models though it seems to be only models based on moments.

P. 423: **risky utility u = transform of strength of preference v, latter doesn't exist**: "This argument, however, was undermined by the rise of the indifference-curve view of utility, due to Pareto, where utility ceased to have any objective significance, and in particular diminishing marginal utility had lost its meaning." P. 425 repeats the point: "First, the utilities assigned are not in any sense to be interpreted as some intrinsic amount of good in the outcome (which is a meaningless concept in any case)."

P. 423 1st para mentions sign dependence.

P. 424: "Ramsey's work was none too clear."

P. 424 3rd para and further: R**CLA**

P. 424/425: **substitution-derivation of EU**: not really, but gives ingredients. P. 424 states weak ordering, p. 424/425 the standard gamble (SG)-assumption, and p. 425 the substitution principle; impressive is Footnote 22 on p. 425, a point that I had found before reading it here after considerable thinking, and showing that Arrow really understood how to prove the result.

P. 425: "If, as seems natural, we demand that all utilities be finite,"

Early mention of maxmin EU: p. 429 second para describes it, and refers to Wald (1950).

P 428 last para points out that the significance level of Neyman-Pearson is arbitrary.

P. 429 3rd para: Wald's maxmin criterion fully reflects the idea of complete ignorance. Note that he formulates Wald's principle in an Anscombe-Aumann setting. He criticizes it for nature not behaving like a zero-sum-game opponent.

P. 429/430 refers to Savage's maxmin regret, apparently stated in a 1948 course, and also to Chernoff's demonstration that IIA then is violated. So, Chernoff (1949, unpublished) already had an example of IIA.

P. 431: that de Finetti's bookmaking is not reasonable for high stakes.

Pp. 431-432 describes a state-dependent version of the theorem of Anscombe & Aumann (1963), referring to Rubin (1949, 1950) and Chernoff (1949, 1950) for it.

P. 432 ℓ. 1 describes the vNM independence axiom.

P. 432, sign-dependence (when discussing Shackle's work): "The exposition is greatly complicated by his insistence on differentiating between gains and losses. It is completely unclear to me what the meaning of the zero-point would be in a general theory; after all, costs are usually defined on an opportunity basis only."

Seems to mention early solutions to the St. Petersburg paradox that assumed nonlinear probability weighting.

criticizing Knight (1921) for low quality: Arrow is cynical and critical of Knight in many places. %}

{% Seems to be among the first to use the state-preference approach where states of nature are like dimensions of commodity bundles.

Théorème 3: risk aversion under EU holds if and only if U is concave; only for 50-50 lotteries. (The risk aversion statement is discussed on p. 95, following the theorem. %}

Arrow, Kenneth J. (1953) "Le Rôle des Valeurs Boursières pour la Répartition la Meilleure des Risques." *Colloques Internationaux du Centre National de la Recherche Scientifique* (Econométrie) 40, 41–47. Translated into English as "The Role of Securities in the Optimal Allocation of Risk-Bearing," *Review of Economic Studies* 31 (1964), 91–96.

{% P. 7 gives, for decision making under risk with a continuum of utility range, the reasoning that, under EU and completeness, U must be bounded by a variation of the St. Petersburg paradox, and refers to Menger for this point. %}

Arrow, Kenneth J. (1958) "Bernoulli Utility Indicators for Distributions over Arbitrary Spaces," Technical Report 57, Dept. of Economics, Stanford University, Stanford, CA, USA.

{% Axiom C4 is IIA, not in the Arrow-social choice sense, but in the revealed-preference sense, for multivalued choice functions. This is the first published version of the condition it seems. Nash (1950, Axiom 3) had a special case of this condition (for single-valued choice functions, where it coincides with some other conditions). %}

Arrow, Kenneth J. (1959) "Rational Choice Functions and Ordering," *Economica*, N.S., 26, 121–127.

{% Moral hazard. Seems to show that under actuarially unfair coinsurance (loading factor in insurance premium) and EU with concave utility, no complete insurance is taken. %}

Arrow, Kenneth J. (1963) "Uncertainty and the Welfare Economics of Medical Care," *American Economic Review* 53, 941–969.

Reprinted in Kenneth J. Arrow (1971) "*Essays in the Theory of Risk Bearing.*"

{% Seems to prove that deductible is Pareto optimal relative to coinsurance etc. Seems to be a famous result.

An amusing pastime is to read justifications of axioms that authors give who don't have any serious argument to give. Here is a strong, often cited, bluff act by Arrow (1971 p. 48): "The assumption of Monotone Continuity seems, I believe correctly, to be the harmless simplification almost inevitable in the formalization of any real-life problem." (**criticizing the dangerous role of technical axioms such as continuity**)

1971, p. 52: probabilistic beliefs: If the probability distribution of consequences is the same for two acts, they are indifferent. Assumption 2.1.2 in Wakker (2010) calls it decision under risk.

1971, p. 64/65 shows that under his Monotone continuity axiom, utility function u of Savage's model must be bounded.

1971, p. 26/27: R**CLA** is rational (called utility boundedness theorem later (??))

1971, p. 35, seems to write: "the behavior of these measures as wealth varies is of the greatest importance for prediction of economic reactions in the presence of uncertainty."

1971, p. 90/91: funny citation, "Brethren, here there is a great difficulty; let us face it firmly and pass on."

1971, P. 96: on quadratic utility, "is unacceptable since it violates the principle of decreasing absolute risk aversion."

decreasing ARA/increasing RRA:

(1) 1971, p. 96, on decreasing ARA (absolute risk aversion), seems to write: "seems supported by everyday observation."

(2) 1971, p. 97, on decreasing ARA/increasing RRA, seems to write: "the hypothesis of increasing RRA [relative risk aversion] is not easily confrontable with intuitive evidence. The assertion is that if both wealth and size of bet are increased in the same proportion, the willingness to accept the bet (as measured by the odds demanded) should decrease. The hypotheses will be defended partly by its consistency with general theoretical principles and partly by its success in explaining economic behavior." It seems that Arrow's theoretical principle is based on the assumption that utility should be bounded from above and from below, which I find unconvincing as an argument.

decreasing ARA/increasing RRA: p. 103/104 seems to give an additional argument for increasing RRA.

Section 11.2 points out that government should not insure, because the stakes are (almost always) moderate given the budget of the government.

1965 in fact does DUR only. %}

{% They do not consider binary preferences over acts (they call them "risks"), but a representing function called risk measure. More precisely, the risk measure is minus 1 times a representing function. Then they do two things.

(1) They provide mathematical results that are not new but have been known before, not only by Huber (1981, Ch. 1, Proposition 2.1, preceding their Proposition 4.1) which they cite but also by multiple prior papers Gilboa & Schmeidler (1989) and Chateauneuf (1991).

(2) They present a naïve interpretation of their axiomatization. If authors/readers did not see axiomatizations before, they can intimidate/get-intimidated by claiming that their axioms are criteria of rationality. Authors in that spirit often use broad uninformative terms such as rationality/consistency/coherence; this paper uses the term coherent. But if you have seen 100 axiomatizations before, you don't get impressed by yet one more, and you don't use such broad uninformative terms anymore.

It so happened that in the field of risk measures, axiomatizations had not been seen before. Hence, the average researcher in that field got impressed by the axiomatization in this paper and it became seminal. It is of course very useful that this paper introduced axiomatizations in the field of risk measures. %}

{% **dynamic consistency. NonEU & dynamic principles by restricting domain of acts**; **updating: nonadditive measures**

The authors examine updating of a nonadditive measure, denoted v, in Choquet expected utility. I will discuss it from the perspective of §9 of

Sarin, Rakesh K. & Peter P. Wakker (1998) "Revealed Likelihood and Knightian Uncertainty," *Journal of Risk and Uncertainty* 16, 223–250,

SW henceforth, a paper not cited by the authors. For updating, v(S|A), three events play a role: $A \cap S$, A\S, and A^c. SW argue that the various updating methods in the literature differ in the rank-order assumptions that they make. For instance, the Bayesian rule, $v(S|A) = v(s \cap A)/v(A)$ assumes $s \cap A$ in the best ranking position, A\S 2nd best, and A^c worst. Dempster-Shafer and Fagin-Halpern assume two different rank-orderings. There are six ways to rank-order the three events, so, one can think of three more update rules in this spirit. For Baysian updating, one should assign the worst outcome to A^c. This paper shows that it can be captured by imposing a lower-constrained dynamic consistency, so, only if A^c has the worst outcome. Upper-constrained dynamic consistency captures Dempster-Shafer.

To have consequentialism w.r.t. a conditioning event A, we need to have Choquet-expected utility conditional on A, involving comonotonicity restricted to A. The authors capture this using conditional comonotonicity. %}

{% On expert aggregation. A big (N = 2400) study of the big probability-elicitation competition that started in 2011. In 2011 the Intelligence Advanced Research Project Agency (IARPA), the research wing of the intelligence community, sponsored a multiyear forecasting tournament. Five university-based programs competed to develop the most innovative and accurate methods possible to predict a wide range of geopolitical events.

They find that simple polls with discussions ("converge") work best, then weighted averaging of simple polls (mix of "merge" and "purge"), then prediction markets, and, worst, unweighted averaging of simple polls ("merge"). In weighted averaging, the weights are not derived from the data set used to evaluate, in which case it would be just data fitting with the more parameters the better, but they were derived from other data in the past, so that it is proper prediction. Still no surprise that it does well because it is using more info (also

the past data). That converge works best is also not surprising, because experts can share info and learn. In the case of converge, at the end they still could all do individual judgment and they need not produce a consensus view. This avoids strategic behavior.

P. 694 2nd column ℓ. 4: "Prediction markets generally produce adequately calibrated prices, with the excepotion of the favorite long-shot bias." Restated, with references on top of p. 698. Following Rothschild (2009), they do recalibration for overconfidence, which seems to be good.

P. 701: in prediction markets, more than 50% of all orders were placed by the most active 5%.

P. 703 bottom of 1st column: maybe experts did not understand well how prediction markets work. Then there is a possibility for improvement. %}

{% This review of my book captures both the general spirit and many details of the book very well. I was happy to see such good reading and understanding. My only objection is that the author uses the term RDEU rather than RDU.:)

Somer minor details:

Footnote 1: The book does not use the term subjective probability for transformed probabilities, and uses subjective probability only for additive probabilities as in Savage (1954). It warns against the former use on p. 49 preceding Exercise 2.3.1.

P. 241 Footnote 2 explains why my book does not consider the Köszegi & Rabin (2006) theory of endogenous reference points.

The "questionable assumption" (book review p. 539 ℓ. −6), assumed to be implicit and critical, that probabilities be weighted the same under risk and ambiguity, is vacuous. Ambiguity is BY DEFINITION whatever the difference is between unknown and known probability. And if probability is weighted differently under unknown probability than under known probability (I have difficulties in understanding what probabilities and their weighting may mean in the first case, but try to understand the author as much as can), then that difference is ambiguity BY DEFINITION. The point is discussed more by Abdellaoui et al. (2011, American Economic Review), p. 719, under "Ambiguity or Different Risk Attitudes?—A Terminological Issue.—". %}

Attanasi, Giuseppe (2011) Book Review of: Peter P. Wakker (2010) "Prospect Theory: For Risk and Ambiguity, Cambridge University Press, Cambridge, UK," *Journal of Economic Psychology* 32, 538–540.

{% The authors present *exogenous* two-stage uncertainties to subjects and fit the smooth ambiguity model.

correlation risk & ambiguity attitude: seem to find negative relation %}

Attanasi, Giuseppe, Christian Gollier, Aldo Montesano, & Noemi Pace (2014) "Eliciting Ambiguity Aversion in Unknown and in Compound Lotteries: A Smooth Ambiguity Model Experimental Study," *Theory and Decision* 77, 485–530.

{% Consider how much an agent in ambiguity would pay to get to know the (objective) probabilities, and propose this, normalized by utility spread of outcomes, as ambiguity premium. Do this essentially if only one prospect is faced, so, no different ambiguous prospects to choose from, which is kind of preference for info. The nice title of Section 2.1 “Buying information without using it” expresses it nicely. (They later also consider cases in which decisions do follow.) Their definition captures all nonadditivity of the weighting function, including nonadditive weighting of probabilities. Hence, they propose their definition only when EU holds for risk. They derive many comparative static results on ambiguity premiums with and without decisions to be taken.

Pp. 128-129 explain that the authors rather use RDU (they write CEU, abbreviating Choquet expected utility) than the smooth model, for one reason because in the latter it will be harder to disentangle things from the utility functions.

A problem is what objective probability is, and how much ambiguity there is about what that true probability is. Eq. 1.a (p. 132) assumes one objective probability $Pr(s_g)$ but the problem is that this does not occur in any decision situation. They next use a symmetry argument to get rid of that probability, but the symmetry argument can be seen to imply $Pr(s_g) = 0.5$ (because then $v(s_g) = v(s_b)$, implying that Eq. 1.a is the same as that equation with $1 - Pr(s_g)$).

Section 3.2 on Abdellaoui et al. (2011): Note that the latter do not take risk as a source with some ambiguity, but instead DEFINE it as unambiguous. Further, the difficulty to disentangle the authors’ definition from probability weighting is as much a problem for the authors themselves, which they avoid only by simply assuming EU (so, no probability weighting).

P. 127, strangely, writes that Andersen et al. (2010) were the first to note that risk and ambiguity attitudes can be different, and that risk aversion can go together with ambiguity seeking (p. 127). The keyword **correlation risk & ambiguity attitude** in this annotated bibliography, for instance, gives many other references on this point, many preceding. %}

{% N = 80 students. For health, obviously no real incentives.

reflection at individual level for risk: although they have the data, they do not report this.

They test PT (I prefer this to their notation CPT for the 92 version of prospect theory) with life duration as outcomes. They use framing to let 30 years life duration be reference point (p. 1060 §3.3 1st para), so, then there are both gains and losses. They only use fifty-fifty prospects, so, only probability 0.5.

P. 1058 3rd para: location of reference point is problem in health.

P. 1059 para −3: under exponential (= CARA) utility, location of reference point is not important for curvature (apart from loss aversion).

P. 1059 para −2: when the authors say exponential utility, they mean that it can be different for gains than for losses.

P. 1061, §4.2 1st para: risk aversion both for gains and losses. P. 1061, §4.2 last para: much risk aversion for mixed prospects.

P. 1061, §4.3 1st para: just a little bit of loss aversion: $\lambda = 1.18$. Much individual variation.

P. 1062 §4.6, nicely redid the analysis assuming EU and then, obviously, found way more concave utility. Data fitting suggests that RDU is better than EU, and PT's sign dependence is yet better, but it is not clear how the authors corrected for extra parameters.

P. 1063 2nd column 1st para: Not at all clear that for life duration U should be convex for losses. Here it is concave for both gains and losses. (**concave utility**

for gains, convex utility for losses).

The results in this paper (almost no loss aversion, and no real sign-dependence of utility) suggest to me that sign- and reference-dependence play no role for life duration. For life duration there is no clear reference point. The authors end the main text (p. 1064 §6) with this opinion, although they go less into the direction of no reference point: "Third, the location of the RP in the health domain deserves further exploration. This location is less obvious for health outcomes than for monetary outcomes, and plays a crucial role in PT. Finally, an extension of this study to a more representative sample of thegeneral population would be worthwhile." %}

{% Asked people to judge the frequencies of letters in English text, compared that to real frequencies; on average, it overestimated frequencies below .04, underestimated the higher frequencies; so, looks like **inverse S** but only overestimation of very small probabilities; there are violations of monotonicity (e.g., D occurring more often but judged lower) showing that judgments depend on more than just (transformations) of real frequencies; this finding can serve as a nice example to explain that not **SEU = SEU** to psychologists.

Guessing games reveal nonlinear probability weights. %}

Attneave, Fred (1953) "Psychological Probability as a Function of Experienced Frequency," *Journal of Experimental Psychology* 46, 81–86.

{% **inverse S:** Cites literature that find inverse S shape. Does a first experiment in which subjects' behavior confirms that they relatively overvalue longshot lotteries (so, small probability for gain). Payments was in "points" (not explained more). Unfortunately, the gambles always seem to deal with both gains and losses, so loss aversion plays a role. Then comes the second experiment. Subjects are first asked for estimations of probability and it seems that they !under!estimate small probabilities and they !over!estimate bigger ones. However, not much explanation is given about experimental details there seem to be many complicating factors. For instance, probabilities are measured by having subjects indicate percentages of occurrences of events when repeated 100 times. They first are asked to calculate the mathematical answer, then they are asked what they think will really be the percentage. They also choose between gambles but it is repeated choices and they seem to play for totals of points. In this second experiment, no clear relation between gambling behavior and estimated probabilities was found. It could be argued that the second experiment deals some with ambiguity, but I don't think really. It is too close to known probability I think. %}

{% They throughout do the RIS for real incentives.

A careful experiment considers intertemporal choice for monetary outcomes and for slightly unpleasant jobs to be done. The delays considered are 3 and 6 weeks. Because real incentives, they can only consider such short periods. They fit data with the β-δ model and Stone-Geary utility of money and parametric utility of work similarly. They find close to linear utility of money. Small present bias for money, much bigger for effort. Their first pages discuss the fungibility problem (utility of money vs. utility of consumption) that intertemporal experiments with money always have, which is why they also did the job experiment, especially in footnote 4. (**time preference, fungibility problem**) They find a positive relation between present bias and desire to precommit, and enthusiastically write on this in the last sentence of the abstract: "Therefore our findings validate a key implication of models of dynamic inconsistency, with corresponding policy implications." P. 1071 describes it as key validation. It is common, and cliché, in theoretical papers nowadays (2016) to refer to policy implications. The positive correlation found is plausible because for dynamically consistent people there is nothing to precommitment for, them always choosing the same anyhow.

One difficulty can be that the job is a negative outcome, and for negative outcomes it is not so clear to what extent people are at all impatient or have present bias. Well, in this paper they do. %}

Augenblick, Ned, Muriel Niederle, & Charles Sprenger (2015) "Working over Time: Dynamic Inconsistency in Real Effort Tasks," *Quarterly Journal of Economics* 130, 1067–1115.

{% The authors measure time preference for subjects who have to do a number of unpleasant tasks at some future timepoints in the next seven weeks. The paper emphasizes that they do not consider monetary outcomes so as to avoid fungibility problems (**time preference, fungibility problem**), a fashionable point in 2022. Subjects could freely choose tasks in future timepoints, but could make predictions beforehand. How much the prediction is off, speaks to sophistication. Confounds here can be that prediction can be (mis)used for self-commitment, and can impact future decisions through the incentives for the prediction being right. The authors go at great length to avoid/reduce these confounds. For me outsider it is not easy to see many other differences with Augenblick, Niederle, & Sprenger (2015). %}

{% **completeness criticisms**; The author considers preferences that satisfy the usual vNM preference conditions, except the weakest one, being completeness. Theorem A (p. 450) characterizes existence of at least one utility u. "Utility" means the analog of the EU functional, implying linearity in (probabilistic) mixing. Further, denoting prospects by x, y, and so on, $x > y \Rightarrow u(x) > u(y)$ and $x \sim y \Rightarrow u(x) = u(y)$. Note that this way we cannot recover preference from utility because prospects can be incomparable, irrespective of their utility value ordering. So, the result is not really a representation. §7 turns to the representation question; i.e., the extent to which the set of all utilities can determine the order. Unfortunately, the writing on formal results is not explicit and often ambiguous. The verbal claims that preference can be recovered from utility (made not only in §7 but also elsewhere in the paper, such as on p. 448 end of 3rd para) seem to be incorrect. So, I think that Aumann cannot be credited for such results, and Baucells & Shapley (2008) and Dubra, Maccheroni, & Ok (2004), two papers written independently and simultaneously, share the priority.

In his §7, Aumann never specifies whether "preference" and "order" refer to the weak or the strict part. By the terminology of the paper, it should maybe be the weak part. However, this cannot be. We consider the preference cone for a binary relation R: There are finitely many prizes, say n; $(p_1,\ldots,p_n)$ in Re^n designates the prospects in the obvious manner. The preference cone is the cone generated by all differences $(p_1,\ldots,p_n) - (q_1,\ldots,q_n)$ with the former prospect R-preferred to the latter. Aumann does not state if the preference cone takes weak or strict preference for R. It cannot be weak because that would not satisfy his regularity condition, containing 0. So, it has to be strict. A function on the prizes can be defined as $(u_1,\ldots,u_n)$ in the obvious manner. It is a utility function if and only if its inner product with everything in the preference cone is strictly positive (another reason why his preference cone can only refer to strict preference; cf. last para of Aumann's §7). So, the set of utility functions is exactly the dual of the preference cone. If then the preference cone is the dual of that, then the preference cone can be uniquely recovered from the set of all utility functions in the usual Bewley (1986, 2002)-unanimous-EU-incomplete-preference representation way. However, this only concerns recovery of strict preference. So, now the million $ question is: does strict preference uniquely determine indifference, in view of independence and continuity? This is not so, as an example by Dubra (2009, personal communication) explained to me. For example, take any preference satisfying Aumann's axioms 1.1 and 1.2 on p. 449;

can even be a complete one. Replace all indifferences by incomparability, only leaving reflexivity intact. Then the relation still satisfies all of Aumann's axioms, has the same strict part as the original one, but is different regarding indifference/incomparability. This shows that Aumann's continuity axiom 1.2 is too weak, not sufficiently distinguishing between indifference and incomparability (his 4.1 on p. 452 could do better). So, his results of §7 cannot be added to Theorem A to give a representation theorem.

Aumann's casual style and way of representation in §7 could be accepted if the mathematics was trivial to him, and impeccable. However, now that it is not and he has mistakes in continuity, one cannot know exactly what his sentences mean, and they accordingly cannot be credited.

Aumann's (1964) addendum corrects Theorems B and C in §5, for which his continuity is also too weak, but it does not address the problems of Theorem D in §7, which is the topic relevant for us here. %}

Aydogan, Ilke (2017) "Decisions from Experience and from Description: Beliefs and Probability Weighting," Ph.D. thesis.

{% **updating: testing Bayes' formula**; **updating under ambiguity with sampling** This paper does data fitting for existing data of decision from experience (DFE). However, its novelty is that it incorporates a parameter for the prior probability of the subjects, and a parameter of how they update during sampling, in particular, how much they weigh their prior belief versus the observed relative frequency. It uses Carnap's updating rule to do so, which is equivalent to Bayesian updating with beta priors. Then it assumes a probability transformation function there as in the soure method, capturing ambiguity attitudes. For instance, for an option that gives an outcome with certainty, subjects cannot be sure about this and may assign subjective probability 0.95 to it. The paper sometimes seems to find higher insensitivity under DFE than under risk, and sometimes lower. (**DFE-DFD gap but no reversal**) %}

Aydogan, Ilke (2021) "The Role of Prior Beliefs and Their Updating in Decisions under Experienced Ambiguity," *Management Science* 67, 6934–6945. https://doi.org/10.1287/mnsc.2020.3841

{% **updating: mistakes in using Bayes' formula**: The authors propose a tractable model of updating, adding two parameters to Bayes' formula. One is for the extent to which people are conservative (overweighing prior beliefs and underweighting signals) or the opposite. The other is for confirmatory bias: how they overweigh signals supporting their ideas and underweigh opposite signals. In an experiment, there is confirmatory bias by 19% misreading of signals contradicting priors and conservatism by seeming to miss 28% of the signals. %}

{% The authors take the three-layer model of Marinacci (2015). The first layer describes an objective probability distribution over states of nature. For (simple) decision under risk, no more to say. Following Marinacci, they call it probability model instead of probability measure. They consider ambiguity, where there is uncertainty about the first layer, captured through an exogenously given set of priors, and a 2nd order distribution on it. It is called model uncertainty. But then there is a 3rd layer of uncertainty, model misspecifiation, reflecting that the true prior may be outside the set of priors considered. It may be related to what is called unforeseen contingencies elsewhere.

This paper provides new insights into the relation between RCLA and ambiguity attitude. Although, in principle, model misspecification cannot be implemented, at least not without deception, the authors have a good proxy for it.

Their experiment has four treatments:, with some 0 < p < 1 fixed:

(1) Risk

(2) Common Ellsberg

(3) Compound risk (P(Red) = p or P(Red) = 1-p, each with 2nd order probability 0.5)

(4) Model uncertainty: P(Red) = p or P(Red) = 1-p but now unknown, ambiguous, 2nd order probability

(5) Model misspecification: like (4), but subjects are told that there is a small possibility that P(Red) is different than p or 1-p.

The authors consider Wald's (1950) maxmin EU model with the set of priors {p, 1-p} as above, Gilboa & Schmeidler's (1989) maxmin EU which I take to be the same as Wald but they model in a deviating manner, imposing a set of priors at a 3rd level, over the set of priors at the 2nd level, two smooth models, KMM and also Seo (2009) which they take as a particular assumption on nonreduction of higher-order risks, recursive RDU, and recursive disappointment aversion. They find less relation between violations of RCLA and ambiguity aversion than preceding studies. Their findings suggest that violation of RCLA is mostly due to complexity. %}

{% The authors argue that the random incentive system (RIS), which they call random problem selection (RPS), is incentive compatible as soon as what they call monotonicity is satisfied, where it roughly is if and only if. They give formal statements. However, what they call montonicity is rather separability, or, more precisely, not RCLA, but the rest of independence, which Machina (1989) decomposed into consequentialism and dynamic consistency. Their condition does not refer to an externally given objective relation over outcomes (then monotonicity is a common term) but to a subjective relation over outcomes. This is better called (weak) separability. It is what has often been called isolation in the context of RIS. That separability can be interpreted as monotonicity, was pointed out by Zimper (2008), Marschak (1987), and LaValle (1992). (**restrictiveness of monotonicity/weak separability**)

To avoid misunderstanding, the result of this paper means

UNIVERSAL (for all experiments) incentive compatibility of RSI

$\Leftrightarrow$

UNIVERSAL (their) monotonicity.

In experiments, one does not need universal incentive compatibility of RSI, but only for the particular questions asked, which can be helped by careful framing of the particular stimuli used. Hence, the result of this paper does not apply to applications as commonly done in experiments. %}

{% Argues that preference axiomatizations of general decision models are neutral as regards what risk attitudes are. (P. 67 §3 1st sentence: "On the face of it, the axiomatic analysis of decision-making under risk does not rely on the risk attitude concepts introduced in the previous section." P. 71 §3 last para: "The neutrality of the decision models between the various risk attitudes is one thread in the history of decision theory at large.") I see it somewhat differently: Those models want to allow for as many interesting risk attitudes as possible, and as few uninteresting ones as possible. I use this distinction in my risk-history lectures. In intertemporal choice the situation is (too) different. The general models popular today (quasi-hyperbolic and hyperbolic) are too much committing to decreasing impatience. As another example, cautious utility (Cerreia-Vioglio, Dillenberger, & Ortoleva 2015) is, I think, too much committing to only risk aversion.

The paper considers three forms of risk aversion, points out that they are equivalent under EU, and puts up the research question under what other models they could be equivalent.

The author repeatedly claims that RDU is very general, probably misled by Cerreia-Vioglio, Dillenberger, & Ortoleva (2015). In reality, it uses lower-dimensional parameters than betweenness expected utility or cautious expected utility.

The paper throughout focuses on risk aversion, and does not consider insensitivity. %}

Baccelli, Jean (2018) “Risk Attitudes in Axiomatic Decision Theory—A Conceptual Perspective,” *Theory and Decision* 84, 61–82.

{% Under EU, if we do allow for state dependence, then we can multiply utility by state-dependent positive constants, divide the corresponding probabilities, and renormalize, which makes probabilities unidentifiable apart from being nonzero. This does not work as easily for nonEU models that can be taken as having act-dependent probabilities, such as RDU (where probabilities depend on the act via the ranking of states) or moral hazard, because then the probability proportions between states vary imposing extra restrictions. The paper shows that if the set of act-dependent probabilities {P_f: f an act} has linear dimension n and there are n states of nature, then in fact U and the probabilities are uniquely determined even if one allows for state dependence, which reinterprets a mathematical result by Drèze. Whereas the common thinking was that this result is typical of moral hazard this paper shows that it holds more generally under act-dependent probabilities. %}

{% **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**: Paper discusses Suppes’ ideas on it, arguing that Suppes favors one cardinal concept of utility, and pointing out that this is their *interpretation* of Suppes’ work (p. 269 end of 1st para), because for him as a non-economist it was not a very central issue.

Abstract: “We identify Suppes’ doctrine with the major deviation from ordinalism that conceives of utility functions as representing preference differences, while being nonetheless empirically related to choices.” They cite Köbberling (2006) as a good paper on axiomatization of preference difference representation. Baccelli (personal communication) told me that Suppes mentions a number of known attempts to reveal preference intensity from choice (e.g., by monetary side payments) but does not clearly advocate one. They all have their well-known problems.

P. 273: The authors distinguish between absolutely cardinal and relatively cardinal, where the latter depends on the desired functional representation of preference. However, I think that cardinal and ordinal are always relative. %}

Baccelli, Jean & Philippe Mongin (2016) "Choice-Based Cardinal Utility. A Tribute to Patrick Suppes," *Journal of Economic Methodology* 23, 268–288.

{% Peters & Wakker (1987) analyzed Yaari's (1969) comparative risk aversion (lower certainty equivalents) for general outcome domains, that may be nonconvex, nonnumerical, and/or finite. They showed that, under expected utility (EU), more risk averse is still equivalent to utility being more concave. In particular, they thus greatly generalized the weak Kihlstrom & Mirman (1974) showing in particular that the assumption of same ordering of riskless outcomes, emphasized so much by K&M, can be dropped because it is essentially implied by the other assumptions. Thus, under EU comparative risk aversion works similarly on finite and infinite domains.

This paper shows that, under RDU (rank-dependent utility), comparative risk aversion works differently on finite than on convex (so numerical and infinite) domains. They show the same for strong risk aversion. They show, a new result also, that under EU comparative weak and strong risk aversion work the same for finite and convex domains.

For general outcomes, a spread of a lottery means that some outcome is chosen as center, and then probability mass is moved to extremes in both directions. It does not require same expected values, those not even being defined for nonquantitative outcomes. That is, the distribution functions single-cross. This is used in definitions of strong risk aversion.

Pp. 383-395 discuss that a characterization of risk aversion (which means weak risk aversion) or its comparative version is open under RDU.

The abstract is enthusiastic when writing, on some results being different under EU than under RDU: "Thus, considering comparative risk aversion over finite domains leads to a better understanding of *the divide* between expected and non-expected utility, more generally, the structural properties of the main models of decision-making under risk." [italics added] %}

{% Eeckhoudt and Schlesinger (2006) proposed preference conditions that axiomatize prudence and higher-order risk attitudes for decision under risk with expected utility. Prudence means you rather have a risk added to a good outcome than to a bad outcome in a lottery you are facing. The present paper uses the Anscombe-Aumann framework, where probabilities in lotteries can serve as utility units, lets those play the role of outcomes in DUR. Ambiguity prudence means a preference for probability loss in an unambiguous event rather than ambiguous, doing it for several events in a partition to control for unknown beliefs. The paper shows that this definition of ambiguity prudence has theoretical implications analogous to

risk in the smooth ambiguity model and recursive expected utility (Theorem 1 p. 1739). Under α-maxmin, prudence holds quite generally (Theorem 3, p. 1741). It holds generally under multiplier preferences (Theorem 4 p. 1742). It holds for CEU under likelihood insensitive weighting function W (under a nonnullness condition), once more underscoring that prudence is like likelihood insensitivity (Theorem 5 p. 1742). In particular, it holds for neo-additive W (Theorem 6 p. 1743) given proper nonnullness. %}

{% **losses from prior endowment mechanism**: they used the random incentive system (p. 85 top) but a priori gave subjects €15 endowment so that never net losses (p. 83 top).

natural sources of ambiguity;

suspicion under ambiguity: they told subjects that for each event they also play the complementary event (p. 87).

Take three disjoint events referring to performance of Dutch AEX stock index in two experiments. (Do the same with Indian SENSEX stock index in experiment 1 and the South African TOP40 in experiment 2. They will always find the same results for different sources: p. 92.) Measure matching probabilities and then derive implications for ambiguity attitudes using pessimism and insensitivity indexes. Do it both for gains and for losses. It is nice that they do it for natural events rather than the over-studied Ellsberg urns.

ambiguity seeking for losses: they find it,

ambiguity seeking for unlikely: they find it.

They find the fourfold pattern of ambiguity attitude, as does virtually every empirical study. End of intro writes (p. 78): "Models that can account for this pattern include prospect theory and α-maxmin expected utility. Models that assume uniform [over different likelihood levels of events] ambiguity aversion or ambiguity seeking, by contrast, are incompatible with most of the patterns that we observed.” **(event/outcome driven ambiguity model: event driven)**

I here denote by m(E) the matching probability of an event, where I do not express the outcome used or its sign and default is that it is about gains.

As index of lower subadditivity (capturing optimism for low likelihoods) they take, for disjoint events E_i, E_j with E_{ij} their union:

$LA(E_i,E_j) = m(E_i) + m(E_j) - m(E_{ij})$.

So, it is the difference between how much each event in isolation adds to the empty set and how much they add jointly.

As index of upper subadditivity (capturing pessimism for high likelihoods) one can take, as natural dual:

$UA(E_i,E_j) = 1-m(E_i^c) + 1-m(E_j^c) - (1 - m(E_{ij}^c)) =$

$1-m(E_i^c) - m(E_j^c) + m(E_{ij}^c) =$

So, it is the difference between how much each event in isolation subtracts from the universal event and how much they subtract jointly.

P. 80: The authors do not use this dual notation $UA(E_i,E_j)$ but write $UA(E_k)$ instead, which has the drawback that the notation does not express how E_k^c is partitioned into E_i and E_j.

I agree with p. 81 bottom: “A limitation of both maxmin EU and α-maxmin is their dichotomous nature: probability measures are either fully included or fully excluded from the set of priors C. A more realistic case is modeled by the variational model”

I disagree with p.82 bottom: “Choquet EU predicts that violations of binary complementarity are the same for gains and losses.” Choquet EU predicts that they are opposite, not the same. Note here that matching probabilities for gains x are measured by $(x_E0 \sim x_p0)$, so, the event and probabilities are attached to the best outcome, but that matching probabilities for losses z are measured by $(z_E0 \sim z_p0)$, so, the event and probabilities are attached to the worst outcome. This is why Choquet EU predicts opposite violations for gains than for losses. Another way to see this is that maxmin EU, α-maxmin EU, and Choquet EU are all biseparable utility, so, should give the same predictions. Hence, I also disagree with the claimed violation of Choquet EU on p. 95 penultimate para.

P. 96 ℓℓ. 4-5: “The only theory that can explain the choices of most subjects is prospect theory”

EXPERIMENT 1:

P. 77: They assume that if matching probabilities were to measure beliefs, they would have to be additive. So, they take subjective belief as additive. One can also argue for nonadditivity of beliefs. They put this view, which I like, forward on p. 97 3rd para. But they automatically connect it with the assumption of sign-dependence and that is something I would not follow.

. 87 bottom: a bit strange that more a-seeking for losses than a-aversion for gains.

P. 88: binary complementarity holds for gains but not for losses.

P. 89 bottom: They find more ambiguity seeking for losses than ambiguity aversion for gains, which is unusual. Hence, while binary complementarity is satisfied for gains, it is not for losses (pp. 88-89), where we find a deviation in the ambiguity-seeking direction.

P. 89 3rd para: They find lower SA *always* confirmed.

EXPERIMENT 2:

Now binary complementarity is also violated for gains (p. 92).

P. 93: more a-generated insensitivity for losses than for gains.

P. 95: they again find the fourfold pattern of ambiguity attitude.

P. 95 2nd para: all models except Choquet EU, α-maxmin, and prospect theory are widely violated.

P. 96: "The superior performance of prospect theory illustrates the importance of allowing for sign-dependence in modeling ambiguity attitudes."

P. 97: "Some recent ambiguity models are too general to generate predictions …"

P. 97: "Moreover, intuitively, it is not immediately obvious why beliefs should differ between gains and losses."

I reproduce the conclusion:

"This paper sheds light on patterns of violations of probabilistic sophistication. We measured matching probabilities for gains and losses in two experiments, using natural (non-Ellsberg-like) uncertainties. Matching probabilities were sign-dependent, additivity was violated, and the violations of additivity were stronger for losses than for gains. Together these violations imply a fourfold pattern of ambiguity attitudes: ambiguity aversion for likely gains and unlikely losses and ambiguity seeking for unlikely gains and likely losses. Our results were most consistent with prospect theory and, to a lesser extent, Choquet EU and -maxmin. Models with uniform ambiguity attitudes could not explain our results.” %}

Baillon, Aurélien & Han Bleichrodt (2015) “Testing Ambiguity Models through the Measurement of Probabilities for Gains and Losses,” *American Economic Journal: Microeconomics* 7, 77–100. https://doi.org/10.1257/mic.20130196

{% **natural sources of ambiguity; updating under ambiguity with sampling**: Measure pessimism and likelihood-insensitivity using the indexes of Abdellaoui et al. (2011). Consider ask prices of IPO stocks, so, natural events. Consider learning, with info about past performance gradually provided. They find little pessimism, but substantial insensitivity. Learning moves towards expected utility, reducing insensitivity, but clearly insensitivity does not disappear and deviation from EU remains. They also derived a-neutral probabilities and those were close to historical frequencies.

This paper was the first to relate the indexes of the source method of Abdellaoui et al. (2011) to indexes used under multiple priors. Multiple priors assumes expected utility for risk, and then pessimism = ambiguity aversion and likelihood insensitivity = a(mbiguity-generated) insensitivity (p. 2184 penultimate para). The paper shows that the insensitivity index of the source method of Abdelloui et al. (2011) is the ambiguity perception index of the epsilon-contamination subfamily of the multiple prior family, and that the ambiguity aversion index of epsilon-contamination is the aversion index of the source method per perceived ambiguity unit. They first did so in the working paper version of 13 August, 2013, downloadable here: link to 2013 version

pp. 10-11, where epsilon-contamination is exactly the neo-additive model of Chateauneuf, Grant, & Eichberger (2007) in multiple priors, as CGE show. Baillon et al. sent their 2013 paper to Dimmock & Kouwenberg who used it in Dimmock, Kouwenberg, Mitchell, & Peijnenburg (2015, JRU).

P. 2184 2nd para of 2nd column 2nd para points out that the value of the aversion parameter b depends on the value of the insensitivity parameter a. This does not mean that they are not different components. An example to explain: If a person is maximally risk averse, then the person can't be ambiguity averse. This does not mean that risk aversion and ambiguity aversion would not be different components.

P. 2185 2nd column 2nd para writes: "On the other hand, alpha$_t$ is a relative measure of ambiguity aversion, which is defined per unit of perceived ambiguity and, *therefore*, does not depend on the amount of perceived ambiguity. This explains why b_t is bounded by $-a_t$ and a_t and thus depends to some extent on likelihood insensitivity, and *alpha*$_t$ is bounded by by 0 and 1 and does not depend on ambiguity perception." [italics added]

P. 2185 penultimate para: "The multiple prior interpretation requires that a_t is positive. As several of our subjects had negative a_t, we could only use the multiple prior interpretation in the aggregate analyses and did not use it in the individual analyses."

Pp. 2187-2188: the authors measure certainty equivalents and fit utility, and do not measure matching probabilities. P. 2188: exponential, power, and expopower utility gave equally good fit. %}

{% This paper examines what reference points are, about the most central question in decision under risk. It is entirely revealed-preference based, using no other data. It starts from a general model in Eq. 6, which contains six of the most popular models of reference points, displayed in Table 12 (p. 96). It uses a data set (N = 139) obtained in Moldavia, where the average payoff per subject was about a day's salary. It uses advanced Hierarchical Bayesian data fitting. The status quo and the security level (maxmin: The maximum of all minima of available prospects) did best. Koszegi-Rabin type expectation-based reference points do not perform well. This is stated explicitly on p. 105.

The authors distinguish between prospect-specific (depending on the prospect and different for each of the prospects available for choice and choice specific, determined by the choice situation. They cite many studies into the location of reference points, and cite papers equating the Koszegi-Rabin approach with disappointment-theory approaches.

The reference points do not depend much on absolute wealth level (p. 104), and probability weighting is too important to be ignored (p. 104); consumption utility can be ignored. Prospect-specific models often violate stochastic dominance (p. 104). %}

{% **source-dependent utility** is criticized here.
endogenous midpoints; this paper uses an endogenous utility-midpoint operation to give theorems on concave utility in great generality, e.g. doing the Yaari (1969) comparative risk aversion without requiring identical beliefs, and doing ambiguity aversion in the smooth model without requiring the unobservable subjective probabilities as input or requiring same risk attitudes. Section 3.4 gives an intuitive interpretation criticizing the smooth model and many other models:

"An objection can be raised when our preference condition in terms of utility midpoints is not just used to analyze utility, but is also interpreted as a condition for risk or ambiguity aversion. Our midpoint condition does not speak to the empirical nature of risk, timing (as in Kreps and Porteus' model), or ambiguity, unlike the conditions that other authors have used. However, (and this is our message) if a theory such as EU or recursive EU implies that our condition is still equivalent to the others, then this implication of the theory cannot be empirically appropriate, which raises doubts about the theory itself." %}

{% **ambiguity seeking for unlikely**: They use matching probabilities to measure ambiguity attitudes, and do it for unlikely events (smallest has a-neutral probability 0.005), where they find overweighting, giving ambiguity seeking for gains and ambiguity aversion for losses, all confirming the fourfold pattern of ambiguity. The also find lower and upper sub/superadditivity in agreement with a-insensitivity.

They use the Prince incentive system. %}

Baillon, Aurélien & Aysil Emirmahmutoglu (2018) "Zooming in on Ambiguity Attitudes," *International Economic Review* 59, 2107–2131. https://doi.org/10.1111/iere.12331

{% The authors test the random incentive system (RIS) for measuring ambiguity aversion. Treatments are between-subjects. The control treatment is one single choice only, the standard two-urn Ellsberg test, with proper control for suspicion by letting subjects choose winning color. Then there are two treatments where subjects make two choices. For each of the two colors, subjects must choose between the known (K) and unknown (U) urn. The unknown urn has a somewhat higher prize, so that observed ambiguity aversion is strict. In the control treatment, 50% was ambiguity averse. In the treatments, averaged, KK (27%), KU (23%), UK (9.5%), UU (41.5%) (Figure 2.4). Remarkable is the small number of UK choices. That is, the deviation from random choice is that subjects in the treatment groups who at first chose U, often also did so the second time. It is a clear spillover effect, confounding the RIS measurement. It means that the RIS deviates from the control treatment, giving some less ambiguity aversion.

As the authors point out, they chose a framing of the stimuli that enhances integration effects and violations of RIS. In this sense, the finding is not very surprising. The more critical question is how RIS performs in best framing, not in worst framing. But this paper shows the principled point that the RIS can bring distortions, and that one has to watch out.

The paper did some other experiments to check. For instance, determining the real choice situation beforehand (but unknown to subjects) or after did not matter. It cites much literature. %}

{% Sadness moves people to ambiguity neutrality, unlike joy, fear, and control group. Abmiguity aversion was measured as 0.5–p where p is the matching probability of the unknown two-color Ellsberg urn. (Study 2 has a-neutral probabilities 1/3 and 2/3.) Emotions are induced by movies. %}
Baillon, Aurélien, Philipp D. Koellinger, & Theresa Treffers (2016) "Sadder but Wiser: The Effects of Emotional States on Ambiguity Attitudes," *Journal of Economic Psychology* 67, 67–82.

{% An exemplary study of WTP and risk attitudes for health insurance of a valuable sample of Philipino households, using the tools of prospect theory, with clear applied relevance. The authors split up the risk premium into (1) belief premium: due to misperception of probabilities (2) weighting premium: due to nonlinear weighting of probabilities (3) utility premium: due to nonlinear utility (4) residual. It is somewhat reminiscent of the cited Hilton (1988). A typical finding here is that people take too little insurance, even if it is subsidized and actuarially fair, and have too low WTP. The authors investigate which factors contribute how and what to do about that. It is well-known that biases push WTP down, and I did not read the paper close enough to see how it handles this. Maybe it is

considered part of the residual premium, which captures about half as much as the risk attitude premiums.

P. 49 discusses the order of calculating the premiums.

Pp. 48-50, end of intro, summarizes the findings. The median belief premium is about 0. Utility and probability premiums are negative, as with prospect theory's risk seeking for losses, and explaining part of the overly low WTPs. But median utility and probability premiums seem to e close to 0. %}

Baillon, Aurélien, Aleli Kraft, Owen O'Donnell, & Kim van Wilgenburg (2022) "A Behavioral Decomposition of Willingness to Pay for Health Insurance," *Journal of Risk and Uncertainty* 64, 43–87. https://doi.org/10.1007/s11166-022-09371-2

{% A difficulty of working with the Pratt-Arrow index of absolute risk aversion is that it cannot be readily derived from a (small) finite number of observed indifferences, but that it requires parametric fitting. This paper provides a discrete approximation. Let $\alpha_E\mu$ denote an act assigning outcome α to event E and μ to event E^c. The paper uses indifferences $\alpha_E\mu \sim \beta_E\nu$ and $\beta_E\mu \sim \gamma_E\nu$ to define β as the endogenous midpoint of α and γ. Under EU, also with subjective probabilities, it implies that β indeed is the U midpoint between α and γ. We write $m(\alpha,\gamma) = \beta$. Assume $\gamma \succcurlyeq \alpha$. The index $A(\alpha,\gamma)$ is defined as $\frac{1}{m-\alpha} - \frac{1}{\gamma-m}$. It can be seen that it is a discrete approximation of the Pratt-Arrow index. The index can be used for many purposes.

Many authors use ad hoc indexes of risk aversion, such as normalized risk premiums, but this normalization is, in a way, not at the right order of magnitude, where the index for instance tends to risk neutrality simply if the interval $[\alpha,\gamma]$ gets small. The index of this paper does not suffer from that and is at a good order of magnitude. (See p. 1385, end of §3.)

Theorem 1 shows that, under common assumptions, for two states of nature, subjective expected utility holds if and only if the index satisfies a consistency condition. Theorem 2 shows that a comonotonic consistency condition holds if and only if biseparable utility holds. Theorem 3 and Table 1 list many conditions that can be characterized using the index, such as risk aversion and comparative risk aversion. %}

{% Whereas Machina (2009) devised a paradox only for rank-dependent utility (also called CEU = Choquet expected utility), this paper shows that it is a paradox for virtually every ambiguity theory existing today in the Anscombe-Aumann framework. As an aside, if we abandon the Anscombe-Aumann framework, then Machina's paradox is only for RDU and no more for the other models. %}

Baillon, Aurélien, Olivier l'Haridon, & Laetitia Placido (2011) "Ambiguity Models and the Machina Paradoxes," *American Economic Review* 101, 1547–1560.

{% Show a generalization of Yaari's acceptance condition for more concave utility that also works under different beliefs and different state spaces for the two agents. In particular, it can be used for within-subject between-source comparisons of utility. Thus, it can characterize ambiguity aversion for KMM's smooth ambiguity model. The condition works as follows:

Let $\{E_1,\ldots,E_n\}$ be a partition for agent A, and

$\{F_1,\ldots,F_n\}$ a partition for agent B. $x_1,\ldots,x_n$ denote outcomes. Π is generic for a permutation of $1,\ldots,n$. f is an act depending on $E_1,\ldots,E_n$. g is an act depending on $F_1,\ldots,F_n$. $\Pi(f)$ is the act with $x_1,\ldots,x_n$ assigned to the Π permuted events and $\Pi(g)$ is similar. For instance, if Π does nothing but interchange 1 and 2, then $\Pi(g) = (F_1{:}x_2, F_2{:}x_1, F_3{:}x_3, \ldots F_n{:}x_n)$.

z is generic notation of a constant act, and >= denotes preference. If events $E_1, .., E_n$ are exchangeable, i.e., preference-symmetric, then $f \sim \Pi(f)$ for every Π. We assume SEU for both agents. Imagine that we have

$z \succcurlyeq_A \Pi(f)$ for all Π $\Rightarrow$ $z \prec_B \Pi'(g)$ for all Π'. Then, even for the most risk-favoring Π and the least risk-favoring Π', $\succcurlyeq_A$ seeks more certainty than $\succcurlyeq_B$. It cannot be that $\succcurlyeq_B$ is more risk averse than $\succcurlyeq_A$. It turns out that excluding this case is not only necessary, but also sufficient, for u_B to be more concave than u_A, whenever there exist uniform partitions $\{E_1, \ldots, E_n\}$ and $\{F_1, \ldots, F_n\}$. The result is easier to state for n = 2, and such versions can also be invoked for general state spaces.

The above condition is alternative to Yaari (1969), allowing for different beliefs and even state spaces. Baillon, Driesen, & Wakker (2012) achieve this in a different manner, using endogenous utility midpopints. The result can also be used to axiomatize ambiguity aversion in KMM's smooth ambiguity model, or in source-dependent SEU of Chew et al. (2008). Or for Kreps-Porteus (1978). %}

{% **proper scoring rules**: They test scoring rules for multiple choice questions where not just right answers get score 1 and wrong answers and nonresponses all get score 0, which encourages random answering if not knowing, but scoring systems where wrong answering is punished by getting a lower score than nonresponse. Their novelty is that they distinguish gain- versus loss framing and that they do it in the field, with scores on exams with university students—I wonder if ethical commitees can approve of such experiments with something as serious as student grading.

Given that, according to loss aversion, losses are perceived more strongly than gains, one may expect improved performance and less nonresponse (random answering was better than not answering), the more so as studies by Yechiam and co-authors (e.g., Yechiam, Retzer, Telpaz, & Hochman 2015) suggest better motivation and performances under losses. The reduction of nonresponse is confirmed, but for the former there is even a nonsignificant tendency to the opposite. The authors, at the end, only cite studies that suggest that losses impair performance, contrary to findings by Yechiam, and cite Yechiam only for another point.

I expect that there is much related work in psychological literature on education, as for instance in Kaernbach (2001). Related, in probably relevant journals, are Budescu & Bar-Hillel (1993), and Echternacht (1972). %}

{% In general, power (CRRA) utility fits data better than exponential (CARA) utility. However, power utility has analytical problems when defining loss aversion under prospect theory in the usual way (unless same power for gains and losses). See, e.g., Wakker (2010 p. 338-342, §9.6). This usual way is to take one normalization outcome $\alpha > 0$ with assumed $u(\alpha) = 1$, $u(-\alpha) = -1$, and set $\lambda = -U(-\alpha)/U(\alpha)$. Then λ can depend entirely on the α chosen with power utility. This paper proposes to take a weighted average over many α, where the αs range over a domain relevant for the applications considered, weighted according to importance/relevance. This is a nice idea. Data come from Ghanaian farmers. Data fitting shows that α can still be very volatile, e.g., w.r.t. power. The authors

argue that one should not sacrifice fit (by giving up power utility) to get a stable loss aversion parameter.

Utility is concave for gains and convex for losses, but is closer to linear for losses than for gains. (**concave utility for gains, convex utility for losses**)

They strongly confirm inverse S probability weighting but, because they fit Prelec two-parameter CI family, there is not much space for other shapes. (**inverse S**). They also find that parameters interact, with the estimation of loss aversion and also of probability weighting depending on the utility family used. %}

Balcombe, Kelvin, Nick Bardsley, Sam Dadzie, & Iain Fraser (2019) "Estimating Parametric Loss Aversion with Prospect Theory: Recognising and Dealing with Size Dependence," *Journal of Economic Behavior and Organization* 162, 106–119.

{% Re-analyze the data of Stott (2006) using Bayesian techniques, with a prior distribution chosen. His stimuli are not fully representative because they always concern a choice between two two-outcome prospects where one of the two has one outcome equal to 0 (p. 112 3rd para). Consider only gains. Fit PT (referring to the new 1992 version that is sometimes called CPT, but that Tversky and I prefer to call PT), which now agrees with RDU, but also Birnbaum's RAM and TAX models and the priority heuristic. Use more sophisticated error theories and Bayesian fitting techniques than Stott did.

They find that PT fits best. Power utility by far best fits rather than exponential or Saha's powerexpo (**decreasing ARA/increasing RRA**). Utility is concave, as is to be expected. For representative agent, probability weighting is more concave (optimistic) than inverse S (**inverse S**; **risk seeking for small-probability gains**). At the individual level, there is much heterogeneity in probability weighting. Much heterogeneity is confirmed by representative agent being firmly rejected. P. 184 writes that probability weighting is less stable than utility.

For error theory, Wilcox's (2011) contextual utility works best.

For a minority of subjects, linear probability weighting (so, EU) fits best, but for majority probability weighting is better.

Whereas Stott's analysis gave Prelec's one-parameter family as best, the alternative analysis of this paper gets two-parameter families as better. %}

{% Test updating in two tasks with children and young adults. Optimal behavior in the two tasks is very simple though. In Task 1, one should gamble on the color observed most. In Task 2, one color is clearly superior no matter what is observed. Yet, young children often deviate from the optimal strategies and the authors analyze several alternative strategies, such as gambling on the last color observed. They use the term “evolutionary” in a strange manner. As I see it, everything comes from evolution and everything can be called evolutionary. However, they use it for the silly heuristic of gambling on the last color observed. They put up a strawman hypothesis: that we are born as Bayesians but at growing older more and more learn to do irrational heuristics. They, of course, find the opposite: the older the more Bayesian/rational. At least from child to young adult.

The authors often refer to which grade school children in the US in 2018 have and (almost) never to age, making it hard for readers from other places or times what that means.

The primary heuristic that I expect to be going on here is never mentioned, i.e., probability matching (Bitterman 1965): not doing the rational thing of always choosing highest probability of winning, but instead randomizing and choosing the highest probability of winning only with that same probability.

Nice for me, Bayesian, to read on p. 305 that the authors consider Bayesianism to be normative. %}

{% **dynamic consistency**; In PT person will prefer long-shot gamble as soon as w´(0) > λ; i.e., probability weighting at 0 can dominate loss aversion. Thus, betting on one number in roulette may already be preferred. Even if only 50-50 bets, the topic of this paper, PT people may prefer it by repeating them, say, 5 times, generating a small (1/32) probability that generates the overweighting. However, this is if prior perspective. If such people involve in playing some rounds then after 3 rounds of winning they face a probability of only ¼ of winning in the next

two rounds, and may decide to drop out, violating dynamic consistency. The mix of prior evaluation, dynamic inconsistency, and naivity can lead people to all kinds of irrationalities such as continuing playing after losing but stopping after gaining, all opposite to prior plans. The author, like me, uses the term prospect theory instead of cumulative prospect theory (footnote 1).

P. 39 end of §2: the author interprets transformed probabilities not as misperceptions, but as deliberate weighting.

Final sentence of paper is very positive about probability weighting:

"Taken together with this prior research, then, our paper suggests that casino gambling is not an isolated phenomenon requiring its own unique explanation, but rather that it is one of a family of empirical facts, all of which are driven by the same underlying mechanism: probability weighting." %}

Barberis, Nicholas C. (2012) "A Model of Casino Gambling," *Management Science* 58, 35–51.

{% **PT, applications**: lucid survey of PT accessible to a wide audience.

Abstract, p. 173: "More than 30 years later, prospect theory is still widely viewed as the best available description of how people evaluate risk in experimental settings." (**PT/RDU most popular**)

Abstract: "I am optimistic that some insights of prospect theory will eventually find a permanent and significant place in mainstream economic analysis." (**PT/RDU most popular**)

Abstract: "The fundamental difficulty in applying prospect theory in economics is that, even if we accept that the carriers of utility are gains and losses, it is often unclear what a gain or loss represents in any given situation."

P. 173 last para, and some other places p. 178 3rd para), write that PT hasn't been applied as much as one might expect mostly because it is not very clear how to apply it, mostly because of the difficulty of what the reference point is.

P. 174 middle prefers the new 1992 PT (better notation than the author's, and common, CPT) to the OPT of 1979.

P. 174: the author only describes PT for risk, with no mention that it was extended to uncertainty/ambiguity. P. 180 2nd para repeats it.

P. 174 bottom takes PT as depending only on changes w.r.t. reference point, and as if independent from initial wealth. This deviates from PT of Tversky &

Kahneman (1992), who allowed value and probability weighting to be different for different reference points. P. 179 end of 3rd para correctly retraces here.

P. 175 last para incorrectly writes as if diminishing sensitivity refer only to the value function, whereas Tversky & Kahneman apply it also to probability weighting.

utility concave near ruin: p. 175 footnote 2.

The paper puts the model of Köszegi & Rabin very central.

P. 177 bottom claims that Kahneman and Tversky emphasize that transformed probabilities do not represent erroneous beliefs but this is not correct because K&T do not commit to one or the other.

P. 179 end of 2nd para (also 192 1st para) do not follow Köszegi & Rabin on expectation as reference point: "in financial settings, a reference point such as the risk-free rate may be at least as plausible as one based on expectations." P. 192 1st para repeats the point, suggesting that in finance people may take some natural levels as reference points, rather than expectations.

P. 180 writes that PT has been most applied to finance; p. 190 writes that not much in health economics; p. 191 writes that to finance and insurance.

P. 183 writes on disposition effect, and studies looking into reflection but, apparently, not into probability weighting.

P. 190 gives some references that negative incentives have more effect than positive ones.

P. 191 bottom suggests that diminishing sensitivity, which in the author's terminology only refers to utility curvature, is less important than the other components reference dependence, loss aversion, and probability weighting. One thing that is important about it is that it is the only rational component!

P. 192 explicitly leaves open that PT may be rational: "because we do not, as yet, have a full understanding of whether loss aversion or probability weighting should be thought of as mistakes." I Bayesian see these things differently!

P. 192 footnote 13 claims that narrow framing is widely viewed as a mistake. Note that Tversky & Kahneman (1981) discusses discrepancies such as between narrow and wide framing and that the, subtle, underlying message is that what is really wrong is that we deviate too much from expected value.

A few things that I would present differently:

(1) This paper exclusively focuses on risk with given probabilities. P. 180:

"Prospect theory is, first and foremost, a model of decision-making under risk." An important innovation of the 1992 paper, expressed in its title (using the term uncertainty rather than risk as in 1979) is the extension to uncertainty/ambiguity. But, indeed, there have hardly been applications of the latter yet, it yet requiring further theoretical work–which is my main research interest today. (2015)

(2) P. 174 uses the unfortunate notation with negative indexes as T&K'92 did, and as Tversky regretted after (personal communication). Although T&K indeed ordered outcomes from low to high, the prevailing and recommended ordering is from high to low, with $x_1 \geq \cdots \geq x_n$, and $x_k \geq 0 \geq x_{k+1}$.

(3) P. 174 bottom claims that PT evaluates outcomes merely as changes wrt the reference point, independently of final wealth, so, independently of what the reference point is. This is not correct, but it is a widespread misunderstanding. Kahneman & Tversky (1979) write about this on p. 277, for instance: "The emphasis on changes as the carriers of value should not be taken to imply that the value of a particular change is independent of initial position."

(4) P. 175 last para, & p. 191 last para: The author erroneously has the term diminishing sensitivity refer exclusively to the utility/value of outcomes, as it is also commonly taken in the decision-from-experience (DFE) literature. It is a general phenomenon on numerical perception that as much concerns probability weighting. (T&K'92 p. 303 2nd para: "The principle of diminishing sensitivity applies to the weighting functions as well.")

(5) P. 177 ℓ. −2 writes: "Kahneman and Tversky emphasize that the transformed probabilities π_i do not represent erroneous beliefs; rather, they are decision weights." There is one sentence, if I remember right, where K&T make such a suggestion, but it is not really the belief of Tversky. He thought that it could be both misperceived probabilities and weighting for other reasons, and several parts in the K&T paper write this. %}

Barberis, Nicholas C. (2013) "Thirty Years of Prospect Theory in Economics: A Review and Assessment," *Journal of Economic Perspectives* 27, 173–195. https://doi.org/10.1257/jep.27.1.173

{% A short and very accessible version of Barberis (2013 JEP), pleaing for the importance of probability weighting. P. 611 2nd para mentions the two-stage model by Fox & Tversky. P. 621 penultimate para claims that the probability weighting function transforms subjective probabilities, but in common terminologies it is objective probabilities. Abdellaoui et al. (2011 American Economic Review) have what they call source function, which transforms choice-based probabilities (which will usually not reflect beliefs). Fox & Tversky tried to use the risk-probability-weighting function to transform introspective subjective probability estimates, but this is a strong empirical hypothesis to be tested, rather than standard terminology.

P. 611 footnote 1 states, in my terminology, that the 1979 OPT is outdated and we should use the modern 1992 PT (what many people call CPT).

P. 612 2nd para end claims that there is more evidence for probability weighting than for loss aversion, but I see this differently. It is true, as explained in footnote 2, that loss aversion is more volatile and, hence, it may be argued (although debatable) that it is less suited to make predictions.

P. 613 §II discusses overweighting versus underweighting of rare events.

P. 614 footnote 5 argues that probability weighting does not concern beliefs. People discuss this point, even for objective probabilities. Probability weighting may reflect numerical misperception, and this can concern belief. %}

Barberis, Nicholas C. (2013) "The Psychology of Tail Events: Progress and Challenges," *American Economic Review, Papers and Proceedings* 103, 611–616.

{% Paper on Thaler's Nobel prize. P. 662 mentions four factors. I disagree from the author in that I think that only the third factor "they found ways of helping people to make better economic decisions" is where Thaler is exceptional. But then, so exceptional and valuable, that I think it was enough for the Nobel prize. P. 668 writes: "It is here that Thaler had his single most influential insight. In the 1970s, after discovering that, unbeknownst to economists, psychologists –most notably Kahneman and Tversky – had been cataloguing the ways in which people depart from full rationality, Thaler recognized that this research was the key to progress in behavioral economics." Again, I disagree. Many people had this understanding. Just following Kahneman & Tversky is too small to call it Thaler's greatest contribution.

The author presents behavioral economics as a reaction to the rational expectations revolution, as the author calls it. Rational expectations was of course

a big idea in macro-economics and finance, but not wide enough to call it a revolution. Behavioral economics is better positioned as a reaction to the ordinal revolution. %}

Barberis, Nicholas C. & Ming Huang (2009) "Preferences with Frames: A New Utility Specification That Allows for the Framing of Risks," *Journal of Economic Dynamics and Control* 33, 1555–1576.

{% Let consumer derive direct utility from changes in income. Define loss aversion in such terms.

P. 17: loss aversion is more important than utility curvature and, hence, they let utility be linear for gains and losses!

P. 18 explains how the house money effect of Thaler & Johnson (1990) can be reconciled with the fourfold pattern of prospect theory: in Thaler & Johnson subjects do not integrate prior losses, but instead shift the reference point and at the same time become more loss averse. %}

Barberis, Nicholas C., Ming Huang, & Tano Santos (2001) "Prospect Theory and Asset Prices," *Quarterly Journal of Economics* 116, 1–53.

{% P. 1069 footnote 1: loss aversion generates first-order risk aversion.

Point out that nonEU without loss aversion can also explain the Rabin calibration paradox as per first-order risk aversion. Then they consider what they call "delayed gambles." What it means is that then background risks are incorporated. I think that background risks can almost as much play a role with immediate payment as with delayed. At any rate, what they call delayed gamble is with background risks involved. Then nonEU models with first-order risk aversion lose most of that first-order risk aversion. Let me explain for rank-dependent utility. With background risk, the rank of any outcome of a gamble now considered is mostly determined by the background risk, and it is similar for all outcomes of the gamble now considered. Thus, the rank-dependence in the gamble now considered mostly disappears. Hence, rank-dependence can only work in "isolated" analyses, without considering the background risks. A preliminary version of this idea, only for linear utility, had been pointed out before by Quiggin (2003). The isolated analyses is what the authors call narrow framing and what others call narrow bracketing.

P. 1072, bottom of 1st column, suggests that recursive is the "typical" implementation of nonEU in dynamic situations, apparently ignoring the several other ways such as propagated by Machina (1989). %}

{% **foundations of statistics**; **foundations of probability**;
Organizes "Séminaire d'Histoire du Calcul des Probabilités et de la Statistique" %}

Barbut, Marc (1997),

{% **inverse S**, confirmed, although the families used assume it.

Test probability weighting families. Their own exponential odds family, introduced by these authors in 2013, performs best. Prelec's compound invariance is second best. They test for gains and for losses, finding very similar shapes only less overweighting of small probabilities for losses than for gains.

A central tool in their analysis is w´(p)/w(p), the derivative of ln(w(p)).

P. 195 Eq. 1 defines biseparable utility but does not specify the ranking of outcomes. For gains the examples in the paper always have $V_1 > V_2$ and for losses always $V_2 < V_1$, so, what is convention these days. For losses I did not check, so, I am not sure if they reflected for losses.

P. 195 2nd column middle suggests that methods such as Abdellaoui (2000) could not accommodate the Allais paradox, but this is not correct because they can.

P. 198 1st column middle takes utility is a concrete entity: "We may assume that there is no utility in earning no points."

P. 198: "This experiment expanded upon the novel gamble-matching paradigm used in Chechile and Barch (2013)." They get indifferences from choices between binary prospects, where they avoid degenerate sure prospects. All the binary prospects in fact have one zero outcome, so, they have only one nonzero outcome. This gives identifiability problems for the power of the weighting function, which will depend on conventions assumed for utility. %}

https://doi.org/10.1023/A:1011420500828

{% A very useful standard text on methodological questions for experimental economics. Now not every author has to discuss all the issues about the random incentive system, and dozens of other questions, in each paper and with each referee again, but can refer to this book for all those issues. As it so happens, in virtually every issue of subjective opinion I agree with the authors.

Pp 26 (§1.4) & 96 (§3.2) discuss the Duhem-Quine problem: result of experiments can always have been distorted because of confounds due to other assumptions presupposed.

P. 32 (§1.4), about real incentives and stochastic choice theory: "We suggest that experimental economists have been too prone to lapse, in the first case [incentives], into unreflective conformism, and, in the second case [stochastic variation], into unreflective

diversity." More extensive to come in Ch. 6.

Ch. 2 is about internal and external validity, the discovered preference hypothesis, with two or three different kinds of domains in which experiments can be thought to be relevant.

Ch. 3 Experimental Testing in Practice

§3.5 discusses that economists, despite empirical evidence of violations of transitivity for instance, nevertheless maintain the transitivity assumption in their thinking (called hard-core commitment).

Ch. 4 experiments and inductive generalization.

§4.9.2 on confounds.

P. 181, §4.9.4, criticizes Plott & Zeiler (2005).

Ch. 5: external validity. §5.4.1 is about ceteris paribus.

§5.7 (p. 240) is on field studies. Write, in the context of the sports-cards experiment of List: "The use of a nonconvenience sample does not make the sample representative of the population of interest. ... Thus, the external-validity inference drawn (albeit tentatively) from this experiment by Harrison and List (2004, pp. 1027-28, 2008, pp. 823-24) that certain lab anomalies might be absent in the wild, and that corresponding naturally occurring markets [be] efficient, seems not to follow."

Ch. 6 is on real incentives. P. 249 §6.3 points out that in individual choice the differences between experimental economics and psychology is sharpest.

P. 249: experimental economists may use real incentives as marketing device. P. 250: or as barrier to entry.

P. 255, §6.4.1 discusses a study by Moffat (2005) who measured decision time and took this as index of effort. He found that for choices between (almost) indifferent options the decision time was about twice as much as between options with a clear preference. This is counterevidence against the flat-maximum problem discussed by Harrison (1989) and others. §6.4.2 is on crowding out, relating it also to cognitive dissonance.

§6.5, p. 265, distinguishes between theoretical incentive compatibility and behavioral incentive compatibility. See also their p. 285.

P. 268 takes single individual choice as gold standard.

P. 269 explains that RIS (RLI in authors' terminology) can remain valid under nonEU. 2nd para: "It is easy to see, however, that the RLI [RIS] could be unbiased in the presence of any form of NonEU preferences given different assumptions about how agents mentally process tasks." Bottom: "the RLI [RIS] scheme can be justified even given the knowledge that subjects violate independence."

§6.5, p. 270, discusses the binary lottery incentive scheme, which means paying in probability of gaining something. Pp. 271-274 discusses the BDM (Becker-DeGroot-Marschak) mechanism and its difficulties.

P. 280 writes that it is probably impossible to incentivize plans (unless assuming **dynamic consistency**).

P. 281 argues against a dogmatic requirement of real incentives: "If, as we have argued, there are certain types of tasks that it is inherently difficult, if not impossible, to incentivize, then insistence on task-related incentives for all tasks puts certain research topics off-limits. ... In view of this, we suggest that a more permissive attitude to the role that incentives should play in experiments would be both defensible from a scientific point of view and consonant with more general attitudes to data that prevail in the broader academic community of economists."

Pp. 283-284 discusses deception. Footnote 39 explains that not giving (all) information is not deception.

P. 285: "There may be trade-offs between the pursuit of theoretical incentive compatibility and intelligibility of incentive mechanisms that should enter as considerations in experimental design." See also their p. 265.

Ch. 7: probabilistic choice theories.

Pp. 287-289, §7.1, explain why techniques used in econometrics may be less suited to analyze experimental data. It is because econometrics is for field data where there is much out of control and, hence, much noise that overwhelms any within- or between-subject errors. In experiments there is much control and the stochastic nature of errors is of a different nature.

P. 299 explains how an asymmetry of a bigger number of risky choices for one prospect pair than for another may not indicate violations of a preference condition (such as independence) claiming that same choices may purely be generated by bigger errors in one prospect pair than in another. It can, then, not explain that majority choices are conflicting, but only that choices are closer to 50-50 in one situation than in another. P. 300 explains in words, without using the term, that a symmetric error theory is underlying the above reasoning.

P. 302 explains that error theories will predict more violations of stochastic dominance than observed.

P. 305 prefers random preference model to Fechnerian models

P. 309, §7.3.1, is on quantal response equilibrium.

Boxes:

2.1 (p. 52): internal and external validity.

2.2 (p. 54): blame-the-theory argument (experiment to test theory cannot be blamed for being artificially simple if the theory is so)

2.3 (p. 58): the voluntary-contribution mechanism.

2.4 (p. 61): instrumentalism and Friedman's methodology of positive economics

2.5 (p. 72): expected utility theory: transitivity and independence

2.6 (p. 74): the common ratio effect

2.7 (p. 77): the discovered preference hypothesis

2.8 (p. 88): partners and strangers designs

3.1 (p. 99): a classic market experiment "inducing" supply and demand in a double auction.

3.2 (p. 108): Popper and the methodology of falsification

3.3 (p. 116): the ultimatum game

3.4 (p. 131): preference reversals

3.5 (p. 135): regret theory and the new prediction of choice cycles

4.1 (p. 152): Chamberlin's [1948] experimental market

4.2 (p. 154): the Ellsberg paradox [3-color]

4.3 (p. 157): the endowment effect and the willingness-to-accept/willingness-to-pay disparity.

4.4 (p. 158): the trust game

4.5 (p. 158): focal points

5.1-5.3 (pp. 200-204): present three papers

5.4 (p. 223): the winner's curse

6.1 (p. 266): the random-lottery incentive scheme (a better name is random incentive scheme, RIS) and its variants. Discusses two ways to incentivize adaptive experiments, one based on Bardsley (2000) and the other by Johnson et al. (2007).

6.2 (p. 271): mechanisms for incentivizing valuation tasks. Explains BDM (Becker-DeGroot-Marschak) and Vickrey auction

6.3 (p. 274): the strategy method

6.4 (p. 282): deception: a case of negative externality %}

{% **paternalism/Humean-view-of-preference**; whole paper is on this. P. 26, end of 2nd para: "We might expect such convergence if the subject has an internal scale of disutility, which obeys the consistency requirement, but the subject distorts this scale when expressing it through certain kinds of questions. When the distortions are removed, different kinds of questions will tap the same underlying scale. This is the theoretical claim made by the idea of scale convergence in psychophysics (Birnbaum, 1978)." P. 31 ℓ. −2 cautions that the limiting scale need not necessarily be a true utility. This is the same point as what Loomes, Starmer, & Sugden (2003 EJ) call the shaping hypothesis.

Let subjects do person-tradeoff (what is better, 10 people blind or 8 healthy and 2 death), and two visual analog scale measurements, AS (scale being blind between being healthy and being both blind and deaf) and ME (how much worse is being blind *and d*eaf relative to being only blind, all versus being healthy). In second experiment, the subjects are confronted with inconsistencies (e.g., if for H

> A > B > D, B is exactly mid between H and D, and A is so between H and B, then inconsistency results if not A is 1/4 away from H), and are asked to resolve them. (Bit like Slovic & Tversky 1974) Leads to more internal consistency, and also more consistency between different methods. %}

{% **risk averse for gains, risk seeking for losses**: In Experiment 1, they find more risk seeking for losses than for gains in one-shot. No real incentives here it seems.

real incentives/hypothetical choice: Experiment 2 had real incentives but loss-amounts were simply not implied but kept at zero.

It is remarkable how much the subjects keep on deviating from expected value maximization in repeated choices with the sum of payments received. Experiment 5 has 400 repetitions! %}

Barron, Greg & Ido Erev (2000) “On the Relationship between Decisions in One-Shot and Repeated Tasks: Experimental Results and the Possibility of General Models,” Technion, Haifa, Israel.

{% **PT falsified**: Subjects have to do common-ratio choices, and others, not once, but repeatedly, say 200 times. They don’t get any info about probabilities etc., only can push one of two buttons and from experience find out what probability distribution can be. They don’t even know that it is one fixed probability distribution. Real incentives: they are paid in points, and in end sum total of points is converted to money. Loss aversion is confirmed. Other than that, all phenomena are opposite to prospect theory, with underweighting of small

probabilities (**(very) small probabilities)**, anti-certainty effect, more risk seeking with gains than with losses, etc. A remarkable and original finding. The authors' explanation is that the subjects in their experiment experience the gambles rather than get descriptions of the gambles. It is surprising to me that subjects do not get close to expected value maximization.

My explanation (ex post indeed) (added Jan. 2023: = Fox & Hadar 2006): The subjects put the question "which button would give the best outcome" central, and not "which button would give the best probability distribution over outcomes." They get to see which button gave best outcomes in most of the cases, with recency effect reinforcing it. Thus, subjects experience only the likelihood aspect, whether or not events with good/better outcomes obtain or not. The subjects do not experience the outcomes, because these are just abstract numbers to be experienced only after the experiment. This procedure leads to likelihood-oversensitivity, and S-shaped rather than **inverse S**-shaped nonlinear measures. Example of recency effect: If subjects, for instance, remember only which option gave the best result on the last trial, then they choose the event that with highest probability gives the best outcome (a heuristic advanced by Blavatskyy). Outcomes will be perceived as ordinal more than as cardinal. The authors themselves may have alluded to this explanation on p. 221 just above Experiments 3a and 3b, when they refer to MacDonald, Kagel, & Battalio (1991, EJ) who found the opposite of what they found in an experiment with animals:

"For example, MacDonald et al. used a within-subject design and allowed the decision makers to immediately consume their rewards." %}

Barron, Greg & Ido Erev (2003) "Small Feedback-Based Decisions and Their Limited Correspondence to Description-Based Decisions," *Journal of Behavioral Decision Making* 16, 215–233.

{% P. 281 penultimate para: they have a nice treatment that is intermediate between experience (DFE) and description (DFD): An urn contains 100 balls with a particular proportion of winning balls. Subjects have to sample without replacement, but they have to sample the whole urn, so that they can exactly know the distribution. So, it is experience, but also equivalent to description (if subjects count properly). Yet the authors find underweighting of rare events. (**DFE-DFD gap but no reversal**: they find reversal) Also, it is not ambiguity, but risk. P. 280 cites other studies on DFE that yet have known probabilities, so, it is risk and not ambiguity. They also correct for preferences by first measuring indifferences and then (adaptively) using those stimuli.

Real incentives: they use random incentive system. %}

Barschak, Erna (1951) "A Study of Happiness and Unhappiness in the Childhood and Adolescense of Girls in Different Cultures," *Journal of Psychology* 32, 173–215.

{% This paper argues for the importance of probability weighting.

inverse S: 400,000 household insurance choices are analyzed. The authors find that likelihood insensitive (inverse S) probability weighting is an important factor to explain the data. Strangely enough, they denote probability weighting by capital omega, Ω; I will use the common w. Do both representative-agent analysis, and estimations at the individual level.

P. 2500: "we then demonstrate that neither KR loss aversion alone nor Gul disappointment aversion alone can explain our estimated probability distortions, signifying a crucial role for probability weighting."

P. 2501: The probability weighting functions that they find deviate from what Gul's (1991) disappointment aversion and Köszegi & Rabin's (2006) model (K&R) would imply, detailed on pp. 2015-2016. As explained on p. 2015 bottom, the web appendix seems to analyze how K&R loss aversion can be remodeled as probability weighting; for Gul it is well known (Wakker 2010). For K&R loss aversion it is central in Masatlioglu & Raymond (2016 American Economic Review).

§IV, starting p.2018, explains that they take quadratic distance approximation of w for individual estimates.

equate risk aversion with concave utility under nonEU: p. 2501 and else: they, unfortunately, use the term risk aversion to designate concavity of utility.

They simultaneously fit utility and probability weighting.

§ I.C, p. 2505 describes how they estimate the probabilities of claims/hazards of subjects.

Utility they approximate 2nd order, which means taking it quadratic.

P. 2511 2nd para explains that the data is rich enough to estimate both U and w.

They do regress wrt a vector Z of demographics and the like.

Section III estimates w. The authors call it parameter-free, but what they do is fit a 20th-order polynomial and then on the basic of BIC choose w quadratic.

§II.A: They find inverse S w. Most of their insurance data concern probabilities below 0.16 (p. 2527). They do not speak to other probabilities.

P. 2512: They, nicely, point out that utility is closer to linear if we incorporate probability weighting. (**utility measurement**: **correct for probability distortion**) They now find relative indexes of relative risk aversion (I regret this term for concavity of U) of 0.00064, 0.00063, and 0.00049 in Models 1a, 1b, and 1c, respectively.

P. 2514: w alone explains data better than U alone.

P. 2515 argues, in my terminology, that most probability transformation takes place for very small probabilities (say $p < 0.01$), with w approximately linear with slope 1 after (?), so that the usual inverse S-shapes do not fit well. It suggests neo-additive w (although then slope of linear has to be < 1). Note that they only consider the range [0, 0.16].

P. 2526 advocates probability weighting: "Perhaps the main takeaway of the article is that economists should pay greater attention to the question of how people evaluate risk. Prospect theory incorporates two key features: a value function that describes how people evaluate outcomes and a probability weighting function that describes how people evaluate risk. The behavioral literature, however, has focused primarily on the value function, and there has been relatively little focus on probability weighting. In light of our work, as well as other recent work that reaches similar conclusions using different data and methods, it seems clear that future research on decision making under uncertainty should focus more attention on probability weighting."

P. 2527 top discusses Rabin's paradox but is confused. For instance, their sentence "This suggests that it may be possible-contrary to what some have argued-to resolve Rabin's anomaly without moving to models that impose zero standard risk aversion and use a nonstandard value function to explain aversion to risk." I first (until 2016) misread the sentence to erroneously think that "use a nonstandard …" was part of the "without" part. However, it is part of the "possible .. to resolve …" So, it says that a nonstandard value function CAN explain.

P. 2527 and many other places: The authors cannot distinguish between probability weighting or probability misperception (but their AERPP 2013 paper is on it). I would say that the authors in fact are studying ambiguity attitudes, where their w's are source functions. They allude to ambiguity in Footnote 57, and pity they are not aware that the source method does exactly what they describe there. %}

Barseghyan, Levon, Francesca Molinari, Ted O'Donoghue, & Joshua C. Teitelbaum (2013) "The Nature of Risk Preferences: Evidence from Insurance Choices," *American Economic Review* 103, 2499–2529.
https://doi.org/10.1257/aer.103.6.2499

{% A mostly theoretical paper, with an application to a data set. They assume a large population with every individual making one choice from a choice set with finitely many risky lotteries. The risk attitudes and choice sets are not known to the researcher, but are parametrized by one parameter, which is estimated. I did not read enough to know to what extent they allow for individual differences. They assume a single crossing-over property. That is, choices only once change if some parameters grow. It reminds me of the same condition in Bell (1988, MS), a work not cited. They suggest that the condition is not very restrictive, claiming in Footnote 2: "The EUT framework satisfies the SCP, which requires that if a DM with a certain degree of risk aversion prefers a safer lottery to a riskier one, then all DMs with higher risk aversion also prefer the safer lottery." I am not aware of such a property of expected utility. It will depend on how one defines being more risky. For instance, Wakker (2010 Assignment 3.3.5) mentions an example of two lotteries with the same expected value but still a risk averse decision maker prefers the one with the higher variance (whereas a less risk averse, risk neutral, decision maker is indifferent). So, higher variance will not do. %}

Barseghyan, Levon, Francesca Molinari, & Matthew Thirkettle (2021) "Discrete Choice under Risk with Limited Consideration," *American Economic Review* 111, 1972–2006.
https://doi.org/10.1257/aer.20190253

{% Explain that one can distinguish between rank-dependent probability weighting and just using wrong probabilities if one has rich enough data, because the latter will exhibit no rank dependence, illustrating it with simulations. %}

Barseghyan, Levon, Francesca Molinari, Ted O'Donoghue, & Joshua C. Teitelbaum (2013) "Distinguishing Probability Weighting from Risk Misperceptions in Field Data," *American Economic Review, Papers and Proceedings* 103, 580–585.

{% They work on risk attitude and probability weighting much like I do, but have a different background with more econometrics working with big field data sets. It is interesting for me to see how this leads to differences. Although the paper presents itself as a survey, in reality it is more a long methodological intro followed by a discussion of relatively few studies, where each is discussed thoroughly.

P. 501: "Most of the literature uses expected utility (EU) theory to model risk preferences. Under EU theory, there are two potential sources of variation in attitudes toward risk: people might differ in (i) their degree of diminishing marginal utility for wealth (their utility curvature), or (ii) their subjective beliefs." The authors do not distinguish as clearly between risk (objective probabilities) and ambiguity or, at least, subjective probabilities, as is common in economic decision theory. For instance, p. 507 writes: "Models of risk preferences describe how a person chooses among lotteries of this form, where we often use X to denote a choice set. Throughout, we express lottery outcomes in terms of increments added to (or subtracted from) the person's prior wealth w. In other words, if outcome x_n is realized, then the person will have final wealth $w + x_n$. The probabilities should be taken to be a person's subjective beliefs. In particular, the models below describe how a person's subjective beliefs impact his or her choices." Here w denotes initial wealth and NOT reference point. The authors also use the HARA parametric utility family.

P. 509: What the authors call approximative approach means taking quadratic approximation and using it only locally. It reminds me of their 2013 American Economic Review paper where, in §III, what they called parameter-free meant first fitting a 20th-order polynomial and then on the basic of BIC choosing a quadratic approximation.

Pp. 509-510, §3.1 end, discusses Rabin's paradox. Whereas in the beginning they point out that when working with EU one wants one fixed utility function to be able to have predictions, they nevertheless propose as their "solution" to Rabin's paradox that one take different utility functions for different choice situations.

As in their other papers, the authors have the unconventional habit of denoting probability weighting by capital Omega, Ω.

§3.2, p. 510 bottom: Very regrettably, when defining RDU, the authors do not use top-down integration as is common today, but bottom-up. So, they are using weighting functions dually, where convex and concave should be interchanged everywhere, and so on. Also, the parametric families (e.g., their Table 1) get different meanings. Oh well. I discuss these things in my 2010 book, §7.6.

§3.2, p. 512, for prospect theory the authors, fortunately, take weighting functions as is common today.

P. 520: for RDU, the authors call utility "standard risk aversion."

§4.4, p. 521, points out the well-known point that for two-outcome lotteries most theories agree. It is explained by Wakker (2010, §7.11).

P 521 again points out that Köszegi-Rabin CPE and Bell-disappointment aversion cannot be distinguished, a central point in Masatlioglu & Raymond (2016 American Economic Review) (not cited here, but mentioned in Footnote 28 on p. 522).

P. 522: "A frequent assumption in the literature is that subjective beliefs μ coincide with objective expectations (e.g., "objective" claim probabilities), which in turn the econometrician can estimate. However, this assumption may fail in a given application. In that case, when μ is assumed to equal objective expectations, the estimated Ω(μ) function captures a mapping Ψ from the estimated objective probabilities to subjective beliefs, thereby yielding another possible source of probability distortions." The weighting function Ω(μ) is applied to goodnews probabilities to give decisions, and just equating this (why not its dual?) with beliefs is too unnuanced.

P. 524: "In most field contexts, however, objective probabilities either do not exist or are very hard to assess." Further text: "For such situations, an ideal approach would be to simultaneously estimate both the agents' beliefs and preferences. As we shall see in section 7.3, however, this presents a fundamental identification problem. Hence, the most common approach to date has been to assume "rational expectations," in the sense that agents' subjective beliefs correspond to objective probabilities (often, but not always, as reflected in past or future outcomes). The researcher then either posits a carefully thought-out model of rational expectations formation, or posits a "reduced-form" model, and estimates probabilities over outcomes conditional on the chosen covariates based on realized outcomes and observed covariates. These estimated probabilities are then typically taken as "data," in the sense that they are treated as an observed input when estimating preferences."

P. 525 bottom: describes two-stage probabilities if probabilities are heterogenous.

P. 527 briefly and factually states the basic revealed preference approach, that Gilboa & Schmeidler's CBDT deviates from: "In particular, risk preferences are estimated by investigating how agents react to changes in choice sets,"

P. 533: "Moreover, while there also is statistically significant curvature in u, economically the lion's share of households' observed aversion to risk is attributed to probability distortions."

(**Prospect theory/Rank-Dependent Utility most popular for risk**: they don't say that but it helps well.) %}

Barseghyan, Levon, Francesca Molinari, Ted O'Donoghue, & Joshua C. Teitelbaum (2018) "Estimating Risk Preferences in the Field," *Journal of Economic Literature* 56, 501–564.

{% **violation of risk/objective probability = one source**:

They assume expected utility with CARA (constant absolute risk aversion) utility. They find, using market data, that many households exhibit greater risk aversion in their home deductible choices than their auto deductible choices. P. 616 reports some PT analyses but the data seem to be too poor to identify much. %}

Barseghyan, Levon, Jeffrey Prince, & Joshua C. Teitelbaum (2011) "Are Risk Preferences Stable across Contexts? Evidence from Insurance Data," *American Economic Review* 101, 591–631.

{% **Z&Z**; P. 538 compares the survey approach to econometrics. Econometric estimations may be inappropriate if heterogeneity of the population is important. (I'm not sure if I understand this.)

For N = 11,707 subjects, aged 51-61, they measure risk attitude through gambles where you either receive a fixed outcome for the rest of your life, or a .5 prob of having X times income and a .5 probability of having x times income, where X = 2, x = 2/3, and then, depending on answer, either X = 2 and x = 1/2 or X = 2 and x = 4/5. This procedure classifies subjects into four risk aversion categories. The most risk averse class I was highly modal: 64.6% in class I, 11.6% in class II, 10.9% in class III, and 12.8% in class IV (Table IIA p. 548).

P. 550: Males somewhat more risk seeking than women (**gender differences in risk attitudes**). Asians and Hispanics are the most risk seeking, blacks and natives less, whites the least. Remarkable because intercultural studies suggest (if I remember well) that Asians are less risk seeking. Then, Asians in US ≠ Asians in Asia? Jews are most risk seeking, then Catholics, then protestants. Western US-ers are more risk seeking than others.

P. 551: Risk seeking index predicts actual behavior regarding health insurance, smoking, drinking, choosing risky (i.e., self-) employments, and investments (p. 560). The latter is not enough to explain the equity premium puzzle in their data (p. 561). However, the variance explained is small.

For n = 198 subjects, they measure intertemporal preference index by asking for future consumption while specifying the interest rate, and varying the latter; 116 useful observations could be used (p. 565). No statistical relation between intertemporal preference and risk aversion (p. 564).

dominance violation by pref. for increasing income: p. 567: people prefer increasing income to decreasing, even if interest rate is zero.

decreasing ARA/increasing RRA: first RRA is increasing, but then decreasing (p. 557). %}

Basili, Marcello (1997) "A Rational Decision Rule with Extreme Events," *Risk Analysis* 26, 1721–1728.

{% PT considers $CEU^+(f^+) + CEU^-(f^-)$, where f is a prospect, f^+ is its positive part where all outcomes worse than 0 have been replaced by zero, and f^- its negative part where all outcomes better than 0 have been replaced by 0. Then CEU^+ is a PT functional; i.e., the Choquet integral of utility of outcomes, and CEU^- is a PT functional too. PT generalizes Choquet expected utility by allowing CEU^+ to be different than CEU^-. This paper considers a generalization that considers three, instead of two, regions: $CEU^m(f^m) + CEU^{m,M}(f^{m,M}) + CEU^M(f^M)$. Here each CEU is a, possibly different, Choquet expected utility form, m < M, f^m replaces all outcomes better than m by m, $f^{m,M}$ replaces all outcomes worse than m by m and all outcomes better than M by M, and f^M replaces all outcomes worse than M by M. Note that, if all CEU forms are equal to some fixed CEU form, then what I just said amounts to CEU(f) + U(m) + U(M). The authors interpret outcomes below m and above M as unusual, because of which they are processed differently. Optimism for the lower part means that $CEU^m(f^m) > CEU^{m,M}(f^m)$; i.e., the different treatment of outcomes below m make the prospect better. It holds iff the capacity of $CEU^{m,M}$ dominates that of CEU^m. Similar things are given for pessimism for the upper part. %}

{% **Prospect theory/Rank-Dependent Utility most popular for risk**: P. 40: "One of the most prominent and most successful alternatives to expected utility theory is cumulative prospect theory (CPT) of Tversky and Kahneman (1992)."
This paper extensively cites axiomatizations of the Choquet integral, Choquet expected utility, and prospect theory (I use this term for the new 1992 version,

often called prospect theory). It would then have been nice to add Luce & Fishburn (1991), who axiomatized 1992 prospect theory independently of others.

This paper characterizes the Choquet integral when the functional is the primitive, and Choquet expected utility to represent preferences when those are primitive, assuming monetary outcomes with linear utility. It then does the same for prospect theory (linear basic utility but piecewise linear global utility, allowing a kink at 0). Although the paper writes that it is not using the Anscombe-Aumann (AA) framework and this claim can be defended, it can also be argued that it is a special case of the AA framework with $\mathbb{R}$ as a mixture space and, indeed, linear so affine utility. Unlike most others, I find the latter case a more satisfactory special case of the AA framework than when the outcome space, a mixture space, concerns a set of lotteries and we have EU there.

The Choquet integral is axiomatized in known manners, using comonotonic additivity of the functional or the preference relation. For prospect theory, first, comonotonic additivity is weakened to what I call sign-comonotonic additivity (their A3). Then an axiom, their $A4^{\lambda}$, is added to combine gain- and loss-parts, related to double matching of Tversky & Kahneman (1992), but explicitly assuming existence of a loss-aversion parameter λ which can be done behaviorally with linear utility but is strong. From Wakker & Tversky (1993 §8.1) it can be seen that Axiom $A4^{\lambda}$ is virtually always redundant.

This paper adds nice interpretations of $A4^{\lambda}$, showing that gain-acts can give special, extra, hedging against loss acts because of sign-dependence even for comonotonic acts. %}

Their criterion is, I think, that x is preferred to y if there is $N \in \mathbb{N}$ such that $x_1 + \cdots + x_N \geq y_1 + \cdots + y_N$ and from coordinate N+1 onwards x Pareto dominates y. %}

Basu, Kaushik & Tapan Mitra (2007) "Utilitarianism for Infinite Utility Streams: A New Welfare Criterion and Its Axiomatic Characterization," *Journal of Economic Theory* 133, 350–373.

{% The VC (Vapnik-Chervonenkis) dimension of a theory is calculated as follows, where the theory has some free parameters. Imagine a game between a falsifier F, who likes to see a particular theory violated, and a Theorist, who does not want the theory violated. First, a theorist chooses a natural number k. Second, the theorist moves again, choosing k binary choice situations. Third, the falsifier can choose, at will, what the observations in these choice situations are. Then, if the theory is not violated, T wins, and receives k from F. If the theory is violated, F wins, and nothing happens. The largest k that T can win is called the VC dimension. For example, if the theory only imposes weak ordering, and the preference domain is infinite, then the VC dimension is infinite. If the theory is single-peak preference and the preference domain $\mathbb{R}$, then the VC dimension is 1. The paper considers, for a finite state space with n states, EU, CEU (what I would call RDU), and maxmin EU (MEU), always assuming linear utility, which is reasonable for comparing these theories.

P. 1280: "In response, decision theorists have sought to generalize the theory of subjective expected utility to allow for ambiguity aversion. The two best known alternatives are the models of max–min expected utility and Choquet expected utility."

P. 1281 (on EU, CEU, MEU): "The three models we have described are arguably the most important models of decision-making under uncertainty."

P. 1281: Unfortunately, the authors make the widespread mistake of equating risk attitude with utillity curvature and write (where it is clear that they refer to linear utility): "In all three cases, we assume an agent who is risk-neutral. If we were to include the utility function as an additional parameter of the theory." (**equate risk aversion with concave utility under nonEU**)

P. 1282 goes wrong when writing: "Overfitting as a concern seems to be new in decision theory and behavioral economics." Such a claim cannot be. Every student doing empirical work is familiar with the elementary statistical phenomenon of overfitting, and so have I been since my youth. Mangelsdorff & Weber (1994) is an early example in my area of expertise. The authors cite that paper elsewhere, but do not recognize the point of overfitting there. Erev and his team organized several prediction competitions, e.g.

Erev, Ido, Eyal Ert, Alvin E. Roth, Ernan Haruvy, Stefan M. Herzog, Robin Hau, Ralph Hertwig, Terrence Stewart, Robert West, & Christian Lebiere (2010) "A Choice Prediction Competition: Choices from Experience and from Description," *Journal of Behavioral Decision Making* 23, 15–47,

and

Erev, Ido, Eyal Ert, Ori Plonsky, Doron Cohen, & Oded Cohen (2017) "From Anomalies to Forecasts: Toward a Descriptive Model of Decisions under Risk, under Ambiguity, and from Experience," *Psychological Review* 124, 369–409,

where overfitting of course iws central. I co-authored

Kothiyal, Spinu, & Wakker (2014) "An Experimental Test of Prospect Theory for Predicting Choice under Ambiguity," *Journal of Risk and Uncertainty* 48, 1–17,

where we discuss overfitting on p. 9. People often use the terms parsimony and fit to discuss these issues, e.g., Harless & Camerer (1994).

The bottom of p. 1283 cites some papers on estimating ambiguity aversion but is very limited. The survey Trautmann & van de Kuilen (2015) could have helped them considerably.

P. 1287 claims that axioms 1 and 3-5 axiomatize EU with linear utility, but give no reference. Chateauneuf (1991) is one reference giving these and related results, although he used additive rather than mixture axioms, but those are readily related to each other. It also follows from Schmeidler (1989) if we take money with linear utility as a mixture space in the Anscombe-Aumann framework.

P. 1288 Theorem 1. Let the state space have n elements, and utility is linear. Then VC(EU) = n.

VC(CEU) is between $\binom{n}{n/2}$ and $(n!)^2(2n+1)$.

If n=2, then VC(MEU) = VC(CEU)=2. If $n \geq 3$, then VC(MEU) $= \infty$.

nonadditive measures are too general: It means that VC(EU) grows linearly in the state space and VC(CEU) exponentially. MEU is worse. Oner can roughly understand these results as follows: With linear utility, every preference gives a linear inequality. For n states, EU has n−1 free parameters, being probabilities. Then n+1 potential inequalities can always be led into contradiction. CEU has $2^n - 2$ inequalities, concerning all nontrivial subsets (trivial are the state space and the empty set), with montonicity restricting it.

P. 1289 2nd para points out that we can add proper restrictions to theories, such as assuming functional families, and then VC can become much smaller, and this is to be done for theories that are too general.

Section 3 is on learnability. This term means that you can with arbitrary high probability get predictions arbitrarily close if enough observations. It should not be confused with learning in the sense of digesting new information. Theorem 2 says, unsurprisingly, that a theory is learnable iff VC dimension is finite. The theorem assumes that the true deterministic theory is chosen randomly, but does not consider probabilistic choice or choice error. %}

{% A follow-up on Battigalli, Cerreia-Vioglio, Maccheroni, & Marinacci (2015 American Economic Review). They assume the smooth model of ambiguity. They show that for self-confirming equilibrium (SCE) sequential and strategic form are not equivalent. Derive monotonicity results for sequential. %}

Battigalli, Pierpaolo, Emiliano Catonini, Giacomo Lanzani, Massimo Marinacci (2019) "Ambiguity Attitudes and Self-Confirming Equilibrium in Sequential Games," *Games and Economic Behavior* 115, 1–29.

{% Study self-confirming equilibrium (SCE). Players face ambiguity about opponents' moves. For the equilibrium they play, they collect more and more information and hence it turns into known probabilities, going away from ambiguity aversion. For agents who play myopically, at every round only optimizing the profits of that round (exploiting) without concern of learning (exploring), ambiguity aversion then increases status quo bias. Hence, more SCE exist under ambiguity aversion than under ambiguity neutrality. A restriction of this result is of course that the agents are assumed to play myopically, so, they are not very rational, and do not behave as rational agents for instance in multi-armed bandit problems.

A problem I have with much of the modern literature on ambiguity is the extent to which it is normative or descriptive. The myopic behavior of the agents means that it is not normative. But it also is not very descriptive because ambiguity aversion and the smooth model assumed here do not fit data well, for instance the fourfold pattern of ambiguity attitude (Trautmann & van de Kuilen 2015). The myopic behavior of agents can be made normative in a different interpretation: In each round, agent i is a new person who only plays that one round. But he does have the info of the preceding agents i. As this happens in information cascades. So, this deviates from Nash's mass action interpretation.

Loss aversion can similarly introduce a status quo bias.

In this paper, when the authors analyze Figure 1 on p. 649, in the second game say, they condition on H^2 and T^2. Both conditional on H^2 and T^2, the agents face ambiguity about the opponent's moves and ambiguity aversion leads to lower evaluations of H^2 and T^2 and, hence, the whole second game. If the agent were randomizing at the individual level, he might as well condition on h^2 and t^2, getting an Anscombe-Aumann framework. If he then playes fifty-fifty, then both under h^2 and t^2 he has (expected) payoff 2. So, then the value of the game is 2 (the same as with ambiguity aversion). However, agents are not randomizing at the individual level. This is Nash's mass action interpretation, where the randomness is only at the population level. Every individual player plays deterministally. Therefore, the conditioning on H^2 and T^2 as assumed here is natural.

Why do the authors choose the conditioning they choose, and not the other one? In the theoretical analysis on p. 652, Eq. 1, they evaluate each strategy of a player separately, which means that they use the same conditioning as in Figure 1, first conditioning on own strategy choice and not first on opponents' strategy choice. %}

Battigalli, Pierpaolo, Simone Cerreia-Vioglio, Fabio Maccheroni, & Massimo Marinacci (2015) "Self-Confirming Equilibrium and Model Uncertainty," *American Economic Review* 105, 646–677.

{% Consider smooth model of ambiguity. Consider set of justifiable choices (optimal w.r.t. some 2nd order belief over probabilistic models, i.e., some 2nd order distribution. They here take utilities u and φ as given and consider existence of 2nd order distribution mu. The set of justifiable choices grows as ambiguity aversion or risk aversion grow. An intuition for the ambiguity result can be that increasing ambiguity aversion is like increasing the set of possible priors, giving more options there. It is like making a surface more concave, giving more tangents. An opposite intuition would be that increasing ambiguity worsens every nonsure act.

They relate the result to the Bayesian analog, Wald (1949), which was famous a generation ago but seems to have been forgotten now (2016). They generalize Wald in the appendix. %}

Battigalli, Pierpaolo, Simone Cerreia-Vioglio, Fabio Maccheroni, & Massimo Marinacci (2016) "A Note on Comparative Ambiguity Aversion and Justifiability," *Econometrica* 84, 1903–1916.

{% **criticisms of Savage's basic framework**: Not exactly that, but the authors do consider alternative frameworks, such as Luce & Raiffa's (1957) that takes states and acts as primitive and lets the outcome set be the product set of the outcome set. Even yet one more deviation: The outcome set can yet be different, and there is a function ρ mapping the mentioned product set into what really are outcomes. This framework becomes equivalent to Savage's (1954) framework if (a) the ρ images of different states are the same (state-independence in the sense that the same outcomes can appear for different states); (b) two different acts that induce the same (or even just that modulo equivalence classes of outcomes) function from states to outcomes are equivalent (called consequentialism by the authors on p. 833); (c) enough richness.

The authors also consider probabilistic mixtures of acts. This is mixing in a prior sense, so that correlations between different states can play a role. It then becomes equivalent to the current version of Anscombe-Aumann (1963) if and only if we have a consequentialism-type condition: All that matters for the prior mixing is what mixing results conditional upon each state, and correlations between these do not matter. This is very similar to an assumption in the original Anscombe-Aumann (1963) paper, who had mixing both a priori and "a posteriori" (i.e., conditional on an act), but then assumed that prior mixing is equivalent/can be reduced to posterior mixing, after which their framework becomes equivalent to the modern version of the Anscombe-Aumann framework, explained by the authors on p. 851. The condition is even more similar, in fact equivalent, to Fishburn's (1966) marginal independence; for that, see for instance §6.5, p. 295, Theorem 6.4 of Keeney & Raiffa (1976). (**restrictiveness of monotonicity/weak separability**) The multiattribute utility of Keeney & Raiffa (1976) is very relevant to this paper because it exactly does prior mixing and provides an ocean of theorems on that. May I also add that I learned from Jaffray that in ambiguity we should do prior mixing and not posterior as in the modern version of Anscombe-Aumann because their monotonicity then implies an undesirable separability of states of nature.
P. 828 properly cites Fishburn (1970) for proposing the modern version of the Anscombe-Aumann framework.

In the 2nd half, the paper presents several revealed preference conditions and ambiguity models fitting into their framework. %}

Battle, Carolyn C., Stanley D. Imber, Rudolph Hoehn-Saric, Antony R. Stone, Earl H. Nash, & Jeromy D. Frank (1966) “Target Complaints as Criteria of Improvement,” *American Journal of Psychotherapy* 20, 184–192.

{% This paper provides formalizations of anticipated utility, experienced utility, and remembered utility, in total utility. The model is called AER (anticipation, experience, remembering). It assumes functional relations and derives implications. It is tested experimentally by asking subjects “Imagine so and so. How would you feel about it?” Psychological distance of Baucells & Heukamp is one factor.

P. 730: “The model is also predictive of choices, but only to the extent that individuals accurately predict future total utility and use such criteria to guide their decisions. In the framework of Kahneman et al. (1997), Read (2007), and Morewedge (2016), where a rational decision maker maximizes the time integral of instant utility, our model provides prescriptions for someone willing to “engineer” his or her own happiness.”

P. 731 and many places: anticipating utility reduces surprise and experienced and remembered utility.

P. 752: “In other words, conceptual consumption must take values that are realistically possible. Formally, the level of conceptual consumption at any point in time during anticipation and recall is a decision variable constrained to take values …”

P. 752: There is a central role for a reference point, always taken deterministically, endogenous during anticipation and recall, exogenous during experience. A value function is applied to the difference between consumption and the reference point.

P. 733: The authors can speak to habit formation. They capture magnitude effects. This, in combination with loss aversion, gives smaller discounting for losses than for gains (p. 734).

P. 741: “The AER model predicts a trade-off between anticipation and memory: the longer the duration of anticipation, the more adaptation, the lower the surprise,”

P. 742: “The extension of the AER model to conditions of uncertainty, together with the

assumption that conceptual consumption is driven by images of upcoming events, would naturally capturre the observation that people react more to the possibility of good or bad outcomes rather than to the probability of those good or bad outcomes (Kahneman and Tversky 1979)."

P. 742: "In conclusion, the anticipation-event-recall model is a step toward providing a more articulated, yet tractable, model of total event utility that captures the psychological elements of adaptation, time distance, and conceptual consumption." %}

{% **nonconstant discount = nonlinear time perception**;

In most decisions, both time and risk play a role, and we should know about their interactions. Hence, there is a need for such models. This paper brings an advanced model (PTT: probability-time trade-off) to capture such interactions, with a unifying psychological distance.

Table 1 nicely puts together stylized empirical phenomena that motivate the model of this paper.

The authors consider triples (x,p,t), meaning one receives $x with probability p at timepoint t. The main general axioms are A3 (p. 833) and A5 (p. 834). To prepare for Theorem 1 (p. 834): The classical rational evaluation is $p \times e^{-rt} \times U(x)$, where p and t are aggregated multiplicatively as $p \times e^{-rt}$. Taking ln gives $\mathit{ln}p - rt$ as an additive aggregation. Theorem 1 captures this through axiom A3 (and some other things), for each fixed x and, hence dependence of r on x, as

$$\mathit{ln}p - r_x t.$$

So, the exchange rate r_x between $\mathit{ln}p$ and t depends on x. We can also write this representation multiplicatively by taking exponent, as

$$pe^{-r_x t}.$$

This leads to a representation

$$V(x,p,t) = V(x,pe^{-r_x t},0) = V(x, e^{-(-\mathit{ln}p + r_x t)},0) \qquad (*)$$

(their Theorem 1).

Then A5 is added, which is additive decomposability (through Thomsen condition) of x and p at t = 0. Given the presence of a null element, the additive decomposition must in fact be multiplicative, giving

$$V(x,p,0) = w(p)v(x) = f(-\mathit{ln}p)v(x). \qquad (**)$$

For general t, we combine (*) and (**), to get

$$V(x,p,t) = V(x,pe^{-r_x t},0) = w(pe^{-r_x t})v(x) = f(-\mathit{ln}p + r_x t)v(x)$$

(their Theorem 2, p. 834).

They add qualitative conditions to capture the magnitude effect and other phenomena, and a parameter-free elicitation procedure.

The paper gives a nice rewriting of the Prelec-Loewenstein (2012) hyperbolic discounting: rewrite $D(t) = 1/(1+at)^{b/a}$ as $e^{-(b/a)\ln(1+at)}$. Write $\gamma = a/b$ and concave time distance function $f(t) = (1/\gamma)\ln(1+\gamma t)$. Then, $D(t) = e^{-f(bt)}$. The slope of f(t) at 0 is always 1; and as $\gamma \to 0$, $f(t) \to t$ (exponential discounting). The discount rate is $-D'/D = rf'(rt) = r/(1+\gamma\, r\, t)$, decreases with time. Thus, γ is a purely behavioral parameter capturing the degree of diminishing impatience; and r is the discount rate for the immediate future. %}

{% **intertemporal separability criticized**: Explicitly model violation of separability in intertemporal choice by having utility of consumption at time t depend on previous consumption through a retention parameter, with the dependence becoming weaker as the time interval is bigger. There may be some sort of violation of dominance if the increase of consumption today decreases the utilities of future consumption much.

The interesting property of local substitution says that (t:x, s:y) becomes equivalent to (t:x+y) as s tends to t, is very natural, but cannot be satisfied by discounted utility. %}
Baucells, Manel & Rakesh K. Sarin (2007) "Satiation in Discounted Utility," *Operations Research* 55, 170–181.

{% Propose a variation of discounted utility, extending their 2007 model. At a timepoint t a reference point is chosen that is a convex combination of past consumptions (also indirectly through past satiation). Habit formation means that past consumption of some good amplifies its present utility, and satiation means the opposite. One has a different sign of some parameters than the other. The interesting property of local substitution of their 2007 paper is also used here. It

says that (t:x, s:y) becomes equivalent to (t:x+y) as s tends to t, is very natural, but cannot be satisfied by discounted utility. %}

Baucells, Manel & Rakesh K. Sarin (2010) "Predicting Utility under Satiation and Habit Formation," *Management Science* 56, 286–301.

{% Book has many good advices for people who do not manage their emotions and expectations wisely, with many nice anecdotes where Sarin's origin from India and Buddhism delivers a delicious mix with Baucell's Christean background.

P. x and other places: happiness = reality – expectation. P. 66 adds nuances, that increase in welfare gives partial adaptation, with partly happiness only because of change but partly extra happiness everlasting. I wish that this nuance had been put more central because, as is, it seems that one can get happier simply by reducing expectation.

P. 6: the authors identify themselves as decision analysts and management scientists.

P. 31, happiness seismograph is like Edgeworth's hedonimeter. The authors put forward what Kahneman, Wakker, & Sarin (1997) called total utility, being the time-integrated instant/experienced utility.

P. 159: "Let's explore some ways to influence expectation so that our lives can be happier within the same reality." P. 163 writes about karma.

Pp. 164-165: anxiety of choice. %}

Baucells, Manel & Rakesh K. Sarin (2012) "*Engineering Happiness*." University of California Press, Berkeley.

{% Gives **completeness criticisms**:

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): intro points out that vNM do not justify transferable utility, used in 2/3 of their book.

§2, called a Review, in fact gives a beautiful new extension of vNM EU to the case of incompleteness in Theorem 1, however, quasi-covering it up with an unappealing mathematical formulation in terms of cones. %}

Baucells, Manel & Lloyd S. Shapley (2008) "Multiperson Utility," *Games and Economic Behavior* 62, 329–347.

{% N = 141. Two sessions 3 months apart. Hypothetical choice, with questions and answers by email.

Each subject had to answer only two choice questions:

(0.10: €3,000, 0.40: €2,000, 0.40: €1,000, 0.10: €0) versus €3000$_{0.50}$€0

(0.10:0, 0.40: –€1,000, 0.40: –€2,000, 0.10: –€3,000) versus €0$_{0.50}$(–€3,000).

So, they consider gain- and loss prospects, and not mixed ones. In this sense, limited data (they argue that they do it deliberately, to get inconsistencies). The prospects were all nondegenerate (no certainty), and risk aversion meant going for the highest variance (in every choice pair the two options had the same EV).

risk averse for gains, risk seeking for losses: They confirm usual findings of risk aversion for gains and risk seeking for losses. Find confirmation of reflection, because violations can be explained as noise: 72% of the subjects satisfy reflection, and 28% satisfy risk aversion for gains and losses. 63% of the subjects change preferences over 3 months (P. 204; 37% gave the same answers to all questions in the two sessions).

equate risk aversion with concave utility under nonEU: P. 196 3rd para explains that risk aversion (preference for EV over prospect) can be driven by probability weighting rather than by utility curvature. But then, unfortunately, it is going to use the term risk aversion for concave utility. Why they call concave utility what it isn't (risk aversion) rather than what it is (concave utility!) is a puzzle to me. If sometimes their term risk aversion still refers to the usual definition is not clear, especially when they discuss literature.

reflection at individual level for risk: Supported although not much data. Table 3, p. 203 the row of average over two sessions shows that (I exclude indifferences) of 72 risk averters for gains, 46 were risk seeking for losses and 26 were risk averse for losses. Of 12 risk seekers for gains, 7 were risk averse for losses and 5 were risk seeking.

P. 209 2nd para: "The existence of two types has important implications in the area of elicitation of risk preferences. For instance, in measuring the value function, rather than taking a grand average of a "representative value function," our results suggest to first classify subjects as either reflective or averse, and then calculate two separate representative value functions." %}

Baucells, Manel & Antonio Villasis (2010) "Stability of Risk Preferences and the Reflection Effect of Prospect Theory," *Theory and Decision* 63, 193–211. https://doi.org/10.1007/s11238-009-9153-3

{% Propose to modify classical utility measurements under EU, primarily CE and PE, to nonEU by adding tail probabilities t with common best and worst outcome, in the spirit of Mccord & de Neufville's (1986) lottery equivalent method, formalizing it. They assume PT with interior additivity which is empirically reasonable and justifies their method. They extensively test it, comparing it to more laborious methods such as the tradeoff method (**tradeoff method**) and find that it performs well. (**Probability weighting linear in interior**) The result is not surprising theoretically, but it is a convenient tool directly applicable to nonquantitative outcomes under nonEU and this is useful for applications. It is a sort of McCord & de Neufville method updated to the modern literature. %}

{% This paper does not discuss the normative status of models, but instead is a methodological analysis of normativeness in general. Normative models, like all models, make simplifying empirical assumptions that only approximate reality. P. 124 writes: "Thus, the puzzling question arises how models involving such false descriptions of agents can provide normative guidance to them." I did not fully understand this objection. P. 128: The authors (mis)use the term independence of irrelevant alternatives for what is mixture indepencence, the main condition axiomatizing expected utility in VNM's theorem (although vNM, as a mistake, did not write the condition but used it implicitly). P. 128 bottom takes transitivity as normative but the other conditions not, somewhat to my surprise.

I was glad to see that my paper Li, Li, & Wakker (2014), giving a litmus test on paternalism stances, is cited.

P. 130 bottom: I agree with the authors that my paper Bleichrodt, Pinto, & Wakker(2001) does not provide justifications for the claim that expected utility is normative. But I do not understand "let alone a discussion of how such models can offer guidance despite involving false descriptive statements, that is, descriptive idealizations." It is a methodological point of the paper that I miss anyhow.

P. 131 has the funny kind of footnote of a reviewer being thanked where one feels that the authors do it reluctantly and the referee insisted too much.

P. 134 bottom probably captures an essential point in the paper that I am missing: "Thus, descriptive idealizations seem to play a different role in normative models than descriptive premises in normative arguments." %}

{% **updating: testing Bayes' formula**: unforeseen contingencies. An experiment is done with it, using the Karni & Vierø (2013) model. Subjects exhibit some common violations of updating, but the reversed nature of Bayesianism here does

not generate new ones.

A great difficulty with unforeseen event experiments is how to implement it without using deception. It is basically impossible. At best, one can do something similar. In this experiment, first subjects gamble on an urn with balls of only two colors, and only two prizes possible. But later content of another different urn with balls of a different color giving a different prize is added to the original urn and subjects are informed about that. This is not unforeseen event about the original urn but, rather, just, change of urn. However, we can never do better than such approximations of unforeseen events. %}

{% This paper presents a rationalization for addiction. End of §I describes as one of the novelties of this work, "We appear to be the first to ... relate even temporary stressful events to permanent addictions." If one is not addicted, one does not have the stock of consumption capital S needed to make utility of non-heroin negative. So, how can nonaddicted ever become addicted? The question is answered on p. 690/691, in particular Eq. (22). I find it easier to state the point in words than in symbols as in Eq. (22): It is simply !assumed! for a person who never used heroin but is, for example, in marital breakup, that this marital breakup generates the same heroin consumption capital as for a person who had used heroin in the past! Voilà the miracle. Hence, nonaddicted can turn into addicted by marital breakup. (Eq. 22 does it by letting stock of consumption capital depend on sum c(t) + Z(t) where c refers to previously consumed heroin and Z to stressful event. So, Z can simply substitute for c.) %}

{% This may be the first experimental test of Ellsberg's ambiguity claims. Chipman (1960) did not really test it.

second-order probabilities to model ambiguity: Not really. It is how they claim to model ambiguity (e.g., p. 64 middle of last para, pp. 64-65, and p. 65 Hypothesis II). They may have been the first to do so. In the experiment, however, they only give probability intervals and no 2nd order probabilities. P. 64: ambiguity is a "distribution of probabilities other than a point estimate". The typical multiple prior thinking.

Subjects choose from known fifty-fifty urn versus unknown fifty-fifty urn where unknown has varying degrees of ambiguity. Greater range of second-order probability then greater ambiguity. However, too few subjects to do statistics.

Pp. 63-64, footnote 4, has the famous reference to a conversation with Ellsberg, where Ellsberg suggests **ambiguity seeking for unlikely** events. He proposes an urn with 1000 numbered balls in unknown proportion. You get prize if randomly drawn ball has number from a subset of n numbers between 1 and 1000. Ellsberg predicts ambiguity seeking for small n, turning to ambiguity aversion as n increases.

P. 72: "there is some reason to believe that preferences for level of knowledge and for variance of outcome distribution are closely related and may, in fact, be perceived by the subjects to be the same or similar phenomenon." Inverse S can be interpreted as increasing variance and, hence, the second part of the sentence can be related to it (**inverse S**).

P. 73 suggests competence effect of Heath & Tversky (1991) (being "second-guessed" by other observers) %}

{% **risky utility u = transform of strength of preference v, latter doesn't exist**; **utility families parametric**; Adapt axiomatizations of parametric families (lin./exp., sums of exp., one-switch) of utility, well-known under SEU, to some nonEU models (rank-dependent, weighted utility, regret/SSBU). Log-power (CRRA) is not included.

P. 5 ℓ. 5 ff. and many other places claim that von Neumann-Morgenstern eschewed the early intensity interpretations of their vNM utility, as had been done in other writings by Fishburn (and possibly by Bell too but I have no concrete reference here). As I explained in a conversation with Fishburn somewhere in the 1990s, I disagree, and think that instead vNM did not commit to anything, neither to accepting nor to eschewing this interpretation.

P. 7 ℓ. 3–2 before Eq. (3) misuses the reputation of Savage (who can no more defend) in a commercial for Bell's work. This writing is of bad taste. %}

Bell, David E. & Peter C. Fishburn (2000) "Utility Functions for Wealth," *Journal of Risk and Uncertainty* 20, 5–44.

{% This paper proposes a simple preference condition, shows how this implies a functional equation for the ptf, and analyzes the latter. This general approach and technique are mathematically interesting. It is nice that they consider **inverse S.** However, the equation introduced is neither empirically nor normatively realistic. Examples and arguments to suggest the latter are not convincing.

Restricted independence brings in a touch of betweenness (which is nice). In its defense in Example 1, the authors simply refer to the appeal of independence in general.

Example 2: In the first choice, Paula prefers the certainty because the .02 chance of getting nothing is risky. In the second choice, the chance has reduced to .0001. Therefore, the multiplier of 0.005 that carried one probability to the other is too small to maintain indifference. However, less extreme but similar examples can be developed with the multiplier .5 as assumed in the axiom of this paper. Somewhere along the line, an x chance of getting nothing is risky but an x/2 chance is importantly less risky. The effect by a factor 2 will be less extreme, but basically the same as by a factor .0001; i.e., it will destroy the indifference for the same intuition. In short, the intuition put forward for the .005 multiplication seems to exist, less extreme but still just as convincing, for the .5 multiplication assumed in their axiom. The example thereby makes me doubt about the axiom.

P. 248 2nd para before Lemma 2: The condition $f(2p) \leq 2f(p)$, imposed locally, is strictly weaker than local subadditivity, which is strictly weaker than local convexity. Therefore, the terminology is not correct.

P. 248, ℓ. –4: “only to π’s extremes”: Those are the most important and most pronounced! This lemma shows that the axiom is not empirically realistic. Note also that empirical evidence suggests subproportionality, with $\pi(p/2)/\pi(p)$ increasing, maybe even tending to 1, as p approaches zero. The model of this paper has this constant and equal to $\pi(1/2)$ in the limit. Similar dual things hold near $p = 1$ instead of $p = 0$.

Contrary to what the authors suggest on p. 247, next-to-last para, Quiggin (1993) does not have RDU representations for arbitrary outcome sets, but he does need continuity of outcomes. %}

{% Use term "preference" also to designate just utility (capturing inequity aversion). It is sometimes hard to know if "preference" refers just to utility or to preference in general.

They study ultimatum games and inequality aversion à la Fehr-Schmidt. Subjects are students but also a representative sample from the Dutch population.

They measure subjective beliefs only through direct judgment, not incentivized. Find that subjective probabilities (of other rejecting offer and so on) better predict decisions than the true objective probabilities (percentage of others in sample that rejected offer). Also find a strange aversion to self-interest-serving inequity, with people rejecting to receive money if it makes them richer than the others.

Nicely refer to rational expectations regarding difference between subjective and objective probabilities (e.g., p. 829). They ask for both introspective probabilities of accepting offer and of the complementary event of rejecting offer. Those do not add to 1, but usually to less, violating binary additivity. They then take midpoints as estimates. In regressions for probability they use two-limit probit models, censoring at 0 and 1. Young and highly educated subjects are most selfish.

Nice sentence on p. 836: "These results suggested that subjective probability data, although suffering from the problem of a substantial framing bias, can be useful to better predict and understand behavior in simple games of proposal and response." %}

{% This paper defines a degree of orness of a Choquet integral, only for positive acts. Orness is an acronym used before in some math. branches. It depends on the comonotonic set considered. In this case, for the special case where the nonadditive measure is lawinvariant (= probabilistic sophistication), the orness index is approximately the area under the curve of the transformation function. More precisely, for n states of nature, it is the usual rectangular-n-rectangle-area sum lower (or is it upper?) bound of the integral. So, it is an index of optimism. The paper cites other indexes proposed in the literature. It takes this as a global measure of risk seeking. For a probability transformation function w, it proposes w(p)/p as a local index of risk seeking. It verbally discussed some properties of these indexes. In the beginning of the paper it points out that some common risk measures are special cases of Choquet integrals, probably to fit with the journal. %}

{% P. 141 2nd para writes that beliefs are motivated. However, everything we ever do is motivated (say by evolutionary procedures), including rational beliefs we seek

to have objectively. Probably the field means: beliefs that deviate from the info we have because we feel interests in believing different things than what is the truth.

P. 149, heading “memory and other neural processes”: isn’t everything a neural process?

In economics, precise meanings are given to many concepts, which may deviate some from natural language. For instance, risk refers to an uncertainty entirely outside the agent’s control and, further, with probabilities given. In natural language this is not so and risk may refer to uncertainties partly under control, and without probabilities known. Psychologists, of course, often do not follow the economic conventions.

In economics, following a Savagean tradition, beliefs are taken to refer to states of information about uncertain events outside the control of the agent and with no utility attached to them by themselves. Utilities are attached to outcomes, such as commodity bundles. So, beliefs are strictly about info and not about utilities, and with outcomes it is the other way around. In natural language, and psychology, this is of course different.

This paper proposes to give up the common terminology in economics regarding beliefs and the authors use the term belief in the natural-language/psychological way. So, beliefs can do just anything and, in particular, can give utility. Subjects can distort their beliefs to solve self-control problems, so, purposefully, or for self-signaling purposes (as in Calvinism). Now beliefs can describe almost everything but, I think, predict almost nothing.

I think that, if beliefs are as commonly taken in economics, but subjects treat them as in this paper, then subjects are subject to irrationalities, such as confusing uncertainties they cannot influence with act-choices that they can influence. So, it would fit into the behavioral approach. However, the conclusion of the paper distinguishes its approach from behavioral economics, suggesting that the irrationalities in behavioral economics are hard-wired and mechanical unlike what the theory of this paper is about. I do not understand this point, in particular, as regards hard-wired/mechanical, I do not understand why behavioral biases would be more or less hard-wired/mechanical than the biases considered in this paper.

If beliefs are partially used for informational purposes and partly purposefully to manipulate future behavior, then distorting beliefs involves a tradeoff with the pro of the intended improving of behavior but later the suboptimalities that wrong states of information can bring with then suboptimal behavior.

There have been models with motivated beliefs before, with self-deception and self-signaling, and moral hazard is a bit related, but those were more concrete and specific, allowing for predictions, which in this paper happens too little to my taste.

The optimistic concluding sentence of the paper is: "This, in turn, leads to novel views of risktaking, prosociality, identity, organizations, financial crises, and politics." The abstract (and other places) was also optimistic, e.g., in writing: "Over the last decade or so, the pendulum has started to swing again toward some form of adaptiveness, or at least implicit purposefulness, in human cognition."

I, when doing economics, prefer not to follow the proposal of this paper and to continue using the term belief in the common economic way. %}

{% **PT, applications**, loss aversion, equity premium puzzle

Christiane, Veronika & I, P. 82 bottom: nominal money is more psychologically relevant than real. Risk-free puzzle: treasury bills have about zero gains in terms of real money.

decreasing ARA/increasing RRA: use power utility;

P. 74: Because of the presence of loss aversion, these aggregation rules are not neutral. The authors use the same marvelous line of reasoning as Tversky & Kahneman (1981). Myopoic and global evaluation give different results. So, which is wrong? Answer: none! The mistake lies elsewhere, being that people deviate too much from expected value, primarily because of loss aversion.

SPT instead of OPT: P. 79 Eq. 3 and the hree lines below.

Use PT in simulations to explain the equity premium puzzle; the weighting function and the value function are not sensitive variables, but loss aversion does it (p. 83 3rd para, p. 85/86). So, nice ref. to suggest that loss aversion is the main factor in risk attitude.

Kahneman & Lovallo (1993) put forward similar arguments against myopic loss aversion.

This paper is typically prescriptive instead of normative. In a strictly normative approach the advice not to be informed about stocks or anything cannot be. The real problem is that people are too loss averse. This paper accepts so as given, and then given this violation of normativity, the smallest evil occurs if people do not inspect their stocks very often.

Thaler is less paternalistic than I am. He accepted, reluctantly, that people do have loss aversion (p. 86 ℓ. 2 "fact of life"), and then advised not to evaluate stocks often. He deliberately does not point at the real culprit. They explicitly write that periods of evaluation can be altered, but loss aversion cannot. This appears from p. 86: Loss aversion "can be considered a fact of life (or, perhaps, a fact of preferences). In contrast, frequency of evaluations is a policy choice that presumably could be altered, at least in principle. %}

{% **real incentives/hypothetical choice, for time preferences**: Consider delays to up to 6 months. Payment in 6 months is by promise that then cheque will be sent to university mailbox.

They consider a discount function consisting of a fixed loss b (say $4) for every delayed payment. This part accommodates the magnitude effect. They also consider a two-parameter hyperbolic discount function $((1-(1-\theta)rt)^{1/(1-\theta)}$, being a powerfunction applied to a translation of t. Then they take the convex combination of these two. This is a 4-parameter family. They assume linear utility. Given that they only have one nonzero outcome, powers are unidentifiable, so this is a pragmatic way to go. (See below for why they cannot have utility curvature.) Then they consider the simplest stimuli possible, being one nonzero outcome. They ask direct matching questions (so not the, nowadays (2000-2023) preferred, choice-based questions), asking for the present value of future payments (Q-present) or the value that at some given future timepoint is equivalent to a present payment (Q-future). Then they fit the 4-parameter function to the data, and discuss the results.

They have only N = 27 subjects. However, by implicitly using the controversial assumption that different choices of the same subject can be treated as statistically independent, they can still do statistical analyses with confidence intervals for individuals and with rejections of nulls.

P. 208 erroneously claims that the BDM (Becker-DeGroot-Marschak) mechanism needs expected value maximization for being incentive compatible.

P. 208 resolves doubts about understandability of the BDM mechanism by firm optimism: "We had no doubt that the subjects understood the incentive properties of the mechanism." Unfortunately, the authors do not understand the BDM mechanism very well, thinking that it requires risk neutrality. The full citation on p. 208 is: "Under risk neutrality it is a dominant strategy to report the true indifference amount in this procedure and this fact was explained to the subjects. We had no doubt that the subjects understood the incentive properties of the mechanism."

On p. 218 (§5.3) middle they do report an estimate of power utility. As just written, powers are in general unidentifiable from their stimuli with only one nonzero outcome. In the same way as discounting becomes identifiable if power of utility is no more free (such as by taking it linear), we can estimate the power of utility if the power of discounting is no more free. This is probably what happened here, with the scaling of the discount function that the authors chose leaving no more freedom of power.

They find that, on average, the fixed cost of $4 for delays works better than quasi-hyperbolic discounting.

P. 206 3rd para describes the contribution of this paper relative to others (psychologists it seems): "While experimental psychologists have collected an impressive amount of data on time preference … rarely have the data been analyzed with proper econometric instruments." What they mean here is simply the usual story: No real incentives. They conclude on their data fitting and statistical analysis (p. 222): "As such, this experiment is one of the few that generates data that is then rigorously estimated econometrically."

Criticisms of the analyses in this paper are in Andersen, Harrison, Lau, & Rutström (2013 Economica). %}

{% Consider three definitions of being more impatient, elaborating on Horowitz (1992). The first, more delay aversion, is very demanding and incomplete: In each outcome stream, preferring an early increase more than a late one by $\succcurlyeq_1$ should imply the same for $\succcurlyeq_2$. Under general discounted utility the condition holds if and only if one utility function is a transformation of the other and some minimal value of $\succcurlyeq_1$ exceeds some maximal value of the other. Utility and discounting interact here (p. 91 last para). The condition requiring it only for otherwise constant outcome streams is called being more impatient. The characterization still involves u and discounting. The third is being more cryonic impatient, restricting the above to one nonzero outcome. The characterization still involves u and discounting. %}

Bentham, Jeremy (1782). *In* Elie Halévy (1901) *La Jeunesse de Bentham*, Felic Alcan, Paris.

{% First to Introduce utility as a full-blown concept. Utility did appear before in Bernoulli (1738) and Smith (1776). Still I like to credit Bentham as the one to "really" introduce the concept.

conservation of influence: Opens with: "Nature has placed mankind under the governance of two sovereign masters, *pain and pleasure*." Further, paras I.II I.VI takes action as deviation from status quo.

Opening para I of Ch. I uses beautiful metaphors, not only distinguishing gains (pleasure) and losses (pain), a distinction that to Bentham will not have carried the same meaning as it now does with prospect theory, but also normative (ought) and descriptive (shall), social science (right and wrong) and natural science (causes and effects) The penultimate sentence does not consider thinking and rationalite to exclude feeling and happiness, but rather as a tool to get the latter.

Para I.IV says that agent need not only be individual, but can also be society.

Para I.X says that "ought" and "right" and "wrong" should be taken as maximization of utility and nothing else. Is the explanation of "normative" that Mongin gave me during a dinner in Rotterdam.

Throughout (e.g., para I.XIII) emphasizes that utility maximization cannot be falsified. Like the reasoning that an altruist must derive pleasure from helping others and, hence, is just selfish.

At about para I.XIV - Ch. III I found it uninteresting.

Ch. IV is interesting because it discusses aggregation over certainty, persons, timepoints, all apparently to be done additively and separably. It distinguishes duration and discounting. This is virtually identical to Ch. 7 of Bentham (1802) "*Traités de Législation.*" See my annotations there.

P. 103 ff: **marginal utility is diminishing**: or in other book?

Stigler (1950 footnote 15) cites another writing of Bentham where Bentham takes **just noticeable difference** as basis of cardinal utility

risky utility u = strength of preference v (or other riskless cardinal utility, often called value) (Stigler, 1950), Bentham let aggregation over duration, certainty, and propinquity (temporal remoteness), in addition to intensity, play a role in one and the same utility index. Stigler (1950, footnote 10) cites Bentham on an, in my opinion appropriate, defense of utilitarianistic addition of utilities over different individuals, explicitly relating it to aggregation over uncertainty.

marginal utility is diminishing which implies risk aversion.

For small amounts of money, u is linear (Stigler, 1950). %}

Bentham, Jeremy (1789) "*The Principles of Morals and Legislation.*" At the Clarendom Press, Oxford.

{% Seems to be selection from many writings by Bentham, composed by his disciple Étienne Dumont.

P. 103 ff: **marginal utility is diminishing**: or in other book?

consequentialism/pragmatism: Stigler (1950) writes that on p. 103 in the Hildreth translation there is the citation hereafter where Bentham argues, as I see it, against consequentialism ("incorporate everything relevant whatsoever," à la Becker), in favor of pragmatism. I tried to check out Bentham's work to find the citation but did not find it. It is hard to know which of his books is which. Here is Stigler's alleged citation:

"It is to be observed in general, that in speaking of the effect of a portion of wealth upon happiness, abstraction is always to be made of the particular sensibility of individuals, and of the exterior circumstances in which they may be placed. Differences of character are inscrutable; and such is the diversity of circumstances, that they are never the same for two individuals. Unless we begin by dropping these two considerations, it will be impossible to announce any general proposition. But though each of these propositions may prove false or inexact in a given individual case, that will furnish no argument against their speculative truth and practical utility. It is enough for the justification of these propositions-1st, If they approach nearer the truth than any others which can be substituted for them; 2nd, If with less inconvenience than any others they can be made the basis of legislation."

Ch. 3 §1 is on "arbitrary principle" of "principle of sympathy and antipathy," where people justify decision only by them liking the decision without any further justification referring to the consequences of the decision, criticizing it much, for instance: "I wish you to think as I do, without giving me the trouble to reason with you."

Last para of Ch. III: good rational decision SHOULD take effort and be difficult.

conservation of influence: Ch. VII, first page:

"When one has become familiar with the process; when he has acquired that justness of estimate which results from it; he can compare the sum of good and of evil with so much promptitude as scarcely to be conscious of the steps of the calculation."

Schlee (1992) refers to a 1975 edn. of the editor Tripathi in Bombay.

marginal utility is diminishing; **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**:

Schlee cites from p. 65: "Though the chances so far as relates to money, are equal, in regard to pleasure, they are always unfavourable. I have a thousand pounds. The stake is five hundred. If I lose, my fortune is diminished one-half; if I gain, it is increased only by a third. Suppose the stake to be a thousand pounds. If I gain, my happiness is not doubled with my fortune; if I lose, my happiness is destroyed; I am reduced to undigence." This text shows that Bentham has some version of expected utility in mind, takes "pleasure" as vNM index, and in a way ascribes a rudimentary version of risk aversion to diminishing marginal utility.

Ch. VIII (this is as Ch. 4 in Bentham (1789) "*The Principles of Morals and Legislation.*") opens with value of a pleasure depending on

1st. Its intensity

2nd. Its duration

3rd. Its certainty

4th. Its proximity (called "propinquity" or "remoteness" in Ch. 4 in Bentham (1789) "*The Principles of Morals and Legislation.*")

but one should also incorporate

5th. Its productiveness (called fecuncity in Ch. 4 in Bentham (1789) "*The*

Principles of Morals and Legislation.”)

6th. Its purity

Here productiveness means it will induce further pleasure in the future, and putity is the opposite.

7th. Its extent

Is nr. of persons involved. %}

{% Re-analyze past data on preference reversals, and compare real incentives to hypothetical choice. (**real incentives/hypothetical choice**) They focus on the classical Slovic-Lichtenstein stimuli, for which they find 11 references. For hypothetical choice they find the usual preference reversals. For real incentives they find less risk aversion. They find as many preference reversals for real as for hypothetical, only for real there are as many usual reversals as unusual preference reversals. They conclude that then EU with error may explain things, rather than real preference reversal. %}

Berg, Joyce E., John W. Dickhaut, & Thomas A. Rietz (2010) "Preference Reversals: The Impact of Truth-Revealing Monetary Incentives," *Games and Economic Behavior* 68, 443–468.

{% **paternalism/Humean-view-of-preference**: the authors clearly don't like classical decision theories, prospect theory, behavioral economics, consistency, utility, and what have you.

The authors throughout think that as-if automatically violates homeomorphic. They do not realize that as-if can still be homeomorphic. Prospect theory can be homeomorphic if somewhere in us processes go on that use the mathematical operations of prospect theory, *but still be as-if if these processes are not or only partly conscious*. This is why p. 141 footnote 1 is not correct.

Ecological rationality is like context dependence, the term that I am allergic to.

P. 137: The authors argue that prospect theory is only an attempt to repair the failing classical models: "Instead of asking how real people – both successful and unsuccessful– choose among gambles, the repair program focused on transformations of payoffs (which produced expected utility theory) and, later, transformations of probabilities (which produced prospect theory) to fit, rather than predict, data. The repair program is based largely on tinkering with the mathematical form of the mathematical epectation operator and cannot be described as a sustained empirical effort to uncover the process by which people actually choose gambles."

Pp. 141-142: "the assumption – almost surely wrong – of universal commensurability between all inputs in the utility function," where they next identify it with the

Archimedean axiom. Here they also kind of confuse restricted solvability and unrestricted solvability, unnecessarily adding an assumption of unbounded functions under additive decomposability for instance.

P. 146 2nd para: the authors are hopelessly confused on visual perception.

The authors throughout do not buy that normative axioms can be based on logic intrinsic nature without exogenous evidence (such as proved happier lives), e.g., p. 148 2nd half. Or see p. 149 ℓ. 3-4: "that logical deduction rather than inductively derived descriptions of behavioral process are the proper starting point for economic analyses." This is why they miss the normative foundation of for instance EU, justifying the interest, also empirically, of its concepts beyond merely as-if fitting data. Their oversight is common among people who only work empirically. Such people, when facing the introduction of a new measurement method, require as imperative an empirical horse-race between the new method and some existing method, and cannot understand that logical arguments can also work because that whole concept is unknown to them.

P. 148 bottom writes: "No studies we are aware of show that deviators from rational choice earn less money, live shorter lives, or are less happy."

P. 149 ff.: they argue for ecological rationality (adapting heuristics to environment) and against the importance of coherence (**coherentism**).

P. 150 ff.: Gigerenzer had decided to embark on proving that expected utility maximization and Bayesian updating are no good. He and his co-author come out with supporting evidence stronger than anyone could ever dream of …:

"Our own empirical research tries to answer some of these questions about the economic costs of deviating from neoclassical axioms, with surprising results. Expected utility violators and time-inconsistent decision makers earn more money in experiments (Berg, Eckel & Johnson 2009). And the beliefs about PSA testing of non-Bayesians are more accurate than those of perfect Bayesians—that is, better calibrated to objective risk frequencies in the real-world decision-making environment (Berg, Biele & Gigerenzer 2008). So far, it appears that people who violate neoclassical coherence, or consistency, axioms are better off as measured by correspondence metrics such as earnings and accuracy of beliefs."

It is like proving that non-elephants are more intelligent than elephants. The authors continue on the path taken: "There are a growing number of theoretical models, too, where individuals (Dekel 1999, Compte & Postlewaite 2004) and markets (Berg & Lien 2005) do better with incorrect beliefs. These results pose fundamental questions about the normative status of assumptions regarding probabilistic beliefs and other core assumptions of the rational choice framework. If individuals and aggregates both do better (Berg & Gigerenzer 2007) when, say, individuals satisfice instead of maximize, then there would seem to be no market discipline or evolutionary pressure (arguments often invoked by defenders of the normative status of rationality axioms) to enforce conformity with rationality axioms, which focus primarily on internal consistency rather than evaluation of outcomes themselves."

P. 161 is negative on prospect theory: "In prospect theory, behavioral economics has added parameters rather than psychological realism to model choice under uncertainty." %}

Berg, Nathan & Gerd Gigerenzer (2010) "As-if Behavioral Economics: Neoclassical Economics in Disguise?," *History of Economic Ideas* 18, 133–166.

{% The paper considers seven common biases from decision under risk and uncertainty, such as probability neglect, outcome neglect, and status quo bias, for policy decisions regarding reclaiming degraded sites. They first discuss in general, which is trivial for decision theorists, but then have, in §3, nice case studies illustrating the biases. Pp. 9-10, on climate change: people rather risk big loss than take sure small loss, which may explain small amount of abatement undertaken. %}

{% Consider choices under risk and ambiguity using known and unknown Ellsberg urns. Some subjects can choose the winning color but for others the winning color is chosen randomly. Subjects who can choose the winning color like that more under ambiguity, exhibiting less ambiguity aversion, but for risk it gives no difference. The authors interpret this finding as illusion of control for ambiguity, so that illusion of control reduces ambiguity aversion. They also did this experiment for decision under risk, where there was no preference for (illusion of) control.

As the authors discuss on p. 262, letting subjects choose winning color is often done in ambiguity measurements to control for suspicion, where it has been understood before that this can bring illustion of control (**suspicion under ambiguity**). We then usually cannot separate if subjects like it becasuse of illusion of control or because of control against suspicion. This paper seeks to do so by having a control treatment where not subjects choose the winning color themselves, but this is determined last moment by a random process carried out by an outsider, so that it is clear that there cannot have been any rigging. This controls for suspicion without illusion of control However, in this control treatment subjects can take it as two-stage with a risk stage added, and this can have all kinds of effects such as bringing extra risk aversion or extra complexity. It could also have an effect of reducing ambiguity in the spirit of Raiffa (1961) although it then would have increased attractiveness, whereas in this experiment it reduces it.

A useful sentence on p. 278: "Studies in economics have only studied the illusion of control in choice under risk, whereas studies in psychology did not distinguish between risk and ambiguity." It is important to be aware of this difference in terminology between the two fields.

P. 281: "Given that the distortion of beliefs seems to best explain the effect of the illusion of control in our study" suggests a bit the source method (if belefs are taken additive), but the authors use α maxmin and recursive expected utility (smooth model) for ambiguity. %}

{% **ambiguity attitude taken to be rational**: This paper discusses the role of uncertainty, taking the current (2021) covid pandemic as example. It pleas for using decision theory for good decision making, which I agree with. But it argues against Bayesianism and for ambiguity models, which I disagree with. The contribution is that it does so in the language of policy makers, bringing in concepts relevant for policy makers, with flow diagrams and so on. The main text does not even mention the particular models. Figure 2 gives a case study where the names of various models are mentioned, but not defined. The latter is in online apppendices.

I as a Bayesian of course disagree with some claims. I display two, which will never appear with my name as co-author.

(1) P. 4 4th para: "However, it may not always be rational to follow this [Bayesian] approach (34–37). Its limitation stems from its inability to distinguish between uncertainty across models (which has an epistemic nature and is due to limited knowledge or ignorance) and uncertainty within models (which has an aleatory nature and is due to the intrinsic randomness in the world)."

Of course Bayesians can distinguish there.

(2) P. 4 top of 2nd colmn: "They assume that policymakers cope with uncertainty without reducing everything to risk, a pretension that tacitly presumes better information than they typically have."

The basic argument the authors have against Bayesianism is that Bayesianism requires probabilities to be specified but this being ("too") difficult. Thus the authors write, on p. 4 4th para:

"In the response to the COVID-19 outbreak, the Bayesian approach requires the policymaker to express probabilistic beliefs (about the impact of a policy, about the correctness of a given model, etc.), without being told which probability it makes sense to adopt or being allowed to say "I don't know." "

One counterargument from Bayesians is that specifying a set of priors, or other ambiguity concepts, is more complex than specifying one prior. A second is that … well, let me not get into it here. %}

{% Many authors take ambiguity aversion in the sense of Schmeidler's (1989) uncertainty aversion, being a preference for probabilistic mixing. I qualified this as a historical mistake in Wakker (2010 §11.6). This paper shows for many models that the two can work out differently. Whereas diversification is always good for risk under risk aversion, it can be bad under ambiguity aversion. For instance, it can lead to an enlarged set of possible priors. %}

{% Consider aggregation over several components at the same time, primarily persons, time, and uncertainty. Consider degrees of inequality aversion in each, and what effects they have on overall constant equivalents under different orders of aggregation. %}

Berger, Loïc & Johannes Emmerling (2020) "Welfare as Equity Equivalents," *Journal of Economic Surveys* 34, 727–752.

{% The paper uses the terms ambiguity and deep uncertainty interchangeably (p. 762 endnote 1).

This paper uses Marinacci's (2015) model of ambiguity with applications in climate change. Here the set of priors is assumed to be objectively given (p. 751). In climate change it is usually assumed to be the probability estimates provided by experts. Although this set can be quite different than the set of probabilities that possibly are the correct ones, which usually is what the set of priors in multiple prior models is taken to be, it is nevertheless used the same way in many papers. The paper assumes a subjective 2nd order probability distribution over the set of priors, and then uses the smooth model for calculations.

P. 754 Definition 2: For each event this paper takes the variance of the probabilities over the set of priors as index of degree of ambiguity (degree of disagreement), at least in the finite case. The definition does not specify if they use the counting measure available on the set of priors, or the subjective 2nd-order distribution. Because the paper focuses on one ambiguous event (a tipping point in climate is reached), this can readily be.

In their numerical examples and results, higher degree of ambiguity implies higher desirability of climate change mitigation and abatement. This may be because in the smooth model such a higher degree implies more ambiguity aversion, which may drive it. In other models, for events of moderate likelihood, bigger degree of ambiguity implies higher insensitivity and, hence, less desirability of precautionary measures. For extreme events, however, the opposite results. The smooth model does not have such insensitivity.

P. 749 writes, criticizing SEU normatively: "Therefore, it [ambiguity] requires a robust decision-making approach that is less sensitive to initial assumptions, is valid for a wide range of futures, and keeps options open (Lempert and Collins 2007), rather than a formal approach that maximizes the expected utility mechanically." P. 750 continues: "In view of this disagreement among experts or models, how should a rational policy decision maker proceed? If one follows the traditional Bayesian/subjective expected utility approach, one will simply aggregate the models by averaging them into a single representative model and then use the (subjective) expected utility framework (Newbold and Daigneault 2009). The problem with this approach is that the decision maker considers the resulting aggregated model in exactly the

same way as one would consider an equivalent objective model representing a specific risk, and model uncertainty has therefore no impact on the decisionmaking process." P. 752 reiterates: "Although the classical subjective expected utility framework has the advantage of being easily tractable, it is unable to take into account different attitudes toward different types of uncertainty that surround the economics of climate change. We now introduce different attitudes toward different types of uncertainty." As a Bayesian, I of course see things differently. Bayesians treat objective and subjective probabililities/ambiguity differently in the sense that in the second case they rather search for more information, and more easily update. Only, in the last second of the final decision, which is what static decision is about, the two are treated the same. At that last second, every ambiguity nonEU model has to be equally mechanic, and replacing a correct mechanic formula by an incorrect mechanic one does not help. If a hospital works 4 years on a treatment decision, objective statistical probabilities are important and collected all the time, whereas subjective probabilities long time play no role at all. They only do at the last second of the final decision.

P. 751 recognizes the predominance of EU: "Although we recognize the existence of a debate about the normative status of nonexpected utility models, and the *predominance of the expected utility theory paradigm for normative purposes in decision making*, we here follow the claim that there is nothing irrational about violating Savage's (1954) axioms in situations of deep uncertainty (Gilboa et al. 2008, 2009, 2012; Gilboa and Marinacci 2013)." [italics added here]

P. 753 ff. derive implications of prudence, which here corresponds with absolute ambiguity aversion decreasing in vNM utility. %}

{% I agree with most claims. M*ain problem today* is that referees have too much influence on *content* of paper because of asymmetric power, and do not try to avoid this (authors write similarly on p. 234 lℓ. –6/–3). Despite this, I am more positive about quality improvements of papers due to referee inputs than the authors are. I am also one of the few who think that the best duration of a referee round is not the fastest one (because of lack of referee resources).

I agree much that referees too much focus on small imperfections, not properly balancing the overall contributions, which favors marginal smooth contributions at the cost of truly innovative nontrivial contributions that are more open to debate, a point properly emphasized many times by the authors. The authors write e.g. p. 234: "The emphasis on superficial perfection over substantive importance"

I also agree much that referees should distinguish essential points for acceptance decision from nonessential suggestions for improvements. I add that another closely related distinction is about points that authors should react to and points they need not. Especially editors emphasize too much today that authors should exactly explain how all comments were incorporated, making authors lose time. Yet another closely related distinction is points of subjective opinion/taste vs. objective criticisms.

May main disagreement with the authors is their claim (p. 238 bottom) that if you have been a referee of a paper before, you should always let the editor know. Especially for top journals, doing so is a death sentence to the paper. The busy editor, knowing his journal was not first choice and the paper has been rejected elsewhere, will find it psychologically impossible to go for the paper. There are more reasons why sometimes it is better not to let the editor know, and why there is a referee-responsibility decision to be taken (whether or not the paper deserves a new independent try) here before involving the editor.

P. 240: another role of the cover letter is to give info to the editor that is not suited for the authors.

I agree that editors should guard against referees trying to push their own work

and, in particular, trying to get their work cited. Whenever a referee asks for citation of own work, the referee is under suspicion. %}

{% This paper is criticized by Wakker (2023) “A Criticism of Bernheim & Sprenger’s (2020) Tests of Rank Dependence,” §9. It suggests that it reacts to the criticisms of Abdellaoui, Li, Wakker, & Wu (2020) of Bernheim & Sprenger (2020), but virtually none of the many problems are fixed. The authors only improve the layout of their stimuli and their explanations to the subjects, reducing fatigue and properly avoiding a cancellation heuristic. However, as Wakker (2022) explains,

contrary to their claims they do not improve the incentives. They ignore all other criticisms, such as wrong formula of prospect theory, identifying unidentifiable functions, having no viable alternative to rank-dependent weighting, and they reiterate their ridiculous claim that all counting statistics would be invalid using it to improperly denying priority of many preceding studies. Further, all their conclusions are based only on accepted H_0 with no power analysis or anything added, something criticized in every statistical textbook. %}

Bernheim, B. Douglas, Rebecca Royer, & Charles Sprenger (2022) "Robustness of Rank Independence in Risky Choice," *AEA Papers and Proceedings* 112, 415-420.
https://doi.org/10.1257/pandp.20221090

{% **PT falsified**: This paper claims to find that, but I disagree. The authors want economists to return to what has been known as separable prospect theory. That is, they want economists to set back the clock by 40 years and return to the state of the art in psychology before 1980. This makes no sense: separable PT has been discarded since then mainly because it violates stochastic dominance, and does so in unacceptable manners. The basic problem of that theory is that it equates over-weighting of a 1/n probability at a worst-ranked outcome (is due to pessimism) with overweighting of all 1/n probability outcomes (giving optimism for gains). This does not make sense and makes the formula completely implausible, also descriptively. For lab-choices between lotteries with up to, say, four outcomes, the damage may not be very big, but beyond it goes nowhere.

SECTION 1. INTRODUCTION

This paper, abbreviated SB henceforth (I avoid BS for linguistic reasons), criticizes rank dependence, introduced by Quiggin (1982) for risk, and independently by Schmeidler (1989) for uncertainty. Rank dependence is central in Tversky & Kahneman's (1992) new prospect theory and many of my works. I co-authored a criticism of SB, at
http://personal.eur.nl/Wakker/refs/pdf/bscritic/abd.li.wak.wu_bernh.sp_linenrs20aug2020.pdf
abbreviated AL henceforth. Thus, I am not a neutral commentator here. I think that SB is very weak, and damaging to the field.

As everyone will guess, AL was submitted to Econometrica (ECMA), and, as will be clear, it was rejected. Given that I still maintain all the criticisms expressed by AL here, it is also clear that I disagree with all of ECMA's objections to AL: They did not provide any serious counterargument. Now that ECMA has let Bernheim & Sprenger publish an incorrect formula of the Nobel-awarded 1979 prospect theory, and has refused to correct it, what else can one do than warn people so as to minimize damage? The same holds for Berrnheim & Sprenger's incorrect identification of an unidentifiable functional, their incorrect claim of invality of general statistical counting tests, their attempt to revive separable prospect theory that was properly abandoned in the 1980s because of not just violating stochastic dominance but absurdly violating stochastic dominance, their unfounded pushing of their misnomer complexity aversion that was empirically rejected decades ago, their incorrect priority claims, and their other mistakes below. When Nilsson, Rieskamp, & Wagenmakers discovered that their 2011 paper in *Journal of Mathematical Psychology* used an incorrect formula of 1979 prospect theory, this alone was enough reason for the authors and journal to publish a correction in 2020. In this regard, ECMA, Bernheim, and Sprenger behaved differently.

AL was written following academic conventions of diplomacy. Here, where I express subjective opinions on works, I can be more explicit and clear.

SECTION 2. ORGANIZATION

References below can be found in this bibliography. I will as much as possible use SB's notation and terminology, often reluctantly:

- "CPT" instead of PT
- "rank-independent probability weighting": This term is uninformative, like non-elephant zoology. SB use it to refer to what is often called separable probability weighting ($\Sigma w(p_i)u(x_i)$). It was popular in psychology (Preston & Baratta 1948; Edwards 1962) until the 1980s, when it was abandoned mostly because Fishburn (1978 JPE) and others discovered that it violates stochastic dominance.

- “complexity aversion”: That subjects supposedly have an aversion to many outcomes, also for gains. The claim is empirically incorrect (see Mistake 3.8 below). The literature uses the term complexity aversion for phenomena other than dependency on nr. of outcomes, where the term is correct.

Next, three more sections follow.

SECTION 3. LIST OF SB’S MISTAKES DESCRIBED BY AL

SB claim a “*novel*” *falsification of CPT showing its* “*stunning failure*.” Mistakes:

3.1. [Ignoring priority of stronger counterevidence]

Even if SB’s experiment had been correct, stronger violations of the same kind have been reported long before (and so have many different violations), ignored by SB, and invalidating their novelty claims. (AL §6.4)

3.2. [Ignoring ocean of positive evidence]

Many more positive results for CPT were obtained. One should look at the balance of all evidence $\Rightarrow$ CPT most popular today. Even if SB had been correct, it would have been a very marginal contribution to an ocean of preceding evidence, ignored by SB, and invalidating their “failure of CPT” claims. (AL p. 16 ℓ. 6-12)

SB claim that *rank-independent probability weighting is better*. Mistakes:

3.3. [Misleading presentation of rank-independent probability weighting]

SB once acknowledge that rank-independent weighting violates stochastic dominance (“This is a serious flaw”, SB p. 1364). But then the rest of their paper still presents it, misleadingly, as a promising alternative, apparently forgetting about the flaw, also prior to bringing in the (irrelevant; see below) complexity aversion (link to misleading citations from SB). SB are apparenty unaware of the problematic absurdity, also descriptively, of the stochastic dominance violations (AL p. 4 $\ell\ell$. 10-16). The following Mistake 3.4 continues on this.

3.4. [Complexity aversion as incorrect remedy for Mistake 3.3]

SB incorrectly suggest complexity aversion as a remedy for the violations of stochastic dominance (SB end of §6). However, it is not; see AL §6.3. A less diplomatic and, hence, clearer, explanation is here (link). Thus, SB's suggested alternative for rank-dependent probability weighting does not work.

SB's *rank-independent probability weighting*, further mistakes:

3.5. [Wrong formula of prospect theory]

SB use an incorrect formula of 1979 prospect theory for rank-independent probability weighting (AL p. 3 ℓ.24 – p. 4 ℓ.7).

3.6. [Models not identifiable from their data]

The models that SB claim to estimate are not even identifiable from their data. (AL p. 4 ℓ. 25 - p. 5 ℓ. 11) Mainly because of this mistake, and also Mistake 3.5, AL (e.g., in Mistake 3.1 above) ignore SB's claims on rank-independent weighting, and focus on what remains: SB's direct tests of rank dependence.

SB claim *novelty/usefulness of complexity aversion*; mistakes:

3.7. [Complexity aversion theoretically discarded long ago]

See AL §6.3 & AL Online Appendix (added at the end of the AL file.) This invalidates SB's novelty/interest claims.

3.8. [Complexity aversion empirically falsified long ago]

See AL Online Appendix p. 3 (added at the end of the AL file). This invalidates SB's empirical claims.

SB claim a *new general nonparametric measurement* of decision weights. Mistakes:

3.9. [Trifle problem]

Their preference measurement does not work because of Ramsey's trifle problem (payoff *differences* too small). (AL p. 7 ℓ. 20 - p. 8 ℓ. 27 & §5)

3.10. [Three-outcome lotteries are too complex]

It has often been pointed out that, in general, three-outcome lotteries, as used by SB, are too complex for subjects. Hence, all cited studies with three-outcome lotteries other than SB did special efforts, with special layouts and visual aids (AL p. 12 $\ell\ell$. 5-9). SB, unaware, did not do so.

3.11. [Linear utility]

The trifle problem can be avoided, but then linear utility is needed, invalidating SB's claims of generality and nonparametric analysis. (AL Assumption 1, p. 6 & p. 11 ℓ. 19 - p. 12 ℓ. 4)

3.12. [Further incorrect generality claim]

SB footnote 13, claiming validity even for nondifferentiable utility, is incorrect, and is based on a mathematical mistake. (AL p.6 Footnote 5)

3.13. [Invalid priority claim on measurement and test]

SB p. 1376 claims novelty: "However, our use of equalizing reductions has no counterpart in the existing literature." However, Diecidue, Wakker, & Zeelenberg (2007) used the (corrected) method before (AL p. 11 ℓ. 19 - p. 12 ℓ. 4) for uncertainty, which is more interesting than risk as in SB.

SB claim invalidity of statistical *counting tests*, used throughout all empirical sciences. Mistakes:

3.14. [Ignorance of randomness underlying statistical tests 1st]

SB do not know that *every* statistical test is based on an underlying probabilistic ("noise") model. (AL p. 13 ℓℓ. 14 -25). I add here the following citation, found May 2022, of Greenland et al. (2016 p. 338 2nd column 1st para): "Many problems arise however because this statistical model often incorporates unrealistic or at best unjustified assumptions. This is true even for so-called "non-parametric" methods, which (like other methods) depend on assumptions of random sampling or randomization."

3.15. [Ignorance of randomness underlying statistical tests 2nd]

SB's claimed first problem for counting tests only shows that *there exists* an error model under which counting tests are invalid. But this trivially holds for *every* statistical test, including all their own tests. (AL p. 13 ℓℓ. 30-33)

3.16. [Invalid no-power counterexample]

SB's claimed second problem for counting tests considers stimuli where EU and CPT make identical predictions. SB criticize counting tests for having no power then. But, again, this then trivially holds for *every* statistical test. (AL p. 14 ℓℓ. 9-19.)

SECTION 4. QUALIFICATIONS AND IMPLICATIONS OF THE PRECEDING SB MISTAKES

Elementary theoretical blunders: Mistakes 3.5 (wrong PT formula), 3.6 (nonidentifiability), 3.14 (randomness in statistics), and 3.16 (no-power)

Elementary experimental blunder: Mistake 3.9

Naive: Mistakes 3.1 and 3.2. Thinking, 30 years after the introduction of CPT, 20 years after its shared Nobel memorial prize, and after 1000s of applications, to be the first to ("properly") test one of its two main nonclassic components, is naive. Thinking that two (in fact only one; see Mistake 5.17 in §5 below) small experiments can speak final verdict, 30 years after, is so too. (Mistakes 3.14-3.16 are also naïve.) It is unbelievable that with dozens of falsifications available, and thousands of corroborations, Econometrica can put one, one!, falsification, well, supposed falsification, central.

*Further: S*B's other mistakes are more understandable, though still revealing lack of dedication/understanding & literature search/knowledge.

*Damage: O*ne can predict much damage to come from SB, augmented by the prominence of its outlet: Use of incorrect formulas/measurement methods, ignoring priority of preceding literature, wrong and useless separable probability weighting, nonsensical claims on general statistical procedures, rejections of papers using the currently best descriptive CPT, and so on.

SECTION 5. MISTAKES BY SB NOT MENTIONED IN AL

AL focused on SB's mistakes that were directly relevant for the main conclusions, and other mistakes whose mention could not be avoided (e.g., incorrect notation). However, having read their paper in detail, I know many more inaccuracies and weaknesses in SB, not mentioned by AL. I list such next.

Mathematical mistakes:

5.1. [Comonotonic independence]

SB p. 1376 ℓ. 8: Schmeidler's (1989) comonotonic independence is different than what SB claim. For instance, it involves a mixture operation.

5.2. [k independent of X]

P. 1367, Footnote 7: SB in fact need linear utility. Then, contrary to SB's claims, k does NOT depend on X there under PT and EU, and neither does it under rank dependence as long as ranks are kept fixed (comonotonicity), as follows from AL Eq. 8).

5.3. [$p = 1$ for common ratio]

P. 1390 ℓ. 10: The common ratio effect is only strong, and often only defined, with probability $p = 1$ involved. Nonlinearity of w in [0.9, 1] does accommodate this, contrary to SB's claim.

5.4. [brackets instead of braces]

SB's notation of lotteries violates mathematical rules (AL Footnote 2). Braces denote sets that are not ordered and cannot be used here.

Further:

5.5. [Reference dependence]

SB claim to also falsify models with reference dependence, but these claims are incorrect for the same reasons as their claims about rank dependence are (wrong formulas, unidentifiable estimates, bad stimuli, and so on).

Incorrect citations:

5.6. [No proper justice to Weber & Kirsner]

Weber & Kirsner (1997) find significant rank dependence for the same kind of stimuli as considered by SB, providing straight counterevidence to SB. SB do not make this clear but only cite them ambiguously in Footnote 6.

5.7. [Identifiability in other studies]

P. 1382: "Tversky and Kahneman (1992) and Tversky and Fox (1995) obtained probability weighting parameters from certainty equivalents by parameterizing both the utility and probability weighting functions and assuming each observation satisfies the indifference condition $u(C) = \pi(p)u(25)$."

Wrong citation. Those papers used essentially richer stimuli. For the stimuli mentioned there and used by SB, the model is not even identifiable (see Mistake 1.6).

5.8. [Real incentives in Birnbaum]

P. 1401 Footnote 69: "Interestingly, in incentivized tasks, we do not see the failure of coalescing noted by Birnbaum (2008) for hypothetical choice."

Wrong citation: Birnbaum used real incentives. His 2008 paper reviews Birnbaum (2004), in particular, his Table 3. His §2 there explains that he used real incentives. Probably SB gambled on their incorrect claim to cover up the puzzling point that their finding is opposite to Birnbaum's (as it is, unbeknownst to them, to most of the literature). Also note that Birnbaum (2008) extensively discussed what SB call complexity aversion, but they do not cite him for that, or the many other papers Birnbaum cites on it.

The next four mistakes show that almost every sentence in SB's footnotes 3 and 4, on prospect theory, is wrong.

5.9. [Only one version of 1979 prospect theory]

SB's Footnote 3: "Kahneman and Tversky (1979) actually provided two formulations of Prospect Theory"

Incorrect. There is only one (AL Eq. 3).

5.10. [No wrong prospect theory formula in other papers]

SB's Footnote 3: "extensions which correspond to our three-outcome formulation are provided by, for example, Camerer and Ho (1994) and Fennema and Wakker (1997)":

Incorrect citations. See AL p. 17 $\ell\ell$. 25-32).

5.11. [Explicit!]

SB's Footnote 3: "They implicitly invoked the same assumption [their Equation 1] when examining the Allais common consequence paradox (p. 282)."

Incorrect citation. Kahneman & Tversky (1979) write it explicitly on p. 282 top.

5.12. [Again, only one version of 1979 prospect theory]

SB's Footnote 4: "Kahneman and Tversky also provided a formulation for two-outcome lotteries with either all positive or all negative outcomes that does indeed respect dominance (see, e.g., Equation (2) of Kahneman and Tversky (1979))."

Incorrect. Their Eq. 2 is part of the ONLY version of 1979 prospect theory and, as is well known, this does violate stochastic dominance.

Weak writings:

5.13. [Statistical analysis lacking for main claims]

P. 1399 last para of §5: "equalizing reductions respond *strongly* to changes in X" [italics added]

No statistical analysis is given to justify this claim. The confidence intervals in Figure 5B overlap, leaving unclear whether what SB call "strongly" is even significant. SB make the same unfounded claim of dependence on X on p. 1396 ℓ. -5/-2 and p. 1398 last sentence of §5.3. Further, their claimed explanation, through utility curvature, is implausible because utility curvature is weak for moderate payoffs as in their experiment.

Besides the above point (SB's third finding end of §5), the first two findings there ((1): nonzero impact of probability; (2): absence of complete randomness) concern trivial strawmen. Their whole claim of genuine effects in their 2nd experiment, needed to claim genuine absence of rank dependence, hinges on the above, unsubstantiated, claim.

5.14. [Unfounded speculation]

P. 1380: "If isolation fails in this context, then our subjects would not exhibit standard patterns of probability weighting in binary tasks. [Then what else? Linear weighting???] Conversely, if our subjects do exhibit standard probability weighting patterns in binary tasks, then one cannot reasonably attribute the absence of implied discontinuities in the equalizing reduction tasks to a failure of isolation."

Unfounded speculations on what happens if isolation fails.

5.15. [Assumed properties u and w?]

SB never say what properties w and u have. Strictly increasing? Stoch. dom? Continuous? Yet they use such properties. This is why AL assumes them explicitly below their Eq. 1.

5.16. [apples vs. pears]

P. 1377: "because the essence of our approach is to measure characteristics of indifference curves (MRSs), all potential confounds associated with unintended variations in "distance to indifference" are eliminated."

A paraphrase: Because we measure apples, all problems of pears are eliminated. Their measurements of indifferences do have the analogous problem. See Mistake 3.15 in §3. For example, if the errors in their indifference measurements are not constant or are extreme, then their claimed p-values and confidence intervals are not valid either.

5.17. [No use reporting Experiment 1]

SB claim that Experiment 2 would show absence of cancellation in Experiment 1, (p. 1367 end of first para: "clearly refuting the cancellation hypothesis.") contradicting the consensus in the field (Weber & Kirsner 1997) and unfounded. SB *only* justify Experiment 1 by referring to Experiment 2. Experiment 1 adds nothing. Thus, one small Experiment 2 of 84 subjects (with no statistical analysis to support the main claim, see Mistake 3.13) should discard a Nobel-sharing theory used in 1000s of studies. SB's misleading claim is repeated in the last para of §5.3. Mistake 3.13 above showed how weak the evidence of their Experiment 2 in fact is.

5.18. [Complexity aversion is misnomer]

SB's complexity aversion for dependence on number of outcomes is a misnomer as explained at the beginning of these annotations and more in AL Online Appendix p. 2 $\ell\ell$. 17-32 & p. 1 $\ell\ell$. 17-21 (added at the end of AL).

If academia can publish a claim “2+2 = 5” and not allow this to be contradicted, then I live in a wrong world. %}

{% **utility families parametric**: utility is logarithmic (paragraph 5 calls it “highly probably”);

marginal utility is diminishing: Contrary to what is commonly thought, the St. Petersburg paradox (discussed on p. 31) is not Bernoulli’s primary motivation for deviating from EV (contrary to Cramer 1728). First, §2 nicely states the view up to then that best (in a rational sense) risk attitude should be objective. Then, §3 writes: “Somehow a very poor fellow obtains a lottery ticket that will yield with equal probability either nothing or twenty thousand ducats. Will this man evaluate his chance of winning at ten thousand ducats? Would he not be advised to sell this lottery ticket for nine thousand ducats? To me it seems that he answer is negative.” And then the main point: “it seems clear that all men cannot use the same rule to evaluate the gamble.” This formulates the big breakaway that EU brings, the necessity to bring in risk attitudes that are different from different persons. Later: “the utility, however, is dependent on the particular circumstances of the person making the estimate.” It is sometimes said that Bernoulli broke away from objectivity, treating different persons differently. But he does not do much so, letting marginal utility only depend on one’s wealth level in his main proposal of logarithmic utility for (almost) anyone. So, he does not sacrifice much tractability.

Arrow (1951, Econometrica, p. 412) suggests that Bernoulli was the first to formulate the principle of insufficient reason and has only this paper in his references. Latané (1959, Footnote 12) writes that Bernoulli is generally credited for being the first to use a utility function. Savage (1954, p. 95 in 1972 ed.) says this also.

P. 26 §6 ff.: I did not understand the analysis of the figure, and there may be mistakes.

P. 30 Para 16 argues that concave utility implies that spreading risks is good. P. 29 para 14 writes that strict risk aversion is rational. %}

{% **questionnaire versus choice utility**: Same experiment as Berns et al. (2007, JDM). Use negative outcomes, losses, being unpleasant electric shocks, received with particular probabilities. First N = 37 subjects are just told what probability distribution is exerted on them and they undergo it. So, experience but no decision. After that, subjects will choose between such things. During the experiencing stage, they measure brain activities, and use those to predict future choices (better said, they correlate them to future choices). In particular, they construct a neurobiological probability response ratio (NPRR). This nicely exhibits the **inverse S**-shape that they also find for probability weighting (although for the latter they only fitted the T&K’92 family which does not have other things than inverse S). They find that these measured experiences predict future choices as well as prior decisions. Nice, giving orthodox revealed-preference advocates food for thought. Implications of such findings for the revealed-preference discussions are in Abdellaoui, Barrios, & Wakker (2007).

P. 2055 discusses separation of probability and magnitude (latter means outcome). %}

{% **completeness criticisms**; Page nrs. refer to the publised version.

Uses Anscombe-Aumann two-stage model with EU in second stage (Theorem 2 (numbered 1.2 in the working paper); in Theorem 1 (numbered 1.1 in the working paper), lotteries have been replaced by their vNM utilities. On horse

space, a family Delta of probability distributions is given. One act is singled out that is the status quo (**conservation of influence**). Another act is chosen only if its EU dominates the EU of the status quo for every element of Delta. Preferences can be incomplete. This model is called Knightian uncertainty. The term "inertia assumption" indicates the priviliged treatment of the status quo. It is defended partially by bounded rationality. P. 84 top: "inertia is not a consequence of rationality. Inertia is an extra assumption which is consistent with rationality."

P. 82 3rd para argues that ambiguity nonneutrality due to this paper's inertia, or also in the Gilboa-Schmeidler models (this was also in the 1986 working paper), is rational.

P. 85 3rd para: "If probabilities are not known, there seems to be no normative justification for completeness." As often, a "there is no reason that not" argument.

P. 94: "Inertia is the refusal to change plans unless doing so leads to an improvement."

{% **correlation risk & ambiguity attitude**: find it weakly negative.

Have administrative panel of clients of investment company. So, all their subjects invest and they cannot investigate whether ambiguity aversion has a positive or negative relation with investing. Measure their risk attitude by one certainty equivalent measurement (positively correlating with some casual measurements of risk attitude) and a matching probability of a gain with completely unknown probability (step sizes p = 0.10). All this is hypothetical, so, suspicion is not really a problem (**suspicion under ambiguity**). Whereas their sample is not very big or 100% representative and their measurements are hypothetical, they have refined data on financial decisions and portfolio dynamics. They find: Conditional on participation in the investments, ambiguity averse people exhibit more home bias, choose riskier contracts, more rebalance contrary to market giving more stable risk over time, and (probably because of risky choices) have better returns in good times and worse in bad times. They have detailed results on how ambiguity aversion affects changes in investments over time.

correlation risk & ambiguity attitude:

reflection at individual level for risk: positive correlation between risk aversion for gains and losses;

ambiguity seeking for losses: they find some ambiguity aversion there, although less than for gains. %}

{% All hypothetical. Find that optimism negatively affects ambiguity aversion for positive frame and not for negative. So, sign dependence of ambiguity!

Studies 1 & 2: They consider the occurrence of side effects for medical treatments. It is a bit of deception because subjects are told probabilities of side effects that may not be real (**deception when implementing real incentives**). They either state it positively (probability of no side effect; can we consider it as gains? Debatable.) or negatively (probability of side effect). They have only low-likelihood nonzero outcome events (≤ 0.14).

ambiguity seeking: They find ambiguity seeking for positive frame and ambiguity neutrality for negative frame in both studies. They are surprised by the first finding (p. 175, Limitations, line 2). On p. 179 they conjecture that the multiatribute nature of their outcomes may be a reason for their unexpected finding.

The findings of ambiguity are not very clear. In study 1 the ambiguous probabilities refer to two studies, which may have raised confidence, as the authors point out. In study 2 there is a trend but it is not significant.

It may also be that the positive probabilities of absence of side effects are perceived as gains by some subjects, but as losses by others.

reflection at individual level for ambiguity: both studies 1&2 have data within individual but do not report this. %}

{% **real incentives/hypothetical choice**: like Kachelmeier & Shehata (1993), he uses actual payments of considerable amounts of money;

decreasing ARA/increasing RRA: both are found.

Only choices between 50/50 lotteries.

I disagree with some suggestions in the literature that this paper be the first to use the choice list. It does present choices that involved bigger and bigger risks versus safety, and takes the point where subjects turn from risky choice to safe choice as index of risk aversion, but this is not really the same as using the choice list to measure indifferences. It is a nice way of: **questionnaire for measuring risk aversion**. %}

Binswanger, Hans P. (1981) "Attitudes towards Risk: Theoretical Implications of an Experiment in Rural India," *Economic Journal* 91, 867–890.

{% **cognitive ability related to risk/ambiguity aversion**: Subjects are asked, introspectively, for their probability of a stock going up next year, where they can give more or less sophisticated answers (§2). There is info about their cognitive level, with special questions to measure it, level of education, and some other things. There is also info about investments of the subjects. The authors find that for subjects with high cognitive skills their investment decision is more driven by their probability estimate. This fits well with the interpretation of likelihood insensitivity, which is related with low cognitive skill and also with decisions being less affected by likelihood information. Low cognitive skills also go together with more inconsistencies in answers.

A difficulty for me in reading the paper is that it is entirely based on the concept of but true existing but unknown objective probability, automatically connected with the multiple prior idea. As a Bayesian I firmly believe in the existence of a "best" subjective probability for an agent, but the concept of a true existing objective probability, which only happens not to be known, has little meaning to me. Thus, the claim on p. 84 penultimate para, that most experts assume one true known probability measure for stocks, is weird to me.

P 84 writes: "Our preferred interpretation is that individuals with lower cognitive skills view stock returns in more fuzzy and ambiguous terms," which I like, although I less connect with the continuation "potentially characterized by multiple priors."

P. 74 4th para cites Gilboa et al. (2008) on nonneutral ambiguity attitudes being rational, and then proceeds to conjecture that subjects of lower cognitive level, who are found to deviate more from ambiguity neutrality, accordingly may be more rational in their handling of ambiguity. Could I as a Bayesian disagree more? P. 84 repeats the point, first using the qualification "particularly rational" for people deviating from ambiguity neutrality, but then fortunately going the other way: "Notwithstanding the merit of this view, there are also plausible arguments why individuals with high cognitive skills can be expected to view stock returns as less ambiguous than individuals with lower cognitive skills."

The authors are enthusiastic about their research and write, on p. 84: "In this study, we bridge the literature on subjective probabilities and the literature on the role of cognitive skills in economic decision making." %}

{% Link to paper
Poulton's (1989) book, reviewed here, comprises a nice survey of biases in subjective quantitative estimations. Birnbaum disagrees with the implicit assumption of the book that every way to have context influence subjects' answers is a bias. It can also be good and lead to more unbiased answers than absence of contexts, where subjects may have no clue. It criticizes Poulton's preference for between-subject designs, where the later Birnbaum, Michael H. (1999) "How to Show That 9 > 221 …" beautifully shows it.

P. 21 top of 2nd column first defines the assumption that context means bias, next to be criticized.

P. 22 top of 1st column: Ch. 7 of Poulton is on contraction biases, which are like regression to the mean. In many places, e.g. p. 22 2nd column, Birnbaum pleas for not avoiding biases, but studying them and then correcting them.

P. 22 last column penultimate para: systextual design: manipulate context and study its effects.

P. 23 1st column 2nd para: Contextual effects and biases can concern subjective values, responses, or both. That is, it can be just measurement error, or genuine error. This point is often discussed in the context of the endowment effect. %}

{% %}

Birnbaum, Michael H. (2008) "Postscript: Rejoinder to Brandstätter et al. (2008)," *Psychological Review* 115, 260–262.

{% A wonderful and useful review of all the findings of Birnbaum on risky choice accumulated over many years.

The author has a deep desire to write negative about prospect theory. Two of the many examples:

(1) P. 468, top, that different versions of prospect theory have differences in descriptions for some choices (how else could they be different), is formulated as: "so it is best to consider "prospect theory" as a large family of different, *contradictory* theories." [italics added here]

(2) p. 466 2nd column 4th para, on the often useful convention of using the same term for a theoretical property and also for its empirical implication, where the latter however assumes some underlying theory (such as equating concave utility with risk aversion where this only works under EU theory) which also happens in prospect theory for loss aversion. The author is unreasonably negative about it ("circular terminology"), even though the point that this can raise confusion is in itself correct.

(3) The author uses terms such as "self-contradiction" for claimed violations of prospect theory.

Most experiments have, apparently, been done without real incentives.

Many violations of prospect theory put forward are only violations of prospect theory of the exact parametric form put forward by Tversky & Kahneman (1992). Of course, that exact parametric form will not predict all choices 100% perfectly well, and finding single choices deviating (such as certainty equivalents not being 100% identical) is by itself trivial.

P. 466, as well as several other parts, claim that configural weighting theory can give an alternative explanation for loss aversion but this is not so. It is simply that configural weighting theory has its way of accommodating risk aversion in general, and simply uses that to accommodate loss aversion. It, then, does not treat risk aversion with mixed prospects in any way different than risk aversion with gains. The definition of loss aversion that the author gives, that it is risk aversion for mixed prospects, is horribly wrong. It is like EU saying that loss aversion is nothing but a special case of risk aversion and that nothing needs to be added to concave utility.

P. 467: I disagree with the interpretation

P. 467: note that stochastic dominance as defined implies coalescing.

P. 467 (also p. 490) suggests that his work on difference between buying-selling = endowment effect. This is not so. Buying-selling has more to do with reflection effect. Endowment effect concerns different framings WITH SAME FINAL WEALTH.

P. 469, 2nd para of 2nd column, mentions scale convergence ("the assumption that two ways to measure utility for the same person in the same context should be the same")

P. 469 bottom of 2nd column: **linear utility for small stakes**

P. 470: prior RAM is RAM of Eq. 7 with $a(i,n,s_i) = i$, $t(p) = p^\gamma$ with $0 < \gamma < 1$ (so, overweighting) and $u(x) = x^\beta$ with $0 < \beta < 1$.

P. 468/470: The prior TAX model and the special RAM model use rank dependence only to transfer weights from high to low outcomes, enhancing risk aversion. Risk seeking as with **inverse S**, what they do for binary prospects, comes from the concave probability weighting.

P. 477 writes, properly: "A descriptive model should be able to predict when stochastic dominance will or will not be violated." Many authors justify a model violating stochastic dominance by the mere existence of violations of stochastic dominance, but that is no good, and there should be concrete predictive power. Similar with transitivity and any other condition.

P. 477: "Birnbaum (2005a) tested the counting heuristic, in which people choose the gamble with the greater number of branches with higher consequences."

P. 478: Gigerenzer's priority heuristic fails.

P. 480 4th para points out that the probability triangle is too small to distinguish several theories. Contrary to the claim in the second para of 2nd column of p. 481, Wakker (2001) does not suffer from this problem. Instead, Wakker, Erev, & Weber (1994) pointed out this point before.

P. 481, 2nd column, 2nd para, nicely explains that the probability triangle is not well suited to test rank dependence, using simulations.

P. 481, 2nd column, 2nd para, incorrectly cites my Wakker (2001) paper as studying the classical paradoxes "trapped inside the [probability] triangle." My paper extensively discusses tests of the comonotonic sure-thing principle that typically involve 4 or more distinct outcomes and it is in no way trapped inside the triangle. Wakker, Erev, & Weber (1994, p. 196 penultimate para: p. 222) signaled the problem: "In addition, most tests have almost exclusively studied the **probability triangle**, which is not a suited domain for testing RDU for the following two reasons. ... Second, the probability triangle considers no more than three fixed outcomes, whereas any test of comonotonic independence requires four or more distinct outcomes."

P. 481 ff. discusses a decomposition of the Allais paradox into RBI and **coalescing**. The author uses this decomposition to dismiss the empirical evidence against the sure-thing principle, saying it is coalescing and not RBI (the other part of the s.th.pr.) that is violated. In this, he implicitly assumes that RBI is "true" s.th.pr. without coalescing, so that the nonreduced choices give a true test of the s.th.pr. This is not well justified. In the noncollapsed presentation subjects may cancel common outcomes, not because it is their true preference, but as an easy heuristic just to simplify their choice. Then Birnbaum's test of RBI gives no insight into true s.th.pr. The author's implicit assumption is explicit on p. 467 1st column ℓ. –3 where he, without justification, equates RBI with comonotonic independence.

inverse S: Pp. 484-486 present the evidence against inverse S initiated by Birnbaum & McIntosh (1996) where in three-outcome-prospect choices with one common outcome increasing the common outcome does not increase risk aversion as PT would predict, but decreases it in the spirit somewhat of risk aversion decreasing with increasing wealth.

P. 493, 2nd column, 1st para suggests finding opposite of Allais if noncollapsed presentation.

P. 493, 2nd column, 3rd para argues that evidence favoring inverse S is confounded by framing effects. However, the author only cites his, in itself valid, counterevidence against one particular implication of inverse S and not much other evidence favoring it.

Much of the counterevidence of Birnbaum (p. 475, p. 479, p. 483) can be explained through the following heuristic, which also underlies much of Wu & Markle (2008). It is a special case of Birnbaum's counting heuristic (on his p. 477; see above), but a strong special case. It underlies the famous violation of stochastic dominance first found by Tversky & Kahneman (1986). Imagine two prospects with 3 outcomes each. The first prospect has its best outcome better than the second prospect, also has its second-best outcome better, and also has its third-best outcome better. Then subjects often immediately decide that the first prospect must be superior by some supposed stochastic dominance, as a heuristic. It is not correct because the probabilities should be considered, with the first prospect maybe assigning much probability to its lowest outcome, and the second prospect to its highest. It is a heuristic where people simply don't even look at the probabilities. The countertest of this heuristic on p. 477 is too coarse.

P. 493: the author himself prefers TAX to RAM.

P. 497, 2nd para of 1st column, **paternalism/Humean-view-of-preference**: Discusses measurements of sizes, which is context-dependent according to range-frequency theory. If we reckon with range-frequency theory and correct for it, we can get back a context-free psychophysical function. Refers to Roe et al. (2001) for a similar approach. So, here Birnbaum exhibits the economists' way of thinking! Similarly, I would like to see coalescing as a bias to be corrected for so as to get the underlying true preference. %}

{% **PT falsified**: evidence against **inverse S**

real incentives: all choices were hypothetical

Finds violations of the s.th.pr. like Birnbaum & McIntosh (1996), falsifying the inverse S prob weighting of PT, also for four-outcome gambles distribution-independence is something of that kind, shifting probability mass from one common outcome to the other. Humphrey & Verschoor (2004) independently found the same. %}

Birnbaum, Michael H. & Alfredo Chavez (1997) "Tests of Theories of Decision Making: Violations of Branch Independence and Distribution Independence," *Organizational Behavior and Human Decision Processes* 71, 161–194. https://doi.org/10.1006/obhd.1997.2721

{% **inverse S:** Find that (Fig. 11, p. 341). As explained by Birnbaum's email, this is the first paper to discover the violations of monotonicity generated by the zero-outcome effect. For example, (.95, $96; .05, $24) receives lower CE (certainty equivalent) than (.95, $96; .05, $0) (p. 339 2nd column 2nd paragraph.). What is going on here is that when considering the CE for (.95, $96; .05, $0), people say "Ah a 0 outcome is nothing and I need not think about it." Then they ignore it too much, are only thinking about 96 which is a high number, and they come out with a high CE number. In (.95, $96; .05, $24) there is a 24 outcome and people will not ignore it but will think about it, give it weight. A similar dual phenomenon is mentioned by Goldstein & Einhorn (1987), who ascribe the idea to Slovic (1984, personal communication).

P. 333 Fig. 2 bottom panel shows how utility, derived under the classical elicitation assumption (so, analyzed under the descriptive assumption of EU), can deviate from the true utility if configural weighting theory is the real model, which for these two-outcome fifty-fifty gambles depends only on the parameter w, where the decision weight of the best outcome is .5 + w.

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): P. 334, 1st column, 2nd paragraph, on configural weight theory: "In this theory, u(x) represents a psychophysical function that characterizes the subjective value of money, apart from risk."

P. 334 discusses buyer's, neutral, and seller's point of view nicely, that income effects depending on whether or not people received prior endowment of lottery/sure amount to be given up is not strong enough to explain empirical differences found, referring to Knetsch & Sinden (1984) for it.

P. 325 clearly explains the idea of asymmetric loss functions to explain the disparity between buyer's and seller's point of view. As far as I can see, this idea is completely plausible from a psychological point of view but I see no revealed-preference interpretation for this loss function. Therefore, if I understand right, the asymmetric loss function is typically useful for psychologists but less so for economists. %}

{% **PT falsified**: evidence against **inverse S**

Real incentives: it was all hypothetical choice;

Considers choices (R_1, R_2, C) versus (S_1, S_2, C), $R_1 > S_1 > S_2 > R_2$. PT with inverse S predicts that there will be fewer risky choices as C increases. (If C increases from worst ($< R_2$) to intermediate (between S_1 and S_2) then inverse S would have the decision weight of S_2 and R_2 increase, enhancing safe choice. If C increases from intermediate to highest (> R_1) then inverse S would have the decision weight of S_1 and R_1 *decrease*, which *again* enhances risk aversion.) However, it is found that there are more risky choices (in agreement, in fact, with Machina's fanning out). As the lotteries get better because of C increasing, people get more risk seeking rather than risk averse. See Table 1 where the percentage of safe choices decreases rather than increases as we move to the right. So, the extreme outcomes seem to be underweighted rather than overweighted.

The paper gives an extensive theoretical analysis. The most extensive tests are in Birnbaum & Navarrete (1998) (the main topic of which, by the way, is another one), which also describes the other preceding evidence. In particular, the B&M paper considers only three equally likely outcomes, B&N considers richer probability triples.

P. 91 gives refs to people who argue that independence-tests are mixed up with other assumptions. %}

{% This book is, mostly, a book on preference axiomatizations for aggregations. That is, it considers a preference relation on Re^n and properties of it that are necessary and sufficient for particular quantitative representations. It considers both n fixed and n variable (the latter called variable population). It interprets the results for welfare evaluations. It virtually always assumes symmetry/anonymity, so, permutation invariance of preference. In most theorems the real numbers, inputs of preferences, are assumed to be individual utilities that have been measured in some way, reminiscent of the Anscombe-Aumann framework. Because of this, it considers many representations that are linear in these inputs, as in expected value. The term generalized, as in generalized utilitarianism, indicates that the input numbers are transformed nonlinearly, as in expected utility. The models in this book are mostly special cases of generalized utilitarianism for same-number and extensions to variable population sizes, with Gini-type generalizations. (§5.7 will open with: "Most of the principles considered in this book are variable-population extensions of generalized utilitarianism.")

Chs. 2 & 3 give didactical elementary results. Ch. 3 gives conditions on social welfare functions implying that they amount to maximizing a preference relation on Re^n.

Ch. 4 starts with fixed-population results; i.e., n is fixed. Part A, sections 4.1-4.5, discusses many principles verbally. Part B, Sections 4.6 ff., gets to business with theorems and axioms, the expertise if the authors. P. 92 defines Euclidean continuity and inequality aversion conditions such as preference for bistochastic matrices.

§4.7 defines generalized utilitarianism as $SUMg(u_i)$ with u_i the utility of individual i (objectively given beforehand, so, like money) and g a nonlinear transformation. (They write g^n to express the dimension n for later purposes.) So, this could be n times expected utility for 1/n probability distributions. Representative utility is g^{-1} of SUM/n, so, certainty equivalent.

P. 102 bottom considers difference of representative utility and average utility, which is risk premium.

§4.9 considers information requirements. Imagine that preference is not affected if we add a prospect (add coordinate-dependent constant). This is what my 2010 book calls additivity in Ch. 1. Under some continuity it implies invariance under multiplication by a positive scalar. Thus, any positive affine transformation does not affect preference. The book calls it cardinal unit comparability (CUC; p. 112). This book interprets it as information invariance, an interpretation initiated by Amartya Sen it seems. The condition is appropriate if we know no more than the cardinal class of the preference inputs. In the same spirit we can interpret constant absolure or relative risk aversion as information requirements. Anyway, CUC is like additivity in my 2010 book and axiomatizes subjective expected value maximization. Anonymity then implies same subjective probabilities, so, just sum.

§4.10 considers fixed population sizes. Same-people independence (p. 115) is joint separability for each fixed n. Theorem 4.7 shows that we get generalized utilitarianism with n-dependent g^n, for each n.

Then follow some theorems (4.9, 4.10) axiomatizing utilitarianism, which is just the sum of inputs. §4.11 considers variable population size but with comparisons only between n-tuples of the same length. Replication invariance: $x \succcurlyeq y \Leftrightarrow kx \succcurlyeq ky$ for each natural k if x and y are of the same length. Theorem 4.22 axiomatizes generalized utilitarianism with same g for each n, as always in this book, g being continuous. Theorems 4.19 & 4.21 prepare, with the latter using population substitution (kind of conditional certainty equivalence substitution; this implies for the representative agent exactly what Nagumo (1930) and Kolmogorov (1930) call associativity) instead of replication invariance (which is implied by it). Wakker (1986, Theory and Decision) is in fact the generalization of Theorem 4.21 to general, possibly noncontinuous, utility.

Ch. 5 turns to variable populations with comparisons between n-tuples of different length. In additive representations, it then is important where utility is 0. This is called the critical level. It is comparable to the reference point for prospect theory although not the same (no different dimensions in PT). Section 5.1 p. 130

mentions that continuity now must be strengthened to go across different n. §5.1.3 discusses what is called the repugnant conclusion (Parfit 1976), where the authors are as emotional as several others, something that I have never understood. Tännsjö (2002) seems to agree with me. §5.2.6 discusses average utilitarianism. For fixed n it is the same utilitarianism, but for variable n is makes a difference. Then comes Part B with axioms. §5.5, p. 158, formulates extended continuity, $\{x \in \mathbb{R}^n: x \succcurlyeq y\}$ must be closed for $y \in \mathbb{R}^m$ also, and same with weak reversed preference.

§5.6 defines same-number independence, being joint independence for each fixed n. Utility independence: Joint independence if length of the two vectors compared may be different (satisfied under generalized utilitarianism but not under average generalized utilitarianism). Existence independence: Preference between two vectors of possibly different length is not affected if common part is added. It implies utility independence but gives links between variable length. P. 160 $\ell\ell$. 5-6 define critical level. There is an existence of critical levels assumption. P. 165, end of §5.6: extended replication invariance: uRv ⇔ kuRkv extended to u,v of different length. There are also number-dampened models, which have each extra dimension weighted less than the one before.

§5.8 discussed average generalized utilitarianism (AGU) and some other models, such as number-dampened, with axiomatizations to come in Ch. 6. §6.2 discusses it again. Part B starts at §6.5. Theorem 6.1 axiomatizes continuous same-number generalized utilitarianism with dimension-dependent utility, and Theorem 6.2 axiomatizes it with dimension-independent utility. These results follow directly from Theorems 4.21 and 4.22. §6.6 has number-sensitive critical levels, §6.7 has them constant, §6.9 considers representative-utility principles (CEs (certainty equivalents) represent). It involves replication equivalence: x ~ kx for each k. Theorem 6.15 axiomatizes it (axioms: continuity, Pareto, minimal increasingness, and replication invariance), with the text following the proof on p. 198 verbally expressing the axiomatization of average generalized utility by adding same-number independence. §6.10 considers number-deampening. Theorem 6.24 axiomatizes power utility by invariance w.r.t. unit change of inputs (called information invariance with respect to ratio scale full comparability). %}

Blackorby, Charles, Walter Bossert, & David Donaldson (2005) "*Population Issues in Social Choice Theory, Welfare Economics and Ethics.*" Cambridge University Press, Cambridge, UK.

{% This paper, pointed out to me by Horst Zank in November 2000, proves some interesting representation theorems. It formulates these results in a social choice context, where individual utilities are given as primitives and social preferences are derived. As pointed out on p. 251 third paragraph, the results are isomorphic to preference representations on Re^n. Theorem 3 shows that additively decomposable functionals that satisfy CARA (constant absolute risk aversion) are, in fact, expected utility functionals with exponential utility. The result precedes Theorem VII.7.6 of Wakker (1989, Additive Representations of Preferences). Corollary 1.1, the special case of Theorem 1 restricted to monotonicity, shows that additively decomposable functionals that satisfy constant RRA are, in fact, expected utility functionals with power utility. It thereby precedes Theorem VII.7.5 of Wakker (1989, Additive Representations of Preferences). A special aspect of the theorem is that they permit both positive and negative inputs, and characterize a case of power utility x^r for positive x, and $-\lambda(-x)^r$ for negative x, with λ positive a scale factor. The authors point out that this result gives a special meaning to the zero outcome. So, the value function often used in prospect theory is already here!

There are references to earlier works in social choice theory on similar functionals. %}

{% Paper characterizes SEU by assuming additive representability through separability (Debreu 1960 etc.), and then assuming symmetry of preference with respect to all n states of nature, so that equal probabilities come out. (It suggests something else, being that they work with general n states that may not be equally likely, but then they assume that there exists an underlying refinement such that … etc.) It may be argued that this is decision under risk with known probabilities 1/n, and that what they characterize is a generalized quasi-linear mean. The assumption of replication equivalence (x ~ mx for any n-tuple x where mx means the mn tuple with x repeated m times), often used in axiomatizations of average utility, is not stated explicitly but is implicit in their Assumption 5, and in their implicit assumption in the proof of lemma 2 that u is independent of ||S||.

{% Jan. 18, 2002 I discussed this book with Mark Blaug. He said that he did not write things to express his opinions, but rather to provoke students and make them think.

Ch. 8: "The marginal revolution." §18.1, p. 278, on period following 1870, "For the first time, economics truly became the science that studies the relationship between *given* ends and *given* scarce means that have alternative uses for the achievement of those ends." (Italics from original.)

§8.4, p. 284, on philosophers emphasizing introspection as an instrument for economics and on hedonism in England in the 1850s. Blaug is negative on Mirowsky.

Ch. 9: "Marshallian Economics: Utility and Demand"

§9.2, p. 313, ascribes, as did Stigler (1950, §V), to Fisher the same way of measuring cardinal utility under additive decomposable MAU. However, Blaug does not ascribe it to Fisher (1892) as did Stigler, but to Fisher (1927). I spent many hours checking both Fisher-works, and found that this idea of standard sequences simply is not there. Blaug (Feb. 12, 2002, personal communication) explained that he had taken the reference from Stigler (1950) without checking the original.

§9.2, end (p. 316) seems to suggest that for utilitarian welfare evaluations the origin of utility must be determined??

§9.4, p. 320, deals with marginal utility derived from vNM utility and is awfully close to equating it with riskless utility, although the text immediately follows by saying that no one can measure the latter yet.

§9.7, p. 330, mentions an observability problem of indifference, as follows, for two commodities x and y (say x are apples and y pears): "we do not presume that he can say how much more y would be equivalent to a unit reduction in x. To make that presumption is to suppose that the individual can compare increments and decrements of marginal utility, which would imply cardinal measurement of utility." That is, Blaug confuses, for instance, marginal rates of substitution with cardinal utility. §9.10, p. 332 seems to (re)state the observability problem of indifference (we can never be sure from an observed choice whether or not the agent was indifference), but claims that, in the absence of introspection, indifference is as unobservable as strength of preference. It immediately gives one solution, indifference can be observed statistically. Another is that indifference can be observed approximately (every ε improvement determines a strict preference). P. 333 ℓ. 1 then goes on to suggest that avoidance of this indifference problem, together with unobservability of strength of preference, were the main motivations for Samuelson to develop the revealed preference approach. I don't think that the indifference problem played such a role, neither that it is in the same league as the unobservability of strength of preference.

P. 337, §9.12, seems to identify the difference between Benthamite utility and choice-based utility with a normative-descriptive difference, and then criticizes others for not having grasped this difference.

P. 338, bottom line, seems to equate violations of revealed preference axioms with changing tastes.

Ch. 17, "A Methodological Postscript," is on empirical status, formal status, and falsifiability. P. 695, §17.3: "… theories are overthrown by better theories, not simply by contradictory facts."

P. 698, §17.4, "After a serious of attacks on utilitarian welfare economics, a new Paretian welfare economics was erected in the 1930s that purported to avoid interpersonal comparisons of utility."

End of §17.4, p. 700, points out that welfare economics must involve value judgments. %}

{% Köbberling & Wakker (2003) defined, for PT with monetary outcomes, a more loss averse concept that implies the same risk attitudes for gains and for losses, in other words, that can only be used if the same risk attitudes for gains and for losses. It means that same basic utility and same weighting functions, but stronger kink. This paper generalizes the condition to general, nonmonetary, outcomes and splits the condition up into two. The first half, called more loss averse, imposes the condition only on mixed prospects that are preferred to the reference point. The second half, called less gain prone, imposes it only on mixed prospects worse than the reference point. It does not formulate the conditions for PT but only for RDU and, preceding that, for the special case of EU. It also gives a probabilistic extension.

Kõbberling & Wakker's (1993) preference conditions compare mixed prospects only to unnmixed sure outcomes, and not to unmixed general prospects as does this paper. Because K&W have a continuum of outcomes, and because the two agent s compared have the same preferences over nonmixed prospects, this difference does not matter.

I prefer a terminology where less gain seeking means just the same as more risk averse, as this has been done in other papers, and in the same way as less risk seeking is the same as more risk averse. So, in this sense I would have preferred a different terminology for this paper.

Köbberling & Wakker (2003) defined comparative loss aversion also under the restriction of same risk attitudes, and presented this as a restriction to be generalized in the future. This author proceeds differently. He argues that this restriction is intuitive and good and is how it should be. See his text below Proposition 1, p. 130: "Thus, to have a meaningful concept of comparative loss aversion, we need to consider individuals with identical preferences over the set of loss-free lotteries." It reminds me of people who, for subjective expected utility, use the particular Yaari-type more-risk-averse-than condition, notice that it implies the same subjective probabilities so that Yaari's method only works for the special case of identical subjective probabilities, and then start arguing that this is a law of nature and that we should never try to compare risk attitudes if different subjective probabilities; a common misunderstanding in the field. %}

Blavatskyy, Pavlo R. (2010) "Loss Aversion," *Economic Theory* 46, 127–148.

{% biseparable utility; Fishburn (1986 EL has something similar). This paper modifies the well-known mean-variance model where variance is replaced by absolute deviation from the mean. This replacement is desirable in many situations. Often, the quadratic nature of variance puts too much weight on outliers. Big point is that mean-variance leads to violations of stochastic dominance and the model of this paper does not. The paper gives a preference axiomatization, no empirical evidence. %}

{% real incentives: RIS. **PT falsified**

Obtains systematic examples of reversed common ratio. If to choose between sure outcome and prospect with considerably higher EV, most choose the latter, risky, option. If then the probabilities of nonzero outcomes are scaled down by a common factor, many switch to a safe choice. For example, $60 \prec 100_{3/4}0$ (64.9%) but $60_{1/3}0 \succ 100_{1/4}0$ (67.1%). I wondered if some error theory could account for it, with simply more errors in the latter choice because then the options are more indifferent. But this does not work well because the paradoxical choices are majority choices. The finding $60_{1/3}0 \succ 100_{1/4}0$ (67.1%) is amazing and puzzling. The paper considers some error theories but they cannot account for the finding. These findings violate every existing theory. %}

{% The author proposes the following definition of ambiguity neutrality, erroneously suggesting novelty: for any outcomes x > y and events A, B, with an obvious notation for acts, if $x_Ay \succcurlyeq x_By$ then $x_{A^c}y \preccurlyeq x_{B^c}y$. However, this condition has been proposed and discussed in numerous papers. It underlies Schmeidler's (1989) definition of uncertainty aversion through $1 - W(A) - W(A^c)$. For several years before now when I write this (2023), this annotated bibligraphy has had a keyword
Ambiguity = amb.av = source.pref, ignoring insensitivity
referring to that definition and criticizing it for ignoring insensitivity. In several papers I proposed calling the author's definition ambiguity indifference rather than ambiguity neutrality. It is amazing that the author even went public with this so obviously wrong novelty claim. As for the editor handling this paper, it is amazing that he has found two referees unaware of the literature. %}

{% **tradeoff method** is used.

Paper assumes choices from choice sets where one of the elements in the choice set is the reference point. It means that the preference relation given each reference point, as derivable using revealed preference techniques, cannot compare options worse than the reference point (they are never chosen because rather the reference point is chosen). This is a very realistic assumption. Sugden (2003) assumed such preferences observable which is unconvincing. Thus, reference dependence leads to incomplete preference (or, put another way in this case, to complete preference on a subset). The author develops additive representations for this case.

This paper is the first to illustrate that reference dependence makes completeness more questionable and adds to the desirability to study weakenings of completeness. %}

{% **tradeoff method**

The first paper to actually measure the regret theory functional quantitatively. This has not been done before, probably, because people thought that something as strange as a nontransitive functional can never be measured in any sensible way. This paper shows it can.

Confirms the main empirical hypothesis that Loomes & Sugden put up in the 1980s, that people are disproportionally averse to large regrets. This is even after controlling for event splitting. (In later papers, after the 1980s, Loomes, Sugden, and others conjectured that their original findings may have been just due to event splitting.)

Under regret theory, we have

$$x > y \quad \text{iff} \quad p_1Q(U(x_1) - U(y_1)) + \ldots + p_nQ(U(x_n) - U(y_n)) > 0$$

where x_i (y_i) is the outcome of act x (y) at state i, and p_i the subjective probability of that state. The tradeoff method with indifferences

$\alpha^{j+1}{}_i x \sim \alpha^j{}_i y$ for many j

still implies that the α^j's are equally spaced in utility units. (It, first, implies that $Q(\alpha^{j+1},\alpha^j)$ is the same for all j. This then implies the same $U(\alpha^{j+1}) - U(\alpha^j)$ for all j. That is, the tradeoff method is robust not only against probability weighting as shown many times before, but also against violations of transitivity. This paper, thus, measures U. Then, with U available, it derives Q from PE questions.

tradeoff method's error propagation; simulations based on a Fechner error model suggest that it is not strong (p. 164). They also have a clever test of whether subjects act strategically in view of the adaptive nature: Two questions from the beginning, when subjects could not yet know about adaptive stimuli, are repeated near the end, where subjects know if they ever. Then the second questions should receive higher answers. But they don't (p. 168). So, this gives evidence of no seeing through the adaptive setup and no strategic answers.

They find no subject doing the linear-constant-distance heuristic for TO. All of this because TO not from matching but from binary choice. %}

{% **equity-versus-efficiency;**

tradeoff method: used that to measure the utility of QALYs.

An impressive sample: not only 69 students, but also 208 members from the general public in 22 group sessions of about 15 each, with three interviewers present at each session.

In an experiment, subjects had to choose between different hypothetical allocations of QALY scores over n individuals. The authors used the tradeoff method to measure how people transformed QALYs into utilities and, next, used these to measure the rank-dependent weights that people assigned to individuals. They found preference for equality in sense of overweighting of the worst-off, but also: **inverse S:** People overweight the richest and poorest, suggesting insensitivity to groupsize. Insensitivity dominated pessimism, so that the typical inverse S shape resulted. The authors then advance an interesting argument: Insensitivity is a cognitive limitation at the level of numerical misperception, so that it is reasonable to correct for it. (**cognitive ability related to likelihood insensitivity (= inverse S)**) They present the equity weighting that results after doing so, which is, obviously, convex and pessimistic. %}

{% **dynamic consistency**: They measured first in standard Ellsberg urn who were ambiguity averse, and there was 32.5%. They put a small price on ambiguity

aversion, to have it strict, and then their result is common. Then came the main experiment, as follows.

The main experiment was with cards, but let me say Ellsberg balls and urns. So, an urn contains 200 numbered balls, 100 odd and 100 even numbered. Both odd and even are three-color Ellsberg: 33 red and 67 blue/yellow in unknown proportion, but same for odd and even. I regret that the authors chose color blue instead of Ellsberg's color black. A priori, subjects can bet on a color for odd-numbered balls and separately for even-numbered. By choosing blue for odd and red for even, they get the biggest possible objective known probability of 67%. Then, they receive a signal if the number was odd or even. (**updating under ambiguity**) Let us assume RCLA or its analog for events. I did not read the entire paper but did not see the authors state it. A decision maker, also if ambiguity averse, can satisfy both dynamic consistency and consequentials by doing backward induction in the prior situation. But, as I learned from Tversky (personal communication), backward induction is not plausible if there are few outcomes with many events, which is the case here.

Now, subjects can then either maintain their choice, or switch. Under ambiguity aversion, dynamic consistency requires maintaining but consequentialism requires switching. 73% did consequentialism, similar to Dominiak et al. (2012) but better implemented experimentally. %}

{% **Kirsten&I**, finitely many timepoints %}
Bleichrodt, Han & Amiram Gafni (1996) "Time Preference, the Discounted Utility Model and Health," *Journal of Health Economics* 15, 49–67.

{% They use the time-tradeoff sequences of Attema et al. (2010) to measure deviations from constant discounting. Do it for (economic) money and (health) life duration. A minority of 25% to 35% exhibit increasing impatience. The authors use Rohde's (2010) convenient hyperbolic factor to analyze their data. They only fit discount families that cannot accommodate increasing impatience, being hyperbolic, quasi-hyperbolic, constant, and proportional. Of these, hyperbolic and proportional are relatively best. The authors write, in their conclusion: "To explain increasing impatience other discount functions are needed (Ebert and Prelec 2007; Bleichrodt et al. 2009)."

Seems that they discuss the problem of transferability of money over time (instead of consumption) when measuring discounting. %}
Bleichrodt, Han, Yu Gao, & Kirsten I.M. (2016) "A Measurement of Decreasing Impatience for Health and Money," *Journal of Risk and Uncertainty* 52, 213–231.

{% This paper aims to empirically measure Hurwicz expected utility (HEU) of Gul & Pesendorfer (2015). However, as explained in my annotations there, this is impossible: it would require a rich set of "ideal events" (events that have EU maximization) and ALL if them to have been measured, and further unrealistic assumptions about "diffuse" (maximally ambiguous) events. Instead, this paper uses what I call the source method of Abdellaoui et al. (2011 AER): assume local probabilistic sophistication within sources and then measure source-dependent probability weighting functions, which I call source functions. The only relation with HEU is that this paper uses a parametric family of weighting function that

satisfies the requirements for those of HEU. One can praise the authors for having ignored the many unobservable aspects of HEU.

The new probability weighting family, called HEU familiy, is interesting: First, in Eq. 8 on p. 1398, the authors define

$$w^*(p) = \frac{(1-\beta)p}{(1+\beta)(1-p) + (1-\beta)p}$$

The function is decreasing in β, which can, hence, be taken as a index of source dispreference. Then, Eq. 9 takes $w(p) = \alpha w(p) + (1-\alpha)(1-w(1-p))$.
Now α is an index of ambiguity aversion, and β of ambiguity perception or a-insensitivity. It satisfies the requirements of Gul & Pesendorfer's HEU.

The authors claim in several places that their family best fits the data of their experiment, but Table 1 shows that Prelec's family does better. They also claim in several places that their parameters of aversion and perception (insensitivity) are cleaner and clearer than others in the literature, but the only argument really put forward is that in Prelec's family the parameters interact. No counterargument is given against the other parameters in the literature and neither arguments are given to support their own parameters. Or it should be that their parameters are uncorrelated in their data. But (1) this is based only on an accepted null hypothesis; (2) they do not test correlations of the other parametric families; (3) this is empirical unrelatedness and not conceptual. For instance, Baillon, Bleichrodt, Li, & Wakker (2021 JET) show that their indexes are mathematically orthogonal, which suggests conceptual independence.

P. 1394 claims that HEU is the first axiomatized empirically realistic theory, but I disagree. Choquet expected utility/rank-dependent utility, prospect theory, and α maxmin were also axiomatized and are better. HEU is a special case of these, but an empirically unsatisfactory one given its ideal and diffuse events.

Many claims in the paper, such as that ambiguity aversion α is independent of source, are based only on accepted H_0, most with $N = 48$ subjects in the first experiment.

When they derive HEU's claimed prediction that ambiguity aversion is positively related to first-order risk aversion, they don't give a real argument but only a terminological move: pessimism in the source function is equated there both with ambiguity aversion and with, what they call there, (source-dependent) first-order risk aversion.

The authors claim to be the first to have an ambiguity aversion index valid for all weighting functions (p. 1408), but their index is identical to the aversion index of Baillon et al. (2018). The authors, incorrectly, claim that the indexes of Baillon et al. (2018) are valid only for RDU with neo-additive weighting (p. 1408). First, Baillon et al. (2018) claim them for all weighting families under biseparable utility and, second, Baillon, Bleichrodt, Li, & Wakker (2021 JET, §7) prove mathematically that their indexes are valid under most ambiguity theories also beyond RDU. %}

{% **tradeoff method**: They use it. P. 1490/1491 gives nice details about their implementation for finding indifferences. They first ask for values that give sure decisions, then narrow these down.

tradeoff method's error propagation: P. 1495 did simulation suggesting that error propagation of the tradeoff method is not very serious.

inverse S: They find that, doing it for health outcomes instead of monetary. The curve is more elevated/curved than for money. Table 1, p. 1488, gives a convenient listing of studies of probability weighting. They clearly find inverse S, more than for monetary experiments. P. 1492 bottom of 2nd column: They find more bounded SA (so, lower and upper SA) than monetary experiments did. Strangely enough, p. 1493/1494 finds slightly more lower SA than upper SA in

one analysis, slightly less in another. So, roughly, it looks equal.

P. 1494 1st column: they find approximately linear probability weighting in the middle region.

P. 1495: compares fit of different parametric weighting function families.

Weighting function for health is both more elevated (abstract, p. 1495; higher δ in Table 4) and more inverse S (p. 1492 bottom; lower γ in Table 4) than commonly found for money. %}

{% Use medical stimuli, i.e., chronic health states with two dimensions, health state and life duration. Consider (i) Effects of varying loss aversion when scale compatibility effects are constant (ii) Effects of varying scale compatibility when loss aversion effects are constant (iii) What happens if scale compatibility goes one way, loss aversion the other? Stimuli: To get $(x_1, x_2) \sim (y_1, y_2)$, three of the four values are fixed and the fourth is established through choice-bracketing, e.g. $(x_1, x_2) \sim (y_1,?)$ with ? to be revealed from the subject. Next, in a return question, the matching value obtained is substituted and any of the other should be substituted, as, for example, with x_1 to be substituted, in $(?, x_2) \sim (y_1, y_2)$.

Results: All effects occur, scale compatibility and loss aversion seem about equally strong for they neutralize each other when they can. Loss aversion is not constant but depends on stimuli: it seems to decrease with life duration.

Suggest to do utility measurement in contexts where scale compatibility and loss aversion are minimal.

restrictiveness of monotonicity/weak separability: Subjects preferred death to a severely impaired health state following stroke. However, if these outcomes resulted with probability .25 (.75 probability of full recovery), then the preferences reversed.” [Death and stroke are not explicitly modeled as multiattribute here but are similar.] %}

{% Quasi-hyperbolic discounting, also called the beta-delta model, has discount function $\delta^0 = 1$ for $t = 0$ but $\beta\delta^t$ for all $t > 0$. For $\delta \neq 1$, it can be rewritten as $\delta^{\tau+t}$ for all $t > 0$, with $\tau = (\ln\beta)/(\ln\delta)$. Whereas for some purposes β is a better index, better capturing the utility loss of nonstationarity, for other purposes τ is, better capturing the time duration ("number of future selves") during which there can be nonstationarities. τ is, indeed, the length of the period during which inconsistencies can occur. The intro does not give a balanced account by mentioning drawbacks of β but not mentioning the similar drawbacks of τ (that it ignores the utility lost). The discussion and rest of the paper similarly oversell τ, using overly strong words, wih the usual cliché policy and even normative claims.

τ and its measurement have big problems for $\delta = 1$. Then τ is undefined or infinite. Further, δ close to 1 gives extreme values of τ. How to do statistical estimations then? The authors duck the issue in their numerical illustration in §6. The beginning of §6 considers $\beta < 1$ and then points out that $\delta = 1$ may be due to a form of high irrationality: that agents do not distinguish between future timepoints, with the only distinction now versus later. Although I did not find it stated in the paper, the authors apparently removed these subjects from the analysis. (How else could they do their regressions?) I have three problems here. First, $\delta = 1$ (with $\beta < 1$) need not be high irrationality but can be very moderate irrationality, if at all. Second, even if irrational, why are these subjects removed from the analysis? Don't we want to analyze irrationalities here? Third, the usual thing when removing subjects from an analysis: can this removal bring biases for the things analyzed, if the group removed is extreme in some sense? %}

{% On July 1, 2010, Drazen Prelec pointed out to us that our CRDI function appeared before in Prelec (1998, *Econometrica*) as conditional invariance in his Proposition 4, and our CADI function was defined there on p. 511, Eq. 4.2. Prelec also provided an axiomatization by his conditional invariance preference condition (p. 511 top), which is almost identical to our CRDI preference condition. Our CRDI condition is slightly weaker, being the special case of Prelec´s conditional invariance with q = r and x´ = y. Thus, our theorem is slightly more general, but this difference is minor. Prelec formulated his theorem for the context of decision under risk, with his p from [0,1] or from (0,1), designating probability. We formulated our theorem for intertemporal choice, with our t (the same role as Prelec’s p) from any subinterval from [0, ∞), and with utility slightly more general. Our details are again slightly more general than Prelec’s, but, again, the differences are minor. Thus, the priority of the CRDI family is with Prelec (1998). I regret that we did not know this at the time of writing our paper and, accordingly, could not properly credit Prelec then.

CRDI generalizes the constant sensitivity family of Ebert & Prelec (2007). Now I think unit invariance is a better name. March 2014 I discovered that Read (2001 JRU Eq. 16) proposed this basic family before, and so did Takahashi (2006 Eq. 6). %}

{% MAUT adapted to PT, with either global reference points (and then also globally determined rank-dependent weights) or within-attribute reference points (and then also within-attribute determined rank-dependent weights). Whereas the title does not make it very clear, this is the main topic of the paper. The global approach is called holistic, and the other is called attribute-specific. Attribute-wise would be a more tractable term for the latter. They cite several other papers, such as the well-known Tversky & Kahneman (1991), on attribute-specific reference points.

Formally, PT uses the holistic approach. This appears, for instance, from Wakker & Tversky (1993) where the outcome set is a connectec topological space, which includes a convex set of commodity bundles with the usual Euclidean topology as a special case. It is stated verbally by Tversky & Kahneman (1981) p. 456, penultimate paragraph. Yet, what is empirically more useful, and what is more interesting, that is another question. The holistic approach has been primarily chosen for pragmatic reasons, having fewer parameters. Similarly, for RDU, Schmeidler (1989) chose the holistic approach.

A preference foundation is given. Decision weighting and loss aversion can depend on the attribute. They give a model that is essentially addition, over attributes, of attribute-dependent PT values.

The attribute-specific approach does still satisfy transitivity and in this sense is holistic still. It is not the regret-theory type of deviation from transitivity.

{% **proper scoring rules-correction**;

Throughout, expected utility is assumed. P. 408: "Cross sections of option prices have long been used to estimate implied probability density functions (PDFs). … Unfortunately, theory also tells us that the PDFs estimated from options prices are risk-neutral. If the representative investor who determines options prices is not risk-neutral, these PDFs need not correspond to the representative investor's (i.e., the market's) actual forecast of the future distribution of underlying asset values." It is reasonable that on average the subjective probabilities equal objective probabilities. This paper corrects by assuming nonlinear utility, and seeing what utility best corrects. They report RRA for both (so, for exponential utility multiply the Pratt-Arrow index by the amount). Table III, p. 424, finds powers such as –4 (i.e., relative risk aversion indexes of 5) as median and mean. Table V, p. 429, has more extreme values, ranging from power 0 (ln) to power –14 for all kinds of time horizons. Table VI, p. 431, is likewise. A nice table of previous estimates is on p. 432, Table VII, with wide variation. Exponential utility seems to fit better than power. %}

{% **state space derived endogeously**:

This paper does not assume Savage's states, outcomes, and acts, but constructs them from, possibly incomplete, preferences on a finite set of other concepts, called syntactic programs. A syntactic program is: If test t then action a, else action b. Tests are like propositions, being true or false. We can construct the algebra generated by tests, which can serve as a state space, although sometimes more states will be needed. Outcomes can be constructed from, I guess, states combined with actions. Thus, it is close to models that take states and acts as given, and derive consequences from those.

Cancellation axioms are imposed, giving additive representations, i.e., state-dependent expected utility. The model allows for state-space and outcome-set constructions thus permissively that state-dependence and state-independence cannot be distinguished (p. 19 middle). It is written there that state independence needs justification external to the theory. (This is the typical case if states and acts are taken as primitive, and outcomes derived from those.) Objective probabilities and mixtures are also introduced, with mixure cancellation axioms on them giving mixture independence (Theorem 1).

It is allowed that an agent deciding, and a researcher studying the agent, have different state spaces. The agent may violate extensionality: May not know that different descriptions refer to the same event. This is similar to Tversky & Koehler's (1994) support theory, which the authors extensively discuss. I discussed support theory much with Tversky. Tversky had in mind one "true correct" state space and then a (mis)perceived state space by the agent. I several times told Amos that there does not exist something like a true correct state space (only the true state of nature "exists"), and that I would prefer that he replace it by just a subjective sophisticated state space of the researcher. I am glad to see that this paper does it that way. Another difference is that in support theory the state space(s) are exogenously given, but here they are derived.

One other thing I liked about the Tversky & Koehler paper is that they maintain additivity of subjective probabilities in the agent's perceived state space. What we model as violation of SEU due to nonlinear probability may then in fact be misperception of the state space. So, I regretted much when later papers on support theory gave up that additivity. Glad to see that this paper has the additivity that I like.

Luce worked on somewhat similar models and is also cited. %}

{% They find strong effects of defaults in saving choices by employees in Afghanistan. They consider five possible causes, writing on p. 2870: "Here, we attempt to differentiate between five explanations offered by the literature; the first three are consistent with rational models, and the latter two with behavioral models. First, defaults may

persist because of an employer "endorsement" effect whereby decision makers, unsure of the best course of action, take the default as reflecting a recommendation by a benevolent planner (Madrian and Shea 2001; Choi et al. 2004; Madrian 2014). Second, there may be significant real or perceived costs involved in switching from the default election, due to mechanical frictions in changing one's contribution rate. Third, and closely related, there may be a large mental cost associated with the complexity of forming a financial plan (Lusardi and Mitchell 2011; Cole, Sampson, and Zia 2011; Drexler, Fischer, and Schoar 2014). Fourth, turning to behavioral theories, the possibility of switching may not be salient in the mind of the employee, or the employee may be inattentive (Karlan et al. 2016b; Taubinsky 2013; Kast, Meier, and Pomeranz 2016). Finally, because changing defaults involves some immediate costs with delayed benefits, individuals may not switch, particularly if they are present-biased and naive about their future preferences (O'Donoghue and Rabin 1999)."

They find that present bias and calculations being too complex are main explanations. %}

{% **probability elicitation**: applied to experimental economics;

Short summary:

This paper considers standard gamble (PE) measurements. The sure outcome is (**10**,10) (**10** for you and 10 for an anonymous other person). The PE question has a good outcome (**15**,15) and a, for you, bad outcome (**8**,22). Which probability p makes you indifferent between (**10**,10) and (**15**,15)$_p$(**8**,22)? I first present the 2nd treatment.

2ND TREATMENT: The probability p refers to some objective probability determined by some random mechanism that does not arouse any emotion (at least not by the info given to the subjects).

3RD TREATMENT: Like the 2nd, but with the payments for the other person removed.

1ST TREATMENT: The probability p refers again to some objective probability, but it is of an event that arouses nonneutral (here, negative) emotions (percentage of people betraying others).

All treatments use a BDM (Becker-DeGroot-Marschak) two-stage resolution of uncertainty. In the first stage an objective probability p is chosen in an ambiguous way (in treatments 2 & 3 no info at all is given to the subjects, and in treatment 1 it is the percentage of betrayal, unknown to subjects). In the second stage it is decision under risk, choosing between (**10**,10) and (**15**,15)$_p$(**8**,22). Under backward induction (*BI*) or isolation (in a strict sense) (or consequentialism as Machina, 1989, called it, or time invariance as Halevy, 2015, called it), the subject should let the indifference p be the indifference probability of the PE, so, it should be the same in treatments 1 and 2. In particular, under BI (in a strict sense) betrayal aversion can play no role. Indeed, rationally speaking, in treatment 2 any aversive betrayal event has happened anyhow and can no more be affected. In particular, it is no more reason to like (**10**,10) more than (**15**,15)$_p$(**8**,22). Still, in the experiment the subjects just dislike the probabilities of aversive events in Treatment 1 extra and hence require a higher probability p there to make them indifferent. This means that BI/isolation in the strict sense must be violated. (Something that Machina (1989) argued for on, for him, normative grounds, although he did not write those very explicitly.) Conditioning on a betrayal event induces extra dislike of (**15**,15)$_p$(**8**,22). Then betrayal aversion can come in. Ambiguity attitude can also come in (if this is considered a component separate from betrayal aversion). Maybe subjects dislike more, or perceive more, the ambiguity about betrayal in treatment 1 than the choice (which may be perceived as uniform) in treatment 2.

Under BI, it can be interpreted as: **violation of risk/objective probability =**

one source

More detailed summary:

GAME 1 [Trust game]: First I define the trust game, then I say what happened. In the trust game, a **principal**, who gets bold payoffs, can choose to either get (**10**,10) (**10** for self and 10 for agent) or move to second stage. In 2nd stage agent can choose (**15**,15) or (**8**,22) (in latter case principal gets only 8 and agent gets 22).

The trust game was not played for real by the principal, but something else is done. Under BI, it is just a task of decision under risk with known probability, as follows: The principal is asked the minimal probability(objective!), denoted MAP (minimally acceptable probability) at the good prize (so, (**15**,15)$_{\text{MAP}}$(**8**,22)) to make him willing to forgo the sure prize ((**10**,10)) and take the risky option. This is implemented in a BDM (Becker-DeGroot-Marschak)-like implementation as follows. Each agent was asked whether he would be trustworthy (go for (**15**,15)) if given the chance (without any other info; they just thought it was a trust game). Then it was measured which percentage p of the agents in the sample chose to be trustworthy. Then each principal was randomly matched with an agent. If p was better than the chosen threshold MAP ($p^* \geq$ MAP) then the game was played, but if p was worse ($p^* <$ MAP) then the sure (**10**,10) resulted. Under BI, for the principal it can be taken not as ambiguity but only as risk with known probability, where a probability equivalent question was asked for (**10**,10) in a lottery with (**15**,15) as good outcome and (**8**,22) as bad outcome. Then real incentives were implemented à la BDM where, however, the probability p was not chosen fully randomly from [0,1] but was determined by the agents' responses in the sample. Under BI, this does not affect the incentive compatibility. However, ambiguity attitudes may come in regarding the probability p chosen in the BDM mechanism, which in treatment 2 is done without any info given to the subjects (so, ambiguous) and in treatment 1 through the (objective, 1st stage) probability of betrayal the 2nd stage uncertainty about which however is ambiguous.

For control, besides the trust game, two other games were considered:

GAME 2 (called risky dictator game): Principal can choose to either get (**10**,10) or move to second stage. In second stage, randomness chooses: (**15**,15)$_p$(**8**,22). Here the principals were only told that it was a probability p, but not how it was determined. It was actually determined as in Game 1, as the probability of the agents in the sample choosing trustworthy, but principals had no knowledge of this.

GAME 3 (called decision problem): Principal can choose to either get **10** or **15**$_p$**8**. Here the principals were only told that it was a probability p, but not how that was determined. It was actually determined as in Game 1, as the probability of the agents in the sample choosing trustworthy. So, this is like Game 2 but without payments to another agent.

They find betrayal aversion: i.e., the matching probability in Game 1 is higher. In reality, and in deviation from BI, one can, pessimistically, expect subjects not to fully see through Game 1 (the same way as I, each time when rereading this paper, need nontrivial time to re-understand that it is just risk under BI) and be confused by and partly guided by beliefs in trust/betrayal still. Or, very plausibly, BI is violated. Then anything can be going on and, in particular, ambiguity attitudes may play a role. Let me henceforth assume BI.

In all games the probability regarding the decision situation of the principal can then be taken as objective. In Game 2 the only reason to be different than Game 3 then is welfare considerations regarding the payoff for the other. In Game 1, besides the welfare considerations, there is also the (dis)like of having been betrayed yourself by your matched agent or not. So, not the beliefs, but only the values of the outcomes matter, formally speaking.

In my preferred interpretation (still assuming BI), the finding of betrayal aversion is a special case of source preference, be it that here both sources concern risk (objective probabilities) (in the source method risk is usually taken as one source): people just dislike uncertainty (risk in this case) having to do with betrayal, in the same way as they just like to deal with uncertainty related to their hobby of basketball rather than other uncertainties (Heath & Tversky 1991). %}

Bohnet, Iris, Fiona Greig, Benedikt Herrmann, & Richard J. Zeckhauser (2008) “Betrayal Aversion: Evidence from Brazil, China, Oman, Switzerland, Turkey, and the United States,” *American Economic Review* 98, 294–310.

{% **second-order probabilities to model ambiguity**: Paper considers ambiguity attitudes through second-order probabilities. People prefer positively-skewed second-order probability distributions, both for gains and for losses. P. 140 Table 1 gives a good impression of what goes on. All effects are weaker for losses than for gains.

ambiguity seeking for unlikely: If interpreted as ambiguity study, this paper finds considerable risk seeking for positively-skewed 2nd-order distributions, so, it is again evidence against the assumption of universal ambiguity aversion. However, I interpret it differently. First, the 2nd-order probabilities are so explicit and simple that I rather consider this to be a study of **RCLA** than of ambiguity. Second, I think that the subjects have simply treated the first-order probabilities as outcomes, somewhat as in Selten, Sadrieh, & Abbink (1999). Much in this paper enhances such processing, e.g., the manager-is-blamed-for-bad-1st-order-probability-interpretation on p. 136 (did author express such explanations to subjects, MBA students who had been taught in decision theory?). The interpretations of the author in many places and in the theoretical model take 1st order probabilities as outcomes. Then the findings of this paper are simply explained as an overweighting of small second-order probabilities. %}

{% The Matthew effect means that young researchers who got grants approved early on, will also have more success later. If one can correct for quality of researchers and some other things, then does the effect remain, so that really the approval by itself has impact? How to correct for quality? The authors use a nice regression discontinuity design. In the Netherlands, applications are graded and all those passing a threshold are approved, those below aren't. Then, for applications just below the threshold and those just above, it is reasonable to assume that the researchers are of same quality and that the approval was random. So, here we control for quality and see if the approval in itself brings extra. The authors find that it does, where they investigate several other factors, and where it is often debatable to what extent those other factors are confounds to be corrected for or are not confounds but are the thing to be part of the Matthew effect and to be investigated. %}

{% They observe choices of contestants in an Italian tv show (it is deal or no deal) and find that logarithmic utility fits the data well both for small and large stakes. NonEU does not improve, and they suggest that they do not find Rabin's discrepancy. However, their stimuli set may not be well suited to detect violations of EU. Further, logarithmic utility gives extreme risk aversion if the status quo is incorporated and given utility $\ln(0) = -\infty$.

The biggest problem in this study is that at each stage the authors model the decision not to accept (so, to continue playing) simply as the probability distribution over the remaining sums of money. In reality, continuing is more attractive because later new information will be received and relatively better bank offers will come. Many studies of these shows have shown that the bank offers at the beginning are indeed relatively more unfavorable than later. Hence, the authors take subjects as more risk seeking than they really are, especially at the beginning of the show when the offers still concern relatively low amounts of money. A second problem is that subjects who face low offers have been unlucky so far and will be in a frame of mind of facing losses and wanting to make up (as losing gamblers in a casino do not take their losses but go for ruin), wanting to break even, and increasing their risk seeking (as found by Post et al. 2008). Because of this complication, I disagree with the authors' discussions of Rabin's paradox and do not think that they provided counterevidence.

Another problem, and this one the authors do signal and analyze, is that the bank offers constitute a complex game. But an extra complication here is that not so much the real bank strategy, but rather the subject's perception of it, is relevant. %}

{% **criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**: Criticizes separability of single states in Anscombe-Aumann framework. A similar criticism is in Wakker (2010 Section 10.7.3). Considers the Anscombe-

Aumann framework, but does not assume EU, or Anscombe-Aumann monotonicity, and only assumes monotonicity w.r.t. stochastic dominance; replacing, conditional on a horse, a lottery by a stochastically dominating lottery is preferred. Then, in the horse-state contingent model imposes the comonotonic sure-thing principle, giving the Green-Jullien-Chew-Wakker type representation there. Part of the analysis consists of replacing a horse-race contingent act by an equivalent objective lottery that has all cumulative events equivalent, in the spirit of cumulative dominance of Sarin & Wakker (1992). It can be considered to be a generalized version of matching probabilities. %}

Bommier, Antoine (2017) "A Dual Approach to Ambiguity Aversion," *Journal of Mathematical Economics* 71, 104–118. https://doi.org/10.1016/j.jmateco.2017.05.003

{% Consider Yaari's (1969) more risk averse than relation (worse certainty equivalents), but also generalizations with richer more-risky-than relations between prospects than only riskless-risky. Their theorems focus on when the distributions cross only once. They cCharacterize more-risk-averse than for various theories, including EU (called Kihlstrom-Mirman) and Quiggin's rank dependence (RDU). The Epstein-Zin model gives no clear results. In the general definition of RDU they assume general, nonlinear utility (Definition 1, u_2 there). But in the sufficiency proofs of Results 2 and 3, where convexity of w (they denote φ) is derived, they take utility linear. This may have come about as follows, as a colleague told me: The authors, in their appendix (but not in the main text) take the more-risk-averse than relation stronger than usually done. They let it imply not only same ordering of riskless outcomes, but also things like same additive representation up to AFFINE transformation, giving a sort of cardinal equivalence. Then being more risk averse than risk neutral, under RDU, automatically implies cardinally equivalent utility functions and, hence, linear utility under RDU. This is an inaccuracy in this paper.

P. 1617 takes vNM utility as additively separable not if it is a strictly increasing transform of an additively decomposable function, but only if it is that function itself.

P. 1616, as do many, cites Kihlstrom & Mirman (1974) on the strange claim that more risk averse comparison is possible only under the prior restriction of same ordering of riskless outcomes. Peters & Wakker (1987) show, to the contrary, … see my annotations of the K&M paper.

Many results are first presented for fifty-fifty lotteries (§3.2), e.g. regarding w(0.5) in RDU, and next for general lotteries (§3.3).

P. 1626 points out that we should acknowledge, rather than ignore by arbitrary choice, the problem that there is no unique definition of more-risk-averse-than, and then choose a definition of single crossing over of distribution functions ("simple spreads"). %}

Bommier, Antoine, Arnold Chassagnon, & François Le Grand (2012) "Comparative Risk Aversion: A Formal Approach with Applications to Saving Behavior," *Journal of Economic Theory* 147, 1614–1641.

{% They assume a group of experts reported their beliefs (mostly assumed additive probabilities) and decisions. They set up an ambiguity model where first the beliefs are aggregated, can be ambiguity-averse/pessimistic, and then an ambiguity model is used to derive decisions, for which they take Bommier's (2017) dual model. Of course, this procedure can violate the unanimity principle where one deviates from a *preference* unanimously held by all experts. %}

Bommier, Antoine, Adrien Fabre, Arnaud Goussebaïle, & Daniel Heyen (2021) "Disagreement Aversion," working paper.

{% Consider decisions with both risk and time involved, with infinite horizon. Study recursive preferences that satisfy monotonicity. Here monotonicity means that, given each state of nature, we have a preferred time profile. So, it first integrates over time and only then over uncertainty. They explain that this assumption is nontrivial because the underlying relation is, in my terminology, subjective (they use the term "not totally ordered") (**restrictiveness of monotonicity/weak separability**), and in Footnote 7, p. 1438, points out that monotonicity in Anscombe-Aumann is similarly nontrivial. (**criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**) I favor the term separability for such conditions instead of monotonicity. They also write that it comprises nontrivial separability. Epstein-Zin preferences are not included. They characterize some functional forms that specify their conditions, where Chew & Epstein 1990 papers are important.

P. 1437: stationarity and the slightly weaker history independence are considered. %}

{% A thorough measurement of 1992 prospect theory (PT). They use the simple pragmatic measurement of Tanaka, Camerer, & Nguyen (2010). In the baseline (Glo: gains low) treatment three choice lists (the authors call them series) are measured, two with only gains and one with mixed prospect. In the Ghi treatment all outcomes are multiplied by 2. In the Llo (loss low) treatment the outcomes of Glo are multiplied by −1, and in the Lhi treatment the outcomes of Glo are multiplied by −2. The authors then do parametric fitting where they fit the most common parametric families, with logpower (CRRA) utility with different parameters for gains than losses, Prelec's two-parameter family with different parameters for gains than for losses, and λ denoting loss aversion. The authors implemented for real, for every subject, one Gain choice and one Loss choice. Although in practice it does not matter if we implement one or two choices, I regret that the incentive compatibility is theoretically lost. P. 598: they do not pay directly in money, but in experimental points, each worth half a cent.

losses from prior endowment mechanism: They do it.

The main findings are: Result 1. The usual findings of PT, with the fourfold pattern, utility concave for gains and convex (but some closer to linear by Result 2) for losses, are confirmed.

Result 3: no effect of doubling stakes, suggesting constant relative risk aversion (**decreasing ARA/increasing RRA**) although only measured for one doubling of stakes only and probably only a H_0.

Further Result: loss aversion is very volatile, depending much on treatment and parametric assumptions made.

The authors seem to find inverse S probability weighting, but write little about it.

They do report no difference between probability weighting for gains and for losses.

reflection at individual level for risk: they have the data but do not report much on it. Suggest a bit to confirm it in that most subjects have both concave utility for gains and convex utility for losses. %}

{% This paper is based on a good and new intuition, but the modeling is problematic. There is a fundamental problem: the model is essentially intransitive (similarly as regret theory is), making it unsuited for virtually all applications in economics and finance. There is also a theoretical problem that needs further fixing: The model as written is too general with too many parameters. Before discussing more, here is the basic idea of the model.

====================

BASIC IDEA

(1) Assume states of nature that have objective probabilities (as with regret theory, although the latter also allows for subjective probabilities);

(2) consider only binary choices between two prospects, say x,y;

(3) let x and y have outcomes x_i and y_i for state s_i, and define the salience function $\sigma(x_i,y_i)$, specifying how salient state s_i is due to the outcome difference. σ is independent of i. "Ordering": it is increasing in the max of $\{x_i, y_i\}$ and decreasing in the min, like, for instance, the difference $|x_i-y_i|$.

(4) Transform decision weights of states in a somewhat complex way: Rank states by their salience value from largest (rank nr. $r_i = 1$) to smallest (rank nr. equal to nr. of states/outomes), so that each state s_i has a salience rank number r_i. So, salience is only used ordinally. Then adjust odds of all state pairs (s_i,s_j) by a factor $\delta^{(ri-rj)}$ where $0 < \delta \le 1$.

Classical EU results from $\delta = 1$ with no overweightings, and the smaller δ the more sensitivity to salience. (The formula is sound in the sense that readjusting the odds of s_i and s_j, and then of s_j and s_k, gives the right adjustment of s_i and s_k. Getting this soundness in is nontrivial. It is reminiscent of Birnbaum's RAM and

TAX models, where probability weights are moved from some states to others as terms.) In this way we can overweigh the salient states. There is a cealing effect in the sense that small probabilities are more overweighted than large ones can be. (This could hardly be otherwise numerically; here a weighting of goodnews probabilities, as in rank dependence, would be worthwhile.) Note that this ranking part is independent of the probability of the state, which will generate discontinuities under convergence to null. There will also be discontinuities of outcomes pass some levels. The authors mention the latter discontinuity on p. 1255. This part also brings in interactions between different states, not precluded by the sure-thing principle, which is not very restrictive in the absence of transitivity. This part is a new part of the theory, distinguishing it from regret theory by having more interactions between states. However, the authors are not strong on this aspect, appearing from their p. 1255, discussed more below.

(5) There is a reference point, and salience becomes less as outcomes, in absolute sense, move farther away from the reference point. The paper therefore favors, in examples, not using the difference $x_i–y_i$, but rather $\sigma(x_i,y_i) = |x_i - y_i|/(|x_i| + |y_i|)$, to assess salience. For doing this, the reference point is crucial.

=====================

THE GOOD INTUITION

As regards the good intuition of salience theory, prospect theory assumes that the state (of nature ≈ event) generating the largest outcome, and the state generating the lowest outcome, are overweighted; they are salient. It is just as plausible that, when comparing two prospects, the state with the largest DIFFERENCE in outcomes (or a transformation of difference) is salient and gets extra weight. The idea that people directly compare outcomes of a prospect to outcomes of the competing prospect before any aggregation of the prospect's value is not new (regret theory has it too, and other theories have it also; it is the basis of the tradeoff concept that I used in many papers). To let this lead to overweighting of large differences is not new either (regret theory has this too, again, and it is central in regret theory). But to model these things through state weighting rather than through utility is new. It makes salience theory an interesting counterpart to regret theory. Salience theory modifies prospect theory as regret theory modified expected utility. Modeling the extra weighting through event weights, as salience theory does, seems more natural to me than modeling it through outcomes and utility as regret theory does. Hence, salience theory can turn into an improved version of regret theory.

Moderating this pro: It is also plausible that people sometimes UNDERweight states with big differences, in something like diminishing sensitivity with respect to difference. If one prospect yields €1 more in 5 states, and €5 less in one state, then being better five out of six times may decide. Similarly, later studies in regret theory found no clear empirical evidence for its original hypotheses of overweighting of big differences. Salience theory can easily accommodate these things by allowing their δ to exceed 1, and I recommend using this generalization.

FIRST PROBLEM (INTRANSITIVITY)

The essence of transitivity is that each prospect is evaluated on its own, independently of the other prospects it is competing with. To wit, skipping minor technicalities, if transitivity holds, then there exists a function V such that, for all prospects x,y, we have $x > y$ if and only if $V(x) > V(y)$. It means that when evaluating x by V(x), we do not even look at its competitor y. This excludes anything like salience. The essence of salience theory (and the above good intuition) is that the evaluation of a prospect does depend on the one it is competing with (only binary choice is treated). Here salience theory is like regret theory. The essence of salience is violating transitivity, and it doesn't bring any novelty outside intransitivity. Problem 1a: Intransitivity entails irrationality at a basic level. For most work in economics and finance such irrationalities are of no interest. Salience theory can, therefore, only be of use in psychologically oriented applications, such as understanding behavior of subjects in labs, and in marketing for instance where such irrationalities are also important. Problem1b: Intransitive models are intractable. It is not clear how to choose from more than two prospects (the web appendix has suggestions but their dependence on whole choice set is too general to be tractable). It even is not clear how to define optimality. Thus, quantitative assessments are hard to imagine, as it is with regret theory. For these reasons, regret theory hasn't been used in quantitative applications, and with salience theory it will be the same. The only paper that measured regret theory quantitatively is Bleichrodt, Cillo, & Diecidue (2010

Management Science), using my tradeoff technique (☺), and this may also work for measuring the salience function.

SECOND PROBLEM

To explain the second problem, expected utility has one one-variate function, utility of money, as parameter. Prospect theory has two such one-variate functions, with probability weighting in addition (and one more number, loss aversion; I assume the reference point fixed, here as with salience theory). Salience theory has a two-variable function, the salience $\sigma(x,y)$ as function. This is much larger generality, and it is something like infinitely many univariate functions. (There is also one more number, being δ; I assume loss aversion is also good to add). This is way too general. Good subfamilies with fewer parameters will have to be developed. Eq. 5, p. 1250, gives a tractable subfamily, but it will take more to prove its value. Regret theory faced the same problem, with two-variable $U(x_i,x_j)$ too general. They quickly went for the special case $\varphi\big((U(x_i)–U(x_j)\big)$ with φ a nonlinear univariate function. Salience theory may go for $\varphi(|x_i–x_j|/(|x_i|+|x_j|)$, similar to their Eq. 5 (p. 1250).

Related to the second problem, there is no preference foundation (properly mentioned as an open problem on p. 1259 end of §III), and no verification of natural conditions such as continuity (will fail for probabilities tending to 0 for instance) or some kinds of monotonicity with respect to outcomes; or, for that matter, transitivity is violated. The editing operations generate discontinuities and suggest other anomalies. There also is no way to measure/calibrate the functions, as in describe-predict. It is not discussed if they are at all identifiable. There are no quantitative assessments, which I think will be very hard at the present stage, and there are hardly ways to falsify the general theory (mostly the sure-thing principle is; see below). The theory does add some qualitative assumptions, and all tests and predictions concern those qualitative assumptions rather than the theory itself. Similarly, a test of risk aversion is not a test of the expected utility model. On the positive side, the two qualitative assumptions are plausible and they well predict right directions in the many examples chosen. It is obvious that the theory captures something substantive.

Because of its many parameters, salience theory can accommodate almost everything, and the paper gives many examples, but it is almost impossible to falsify the theory. This second problem, concerning the theoretical problems, can be fixed if specific subfamilies are developed, and possibly some changes are made to the decision model itself.

The only clearly restictive (so, falsifiable, which is desirable) implication that I see (explained on pp. 1259 and 1267 for instance) is the sure-thing principle: States with the same outcome for both prospect have 0 salience and can be ignored, so that it does not matter if the common outcome is changed there. I add here that the sure-thing principle is not very restrictive under intransitivity. Under transitivity it amounts to completely excluding interactions between disjoint events, but here it need not. Tradeoffs between two states can be affected by a third state, which can interfere via the salience rankings I guess.

DETAILS

- Throughout, the authors do not make sufficiently clear, and do not sufficiently realize, that the essence of their theory lies in violating transitivity. They mention intransitivities once casually (p. 1246 ℓ. −4). Near the bottom of p. 1259 they claim a positive result on transitivity on a subdomain (meaning their theory does not bring anything new there!). And at the bottom of p. 1273 they criticize intransitivity of regret theory.

- The editing of the paper is not very good. Footnote 10 (p. 1255), referring to empirical measurements of probability weighting, an active field during the last two decades, cites only one 1996 paper, (nonincentivized and) 16 years old at the time of appearance of this salience paper (2012), and calls it “recent.” Pp. 1257-1258 out of the blue discuss contexts with apparently more than two choice options (whereas the paper restricts to binary choices), with vague claims and a vague consideration set (can be bigger than the choice set, but also smaller …). The idea about prospects that are permutations of each other at the bottom of p. 1257 is vague and ad hoc. (One problem: It matters much which of the permutations is randomly kept, because the correlation with other prospects matters.) When referring to “Both forms of editing” the paper means, besides the permutation idea, also the removal of dominated prospects.

- The paper does not use the terms risk seeking (and risk aversion) in the usual way, but risk seeking means choosing the riskier of two prospects. For example, a preference $100_{0.9}0 \succ 50$ is called risk seeking.

- I regret that the authors throughout use original 1979 prospect theory, and not the corrected 1992 version (e.g., footnote 2 on p. 1248 does not help).

- The differences with regret theory listed on p. 1259 1st para are not important: Adding framing, reference dependence, and reflection in the definition of regret theory can trivially be done; the non-trivial parts of these moves, maintaining tractability, is not done by salience theory either. Salience theory is a weighting-counterpart of utility-regret theory. But providing such a counterpart is interesting enough! However, the authors do not have a strong opinion on this counterpart-point at all. P. 1255, in passing by, mentions a "continuous" variation of the theory. Here odds are adjusted simply by multiplying the weight of a state s_i by a function $f(\sigma(x_i,y_i))$. One can then renormalize but, given that the preference functional is unique up to multiplication by any positive function g(x,y) that can entirely depend on gambles x and y (only its sign matters), this is not important. Anyway, then salience theory is simply a special case of generalized regret theory:

$$\sum_{j=1}^{n} V(x_i,y_i).$$

It seems that in 2021 most authors take salience theory in this manner, which I would call regret theory rather than salience theory. See Herweg & Müller (2021) and Herweg & Müller (2021). Pfff! Such is marketing in research. Then there is an ocean of theoretical work by Fishburn and Karl Vind on it. Then there is no novelty in salience theory!

P. 1259 2nd para is neither to the point. First, ordering and diminishing sensitivity do not make strong predictions, being only qualitative (although still good in their kind). Second, regret theory and the SSB theories by Fishburn (1982) also satisfy the sure-thing principle (although Fishburn 1982 concerns decision under risk and the analog there is bilinearity; other papers by him are directly for uncertainty and directly have the sure-thing principle there). As an aside, Vind (2003) provides advanced mathematics on intransitive preferences, where the sure-thing principle can still be satisfied. Third, the transitivity and dominance for independent prospects, suggested as a positive result, in fact means that salience theory has nothing new to offer there.

P. 1264: The violation of prospect theory is not tight: The common view is that utility (value) becomes less concave as stakes increase, and then risk aversion may turn into risk seeking (risk seeking by w may start to dominate the concavity of utility for high stakes). The footnote ater only claims that the common calibrations of prospect theory do not accommodate, which is a weaker criticism. The more so as no common calibration of salience theory is available yet.

P. 1267 ff. put forward as defense of salience theory, that the predicted sure-thing principle holds in framing that make the common consequence event clear. This is indeed a positive argument. It is weakened though because several people have argued that such independence of common consequence may reflect a heuristic that subjects use to simplify their task, rather than their preference. (This also weakens the, still positive, argument discussed on p. 1270, regarding what Kahneman & Tversky (1979) called the pseudo-certainty effect (term not used in this paper).) Important: A psychological effect such as salience perception will not be restricted within a state but it will be global, generating violations of the sure-thing principle.

P. 1276 claims as positive point that salience theory can explain the fourfold pattern while assuming linear utility, whereas prospect theory supposedly could not do this. This is incorrect. Prospect theory also predicts the fourfold pattern if utility is linear, where it then is generated by probability weighting. P. 1278 incorrectly writes: "In prospect theory, the main driver of risk attitudes is the curvature of the value function." In PT, probability weighting is also a big driver or risk attitude (and also loss aversion, taking this "kink" not to be part of utility curvature).

The authors throughout use the term local thinker to refer to an agent behaving according to their theory. I guess local means missing things. In this way everything can be called local. The prospect theory probability weighting function means that people pay too much attention to small probabilities and too little to large probabilities. So, they are missing the importance of large probabilities. Why not call this local?

CONCLUSION. Positive: The basic intuition, that states with large *differences* of outcomes are overweighted, is good. Modeling it through event weighting is good and more natural than regret theory's modeling through outcome utility. The qualitative assumptions of ordering and diminishing sensitivity work well to accommodate many findings. Negative: Biggest restriction is that intransitivity is the essence of the theory, limiting usefulness for economics and finance, and not well realized or presented by the authors. A problem that may be fixed (further work and creativity needed here) is that the model as is, especially with the bivariate salience function, is too general. There are no preference conditions to suggest that the model chosen is natural, and several aspects of it are not. Another problem is that the authors do not compare well with regret theory and prospect theory. Different fields should be able to exchange inputs and, therefore, this is not a serious problem. %}

{% Show that salience theory can accommodate may phenomena. Problem is that salience can accommodate too many phenomena. Again there is no discussion of the violations of transitivity. The conclusion compares with probability weighting of prospect theory and, incorrectly, claims that the overweighting of small probabilities would imply that risk aversion would increase in good times and decrease in bad times. Here is the sentence with the mistake: "In a recession, when the objective probability of left-tail payoffs increases, standard probability weighting would imply that the low payoff will be less overweighted than before." If the probability increases from 0 (or something very small) to ε, the overweighting will INCREASE. Another problem for the authors, also underlying the preceding reasoning, can be inferred from the sentence in the conclusion where they try to separate salience theory from prospect theory: "In our model, extreme payoffs are overweighted not because they have small probabilities but because they are salient relative to the market payoff." Here one sees, as in the other papers by the authors, being that they go by the outdated and incorrect 1979 version of prospect theory, and not by the updated and corrected version of 1992. In the latter, not the small probability of an outcome makes it being overweighted, but the extremity of being best or worst. Which is as close to salience as one can get without giving up transitivity. %}

{% A nicer result is in Kim (1996). (So, there Kim is not first name but family name). I assume that the reader red my annotations there, such as on Border’s nice discussion of observability. Border considers the special case where the outcome set is a compact subset of $\mathbb{R}$, such as a bounded closed interval. As often, the more general the result (such as Kim’s), the nicer and more accessible. Border has the special case where we can have stochastic dominance, and “misuses” it to state the preference condition involving stochastic dominance. His condition now varies on Kim’s by requiring that the probabilistic mixture $\sum_{j=1}^{n} \lambda_j Q^j$ should not stochastically dominate $\sum_{j=1}^{n} \lambda_j P^j$. This is more complex than Kim’s condition. It is also more restrictive, because one can always add some stochastic-dominance preferences to Border’s condition to turn it into Kim’s condition.

Border, in turn, is mathematically very close to Fishburn (1975, Theorem 3), but makes it quite nicer, by reinterpreting Fishburn’s duality weights as prior mixing conditions. See my annotations to Kim (1996) for those interpretations.

Border extends Fishburn’s Theorem 3, in Border’s main Theorem 2.4, to general, possibly infinite, sets of preferences, by adding continuity conditions, such as the set of outcomes being a compact subset of the reals, being money. Late, only on p. 31 para -3, Border writes that Fishburn (1975) [5] is closests. This is important for novelty and would better have been stated in the intro.

A nice sentence is on p. 30: “One way to view my results is that they describe when this partial ordering has an extension to a continuous total ordering which satisfies the independence axiom.” (**desirable to extend preferences while satisfying/maintaining conditions**:) %}

{% **Ambiguity = amb.av = source.pref, ignoring insensitivity**: this paper does it (Definition 1), but in the maxmin EU model, where it is this way because of the restrictive nature of maxmin EU. Definition 1 defines as unambiguous events that have source preference over all other events. This holds iff al priors assign the

same probability to the event. Priors should be finitely additive and need not be countably additive.

The paper works with Savage-type richness in the sense that every element of the set of priors is convex-ranged (what is sometimes called atomless). Theorem 1 axiomatizes maxmin EU with this as only restriction. Very nice! A similarly nice derivation but with richness of outcomes is in Alon (2022), not cited here.

Key in this paper is a division of an ambiguous event A into two equally likely events $A \cap E$ and $A \cap E^c$ where E is unambiguous, so that E serves as an independent randomization device reminiscent of the Anscombe-Aumann framework. This follows if E is unambiguous and $A \cap E$ and $A \cap E^c$ are exchangeable in the sense that

$$E^c = (A \cap E^c) \cup (A^c \cap E^c) \sim (A \cap E) \cup (A^c \cap E^c).$$

In any multiple priors model, this readily implies that $P(A \cap E) = P(A \cap E^c)$ for all priors P. If such a thing is possible for each event, then it becomes possible to define endogenous fifty-fifty mixtures of acts f and h, denoted g. Take any event $A = \{s: f = \alpha \text{ and } h = \gamma)$, divide it into two halves as above, and let g take value α on one half and value γ on the other. Axiom 9 assumes that such is possible for each act. That this can be done if the case is isomorphic to Anscombe-Aumann is easy to see. But the surprising (to- me) thing is that this is always possible if all priors in the set of priors are convex-ranged (Axiom 9). The derivation is, I assume, in the spirit of Liapunov (1940). To illustrate, assume that P and Q are defined on [0,1), $P([0,1/2)) = 1/3$, $P([1/2,1)) = 2/3$, but $Q([0,1/2)) = 2/3$, $P([1/2,1)) = 1/3$, and both P and Q are uniform on [0,1/2) and [1/2,1). Then we can divide the event A = [0,1) into two halves as $[0,1/4) \cup [1/2, 2/4)$ and $[1/4,1/2) \cup [3/4,1)$, which both have probability 0.5 under both P and Q. Similar things can always be done, apparently, for any set of priors, even if infinite, that are all convex-ranged, and even if only finitely additive. This is all somewhat reminiscent of Machina (2004), who showed that in a rich-enough Savagean statespace one can always specify events with objective probabilities, although he heavily uses differentiability in the statespace.

Important axioms are:

Axiom 2.1 [unambiguous sure-thing principle]: consider f_A (act f restricted to event A) and f'_A to be unambiguous if f_Ax and f'_Ax are unambiguous for some

outcome x (my interpretation). Then we have $f_Ag \succcurlyeq f_Ag' \Leftrightarrow f'_Ag \succcurlyeq f'_Ag'$\
Axiom 2.2 [homotheticity]: If, for unambiguous events E,F and outcome x, f_Ex is subjective midpoint of act f and outcome x and g_Fx is subjective midpoint of act g and outcome x, then $f \succcurlyeq g \Leftrightarrow f_Ex \succcurlyeq g_Fx$.
Axiom 3 [Mixture monotonicity] I did not try to understand.
Axiom 4 (Savage's P4)
Axiom 6 [Ambiguity Aversion] $f_Ag \sim f_Ag' \Rightarrow f'_Ag \succcurlyeq f'_Ag'$ whenever f_Ag' is unambiguous. Further, if ~ is replaced by ≻ then there is ≻ in the conclusion. The axiom says that turning part of an unambiguous act into ambiguous always does more harm there than the same turning in an ambiguous act. The idea is that interactions in the ambiguous act can bring desirable hedging, which will not happen in the unambiguous act.
Axioms 8 and 9 are the only ones not necessary for maxmin EU: Axiom 8 is unambiguous solvability and Axiom 9 is discussed above.

P. 2 end of 2nd para is naïve in claiming that in medical decisions one faces only a few deterministic consequences.

Many motivations in this paper agree with my opinions. For instance, p 2 top indicates that ambiguity aversion can be different than probabilistic mixture preference. (I called equating the two a historical mistake in my 2010 book.) A drawback of the axioms in this paper is that it heavily uses the endogenous midpoint operation in its axioms, where that operation is not directly a (preference) primitive but a derived concept (**derived concepts in pref. axioms**). But the author is aware of it and discusses it p. 4 penultimate para. I did a similar thing in my youth when used derived tradeoffs, but always verified that the rewritings directly in terms of preferences were not complex, as appears from its use in many experiments. See the keyword **tradeoff method**.
A difference in motivation: the paper takes unambiguous endogenous whereas I prefer it exogenous.

Section 4 presents comparative ambiguity aversion but, as common in the field, uses the Yaari-type certainty-equivalent condition (extended to subjectively unambiguous acts) that only works if everything else than the thing to be compared is identical. Here, the utility functions must be the same. Given that, we get the Yaari-type condition if and only if one set of priors is contained in the other. Which still is a thin ordering leaving most things incomparable. %}

{% **risk seeking for symmetric fifty-fifty gambles**: they don't have fifty-fifty gambles, but do find risk seeking for small amounts.

PT falsified.

Consider gains and losses, and probabilites 0.20 and 0.80 of getting the gain or loss.

Compare $\$80_{0.2}\$0$ and $-\$80_{0.2}\$0$). Can be done in two steps: Step 1, translation by subtracting \$80, so that $\$80_{0.2}\$0$ is changed into $\$0_{0.2}{-}\$80$. Step 2, switching good- and bad-outcome probability, so that $\$0_{0.2}{-}\$80$ is changed into $\$0_{0.8}{-}\$80$.

They find that translation from gains to losses always increases risk seeking, both for high-probability and for low-probability for best outcome. They find that switching probability of bad outcome from 0.2 to 0.8 always increases risk seeking, both for gains and for losses.

Testing reflection for high-probability nonzero has translation and switch go in same direction, enhancing risk seeking for losses. Testing reflection for low-probability nonzero has translation and swiches go in opposite directions. In prospect theory, probability weighting and utility curvature have opposite effects for small-probability-nonzero-outcomes, although they both support the reflection effect because they both switch from gains to losses.

Also consider seven different stakes. People are risk averse for high stakes and risk seeking for small, for high and low probabilities and for gains and losses (**probability weighting depends on outcomes**). Maybe some **utility of gambling** generating the risk seeking for small amounts!? So that we may want to avoid small-amount prospects, considering this just a bias? %}

{% **ambiguity seeking for unlikely & ambiguity seeking for losses**: They find both.

$N = 157$ subjects from Ethiopia, students from Addis Ababa University. Measure certainty equivalents (CEs) for binary prospects, both risky and Ellsberg ambiguous, using choice lists, for all probabilities j/8. Incentives like weekly income. For gains and losses (**losses from prior endowment mechanism**). First risky gains, then ambiguous gains, then risky losses, then ambiguous losses. The authors prefer order effects to the cognitive difficulties for subjects if losses precede gains.

The authors find the best fit for

CE/X = c + s $\times$ EV/X

with X the maximum amount of the prospect and EV being expected value. With $c > 0$ and $0 < s \leq c$ this means that for small EV/X, so, small probabilities, CE > EV with risk/uncertainty seeking, and for large EV/X risk/uncertainty aversion. This measure relates to proportional risk/uncertainty aversion. Then from c and s they derive sensitivity (through s) and optimism (through $c + s/2$) the usual way. This agrees with measures in Abdellaoui et al. (2011 AER) for weighting functions under linear utility, as the authors point out in footnote 2 (version of March 29 2012). Concave utility will push c and s down for big gains as opposed to small gains. It is not clear to what extent the findings concern utility or probability weighting and, hence, it does not directly speak to: **probability weighting depends on outcomes**.

The paper, unusually, finds prevailing risk seeking, and no prevailing uncertainty aversion. It finds that increasing (doubling, between-subjects) stakes increases ambiguity seeking for small-probability gains and large-probability losses, and more ambiguity averse for large-probability gains and small-probability losses. That is, a-insensitivity is increased. The text suggests that for gains mostly uncertainty aversion for high probabilities is increased.

reflection at individual level for risk: The authors consider it, but it is hard to interpret with prevailing risk seeking for gains. The authors also consider it for ambiguity and losses, and many correlations between the various variables.

decreasing ARA/increasing RRA: the authors study relative risk aversion, and find that it increases, rather than decreases, with stakes, over the whole probability range. %}

Bouchouicha, Ranoua, Peter Martinsson, Haileselassie Medhin, & Ferdinand M. Vieider (2017) "Stake Effects on Ambiguity Attitudes for Gains and Losses," *Theory and Decision* 83, 19–35.

{% Comments on Dec. 2024 version.

This paper compares choice lists, where *binary choices* are grouped together in a way to make them transparent to subjects, with binary choices that are not grouped together. A preceding paper on this difference, not cited here, is Bostic, Herrnstein, & Luce (1990). The authors call the first form of binary choice evaluation, and the second form choice, and this termonology is central in their marketing. However, it is misleading because what they call evaluation is as much binary choice as what they call choice. The former could better be called transparent choice and the latter complex choice. Thus, Tversky & Kahneman (1992, p. 306), who used what I call transparent choice, wrote:

"We wish to emphasize that although the analysis is based on certainty equivalents, the data consisted of a series of choices between a given prospect and several sure outcomes. Thus, the cash equivalent of a prospect was derived from observed choices rather than assessed by the subject. The computer monitored the internal consistency."

The authors do what many authors do: target their arrows solely to prospect theory, especially inverse-S probability weighting. However, the discrepancy between transparent choice and complex choice that they find rejects every deterministic choice model satisfying basic properties such as transitivity. Every economic and decision-analysis model assumes the latter. One can't do economics or decision analysis anymore then. Their finding is of the same fundamental kind as preference reversals from the 1980s, with differences between choice and matching. The term evaluation (versus choice) fits better with matching than with the choice lists of this paper.

Now to probability weighting. Although findings on loss aversion are the strongest for risk attitudes, they are also most volatile. Findings on probability weighting are not weaker, but they are more volatile, then findings on utility curvature. In general, the overweighing of small probabilities is less strong than TK92 suggested. As for volatility, several studies found a majority UNDER, rather than overweighting of small probabilities, without clear explanation for why. One such was a paper by van de Kuilen and me (2011 MS). Kahneman and Tversky pointed out that for small probabilities there are many irregularities with also underweighting, so much that Kahneman & Tversky (1979) left it unspecified.

The authors propose Vieider's (2024) Bayesian inference model (BIM) model for better fitting the data. However, his model does not separate a deterministic and probabilistic part but has them joint, implying, again, that it cannot be used in usual economics or management science models. See my annotations to the Vieider paper. There are other models that better describe and predict than prospect theory, such as Birnbaum's RAM and TAX, and Erev's BEAST, but they share the drawback with Vieider's BIM model that they cannot be used in economics or management science.

What the authors call evaluation but I call transparent choice is more popular these days because it gives less noise. Therefore, its support for inverse-S probability weighting is more convincing than the, apparently deviating, findings of the authors' complex choice. Could it be that on the latter they only found H_0? For what they really do, showing fundamental problems, they seem to do a thorough job, especially with the meta analysis. %}

Bouchouicha, Ranoua, Ryan Oprea, Ferdinand M. Vieider, & Jilong Wu (2024) "Is Prospect Theory Really a Theory of Choice?" working paper of Dec. 2024.

{% Find risk seeking for small outcomes but risk aversion for large ones. A generalized logarithmic utility (ln (x + a)) fits better than the common log-power or linear-exponential. The authors use hypothetical choices for losses and so as to examine real large stakes. They also find some violations of separability of probability weighting versus utility of outcome. (**PT falsified; probability weighting depends on outcomes**).

decreasing ARA/increasing RRA: they find increasing relative risk aversion!

{% Useful for me as decision theorist working on ambiguity to learn about the ideas of the imprecise probability (IP) community.

This paper is written in the spirit of multiple priors. This is popular in the IP community, although also other approaches are considered. First, it assumes a true existing but unknown objective probability, which I find a problematic concept the moment one leaves Ellsberg's urn and goes to natural events. Second, it assumes that we don't know exactly what that true probability is, but we do know an exact set that contains that true probability, which again is ad hoc to me. It sometimes seems to me that many people working on ambiguity can only think this way.

The intro lists many fields where IPs are used. It assumes linear utility for risk, and "indifference" to risk, which means expected utility and even expected value for risk. §1.2 states that the main interest of this paper is normative. The section distinguishes between imprecision due to absent info or due to imperfect processing of info. To me this distinction can sometimes be useful but is not very fundamental.

§2.2: indifference ties will be broken by very small extra payments, but incompleteness ties will not.

Important: End of §2.3 cites the nice Skyrms (2011) and Leitgeb (2014) who seem to use the terms resilience and stability, respectively, to indicate that Keynes' weight of evidence (vs. balance of evidence) should play no role in static decisions, but only in updating, which surely is my opinion.

End of §2.7: Set of priors is set of all probability measures consistent with your evidence. It was called the credal committee by Joyce (2011). This is an informational basis for the set of priors, and not a decision-basis. I as critic if multiple priors argue that it usually is not the black/white consistent/inconsistent, but it is gradual more/less plausible.

§3.1 has the nice topic of dilation. Unfortunately, the example regarding Figure 1 is not well explained. In the 3rd para ("Let's imagine …") it is not explained what is written if coins lands up (from context: then a lie is written), and the difference between H being true or H being written is also something to keep in mind. Here is a simpler example of dilation, although not with conditioning involved.

MY EXAMPLE OF DILATION; BEGINNING

Imagine an Ellsberg two-color urn containing 100 numbered balls, each red (R) or black (B). There are 50R and 50B, as follows. Of the odd-numbered balls, (50+ε)% are R and of the even numbered balls, (50−ε)% are R. Here ε is unknown but can be anything between −50 or 50. So, ε can as well be positive as negative. P(R) from the whole urn is a known probability and is 0.5. But if we get informed about whether the number of the ball drawn is odd or even, then it is ambiguity. Extra info changes risk into ambiguity (without making things more favorable or unfavorable under Bayesian ambiguity neutrality).

MY EXAMPLE OF DILATION; END

Here is Bradley's example, if I understand it right. Imagine the following probabilities:

	H	−H
X	¼+ε	¼+ε
−X	¼−ε	¼−ε

where ε is unknown, say if may as well be +1/10 as −1/10. Then P(H) = P(−H) = ½. Y = (X&H) or (−X & −H). P(Y) = ½. Conditioning on X does not affect P(H), but if we first condition on Y, then conditioning on X turns H into ambiguous. This is complex.

In general statistics, dilation seems to mean that the posterior distribution is wider than the prior one. A good illustration that risk need not reflect more info than ambiguity.

End of §3.1 (on dilation) writes: "We cannot take narrowness of the interval [lower probability, higher probability] as a characterisation of weight of evidence since the interval can be narrow for reasons other than because lots of evidence has been accumulated."

Section 3.5: Lindley (1996) and others have argued that we can neither know the set of priors exactly. This section considers if we should then consider sets of sets of priors. It argues for not doing so for pragmatic reasons, because things then get too complex. Using sets of priors nicely captures some aspects of ambiguity/IP and Bradley is satisfied with that. He writes, 1st para of §3.5: "For the functionalist interpretation suggested above, this is something of a pragmatic choice. The further we allow this regress to continue, the harder it is to deal with these belief-representing objects. So let's not go further than we need." I think this deprives the approach of any normative force. He doesn't say: "if there is ambiguity then one should use sets of priors." He says, in my words: "We use multiple priors only when it pleases us." %}

{% The priority heuristic works as follows: for gains:

(1) Compare worst outcomes. If their difference is more than 1/10 times the best outcome, go for best worst outcome. (So, no probabilities inspected apart from them being nonzero. Ratio-scale structure.)

(2) If (1) did not decide, consider probabilities of worst outcomes. If they differ by more than 1/10, go for minimal probability.

(3) If (2) did not decide either, consider best outcomes. For two-outcome prospects, now the best outcome decides (by point (2) their probabilities do not differ by much). For three- or more outcome prospects, if the difference of the best outcomes is more than 1/10 times the best outcome, go by the best one here.

(4) If (3) did not work (then prospects have more than two outcomes), if probabilities of best outcomes differ by more than 1/10, go by them.

(5) If not (4), then I guess indecision.

For losses things are reflected. So, we start with inspecting the best losses, and so on.

There is only one example with mixed prospect, suggesting a bit that then the treatment is as with gains and with signs ignored, but it is not clear to me. %}

{% **utility depends on probability**

inverse S: Confirm it. In exp. 3 elicited certainty equivalents for some gambles (hypothetical only) using ping-pong à la Tversky & Fox (1995), only for one nonzero outcome. Assume that utility is $x^{0.88}$ and then find inverse S w confirmed. Do not say whether or not they used real incentives.

They propose that inverse S, overweighting of extreme outcomes, may be due to the surprise (elation if positive, disappointment if negative) that you feel about them if they are unlikely, and the extra utility or disutility that that surprise gives. So, utility depends on probabilities. They ask people how surprised they feel if some low-probability outcome occurs, and like that grade the degree of surprise. Propose a formula that derives inverse S from the degree of surprise (**inverse S (= likelihood insensitivity) related to emotions;**

cognitive ability related to risk/ambiguity aversion): They don't link data on surprise to data on probability weighting. They don't consider whether subjects with more surprise have more extreme inverse S. The basic idea, that inverse S is not through probability-perception per se, but through utility, is interesting. %}

{% %}

Bréban, Laurie & André Lapidus (2019) "Adam Smith on Lotteries: An Interpretation and Formal Restatement," *European Journal of the History of Economic Thought* 26, 157–197.

{% This paper shows that in the financial market one can obtain any indicator function for any event and, thus, and simple event-contingent payment. That is, one can get an essentially complete Savagean act-space. The authors refer to it as the time-state preference approach by Arrow (1964) and Debreu (1959). %}

Breeden, Douglas T. & Robert H. Litzenberger (1978) "Prices of State-Contingent Claims Implicit in Option Prices," *Journal of Business* 51, 621–651.

{% The authors let subjects choose twice from budget sets of lotteries with one nonzero outcome: subjects can choose $0 \le x \le M$ and then receive the lottery

x_p0 $\big(= (p{:}x, 1{-}p{:}0)\big)$ with $x + pM/m = M$.

That is, they choose a lottery from the line between (M_00) and (0_m0), being $(1-\lambda)M_{\lambda m}0$ for a $0 \le \lambda \le 1$. I must admit that even I as expected value maximizer with math degree specialized in probability theory and linear optimization, need time to know what to choose ($\lambda = 0.5$; with thanks to Nash bargaining solution). Next subjects get the chance to reconsider their choices.

P. 228: "We propose and carry out a methodology to study mistakes, which we define as deviations from the decision maker's true preferences. Specifically, we argue that if a choice is revised *without any new information or change in circumstances*, then either the initial choice or the revision is revealed to be a mistake." [italics from original]

That is, whenever a subject revises a choice, the authors assume that the first choice was a mistake and was not a "true" preference. Modifying a choice from a budget set is more readily done than revising a binary choice. Indeed, 75% of initial choices were revised.

§6.2: Subjects revised choices better satisfy normative principles such as stochastic dominance, and can better be fitted with standard models. Further, choices made early on in the first stage are more likely to be revised in the reconciliation stage than choices made later on in the first stage.

Subjects are more revisions for low-probability prizes, suggesting that these are more difficult to process. %}

Breig, Zachary & Paul Feldman (2024) "Revealing Risky Mistakes through Revisions," *Journal of Risk and Uncertainty* 68, 227–254. https://doi.org/10.1007/s11166-024-09429-3

{% Argues for the use of machine-learing techniques to replace many statistical modeling techniques. The author first did research, then consultancy, and then went back to research. For predictions from large data sets machine learning works better than statistical modeling techniques.

P. 202 §5 1st para, on data models: "This enterprise has at its heart the belief that a statistician, by imagination and by looking at the data, can invent a reasonably good parametric class of models for a complex mechanism devised by nature."

P. 204: The author several times points out that statisticians uncritically start from some common modeling assumption, e.g. multivariate normal distribution of regressions, which will usually not hold: "Nobody really believes that multivariate data is multivariate normal, but that model occupies a large number of pages in every graduate textbook on multivariate statistical analysis."

P. 205 2nd para points out that machine learning etc. usually does assume iid drawings. The author gives many examples where optimal fits in classical statistics and elsewhere have many local optima almost equally good but far apart, with minor changes in the data completely changing the solutions.

P. 210 displays a claim: "The goal is not interpretation, but accurate information." This may be true if in an application all one wants is good predictions there, but is not true in academic studies where one wants interpretations connecting with other fields and studies to acquire general knowledge. %}

{% **natural sources of ambiguity**: Empirically measures ambiguity attitudes and risk attitudes and subjective beliefs for natural events, which is desirable to have rather than Ellsberg urns or experimenter-specified probability intervals. The natural events concern equity markets. Now, when correcting for beliefs and ambiguity attitudes, the authors find a positive relation between risk and expected returns which is natural, and deviates from puzzling preceding opposite findings. They find that ambiguity attitude ("aversion" rather than "attitude" is the proper term here) depends on the a-neutral probability ("expected probability" in the two-stage model of this paper), referring to it as probabilistic contingent ambiguity attitude ("aversion" is, again, the proper term also here). See p. 519, Figure 3, with ambiguity seeking for unlikely gains and ambiguity aversion for likely gains, reflected for losses, and perfectly agreeing with the fourfold pattern of ambiguity described by the survey Trautmann & van de Kuilen (2015; not cited here) (**ambiguity seeking for unlikely**).

I prefer to interpret this as a(mbiguity)-generated insensitivity, and as independent of a-neutral probability. Aversion is not the right concept here, but insensitivity is, similar as in well-known philosophical discussions where the colors bleen and grue are not the right concepts, but the colors green and blue are.

The authors distinguish ambiguity, a property of info, from ambiguity aversion, an attitude, as do so many studies. Ambiguity is captured by a second-order probability distribution. They achieve this distinction in the experiment by

ASSUMING a set of priors derived from monthly variation in daily priors (daily mean and variance of returns on the SPDR), and ASSUMING normal distributions of 1st order distributions (§3.2, p. 509 above Eq. 8), and ASSUMING that this captures ambiguity of the info. These assumptions are pragmatic and plausible but essentially ad hoc, relating exogenous finance variables and ambiguity perception, not derived from preference.

P. 505 penultimate para reports a test that it must have been a set of probabilities, and not a unique one, but this test is GIVEN the assumptions made as just derived, and does not preclude deviating models. §2, pp. 506-507, surveys other approaches in the literature that assume sets of priors or other parameters to capture ambiguity. They are always just assumed and not justified by preference conditions.

The authors derive risk- and ambiguity premia (Eq.1 p. 504), expressed in monetary units. Ambiguity attitude and premium is a component separate from risk attitude and risk premium (p. 504 bottom), which is desirable. Many studies in the literature will compare ambiguity attitudes only if risk attitudes are the same, but this is undesirably restrictive.

Footnote 3, p. 505, properly points out that studies by Baillon and others do not use particular functional forms, and that that is the difference with the present study. %}

{% Use PT to analyze resource allocation, finding that loss aversion is the main factor. %}

Bromiley, Philip (2009) "A Prospect Theory Model of Resource Allocation," *Decision Analysis* 6, 124–138.

{% **PT, applications**: Table 1 lists many applications of prospect theory in strategic management.

Two specialists in strategic management write about applications of prospect theory there, making it lively for managers by adding examples such as "thus a manager who faces …". One cannot expect theoretical perfection with people from other fields and, hence, there are theoretical inaccuracies.

The paper does not distinguish between prescriptive and descriptive as clearly as I would want to. It mentions it in passing by on p. 137 ℓ. -5.

P. 2022 3rd para strongly suggests that probabilities would always be underweighted, contrary to the prevailing inverse S shape, but later the paper will write about inverse S.

P. 127 2nd para ℓ. 4 suggestst that OPT would only concern two-outcome lotteries. However, for two-outcome lotteries OPT agrees with PT (this is how I abbreviate new 1992 (cumulative) prospect theory) [given that sign-dependence of w is at will for both theories]. OPT allows for three-outcome lotteries if one outcome is 0, and only there deviates.

An elementary confusion throughout is that the authors confuse steepness of utility with curvature/degree of concavity (risk aversion under EU), which is roughly like confusing first and second derivative or, more precisely, first derivative u´ and –u´´/u´ (the Pratt-Arrow index). The authors accordingly think that if you multiply the utility function by 2, then risk aversion will double, whereas in reality risk aversion is unaffected by this. Thus, on p. 2022 end of 1st para they claim that there is more risk seeking for losses then for gains because utility is steeper for losses. However, in reality utility is LESS convex (thus LESS risk seeking) for losses than for gains. The whole rest of p. 131 is based on this confusion. Thus, the 2nd para there continues on the confusion, leading to erroneous criticisms of claims on associations between risk and returns put central and repeated several times. P. 131 2nd para writes "This decrease in marginal value for potential outcomes far from the reference point and the resulting almost-linear value function in this region implies risk neutrality (i.e., neither risk aversion nor risk seeking)."

clearly showing this confusion. Throughout all the rest of the paper, all claims on degrees of risk aversion are confused and erroneous because of this. One symptom of problems here is that the authors never define what degree of risk aversion is. Thus, they claim that pople are less risk averse for higher gains, whereas the empirical finding is more absolute but less relative risk aversion. (Yes, there are different versions of risk aversion!)

Another elementary mistake is that the author many times, in many parts of the paper, erroneously claim that PT can only be used if known probabilities are available, i.e., for risk, and not for uncertainty/ambiguity. Well, most of my work today (Aug. 2022) is on PT for ambiguity, as expressed even in the title of my book Wakker (2010).

P. 133 3rd para criticizes people who only use loss aversion, and not probability weighting, writing: "By ignoring the probability weighting function, scholars ignore half of the theory." Several other places repeat this criticism. However, it can completely be justified for reasons of tractability.

P. 133 last para is too strong on claiming that PT looks at every single decision in isolation and never integrates seveal choices. Several other places repeat this claim. However, PT is not at all that strict on this point. It allows for it, but does not claim it to be universal.

Several places argue that more things in life are relevant than PT. For instance, P. 135 after first para discusses strategic complications. However, PT does not preclude such! It never claimed that it can solve all problems in life.

P. 137: "For example, we do not see prospect theory as necessary to argue that people do not behave according to expected utility theory." Everyone will agree!

P. 138 1st para cites Stanford (2017) on theories that are empirically indistinguishable but then goes on to write that they are empirically distinguishable after all.

P. 139 final sentence is nice: "We hope our discussion sparks a conversation on how to best balance the use of an academic theory in a complicated real world." %}

Broome, John R. (1990) "Bolker-Jeffrey Expected Utility Theory and Axiomatic Utilitarianism," *Review of Economic Studies* 57, 477–502.

{% This book has been one of the most influential works for my academic thinking. The book focuses on aggregation over persons, time, or uncertainty. See its subtitle. (Also Section 2.2. "These are the dimensions I shall be dealing with in this book. Perhaps there are other dimensions that could usefully be treated similarly, but I cannot think of any.")

Preface: the book considers "good" rather than preference (whenever those two might deviate).

The book argues that aggregation over uncertainty and maybe also persons and time, should be additivite with respect to one same cardinal index, being "goodness." Goodness is a kind of cardinal utility (may deviate from preference if latter are irrational). The required separability can be justified by assuming that "all relevant" be incorporated in the outcomes ("individuation of outcomes"). The book gives an advanced discussion of this point in §§5.3-5.7.

Ccr. 1: "good" = "relation of betterness." It adheres to consequentialism, rather called teleology (adj: teleological), by saying that anything relevant should be incorporated into consequences.

Often: the "right" act is the one that brings most "goodness," so as to reconcile teleological and nonteleological theories.

Section 1.2, p. 7 reminds me of my tradeoff thinking: "metaphor of weighing often fits teleology ... good and bad features are weighed against each other."

P. 11/12: "being more Westerly" is a nice example of intransitive relation. "At least as good as" should be transitive and reflexive (and for that the term ordering will be used. However, p. 65 defines ordering as also being complete). Need not be complete by an "I see no reason" argument. It is permitted that different things are incommensurable. (This is stated explicitly later, Section 5.1 p. 92/93.)

P. 16, end of Section 1.3: Announces that book will defend that EU is normative. End of Section 2.2 will say book is not to be understood as defense of utilitarianism, but only as exploration of its logical relations to separability.

coherentism: Section 1.4, P. 19, ed of 2nd paragraph: "It follows that teleological ethics cannot be *fully* justified on grounds of internal consistency ... It also follows that there are, actually, external criteria available for assessing the goodness of acts."
Same section, p. 20: "The view that one should maximize pain is excluded by a substantive limit. This book is concerned with the structural limits." Beginning of Section 2.4: "This book is about the structure of good, not the content of good." Points out that structural work cannot deal with substantive issues but thinks it still is valuable. Such a fine, nuanced, statement, right on target, is not to be found in any of the writings of Sen for instance!

Section 2.1 points out that decisions come about by weighing of goods, or aggregation. Points out that the weighing metaphor fares well if separability, less so otherwise. Presents separability for uncertainty, interpersonal, and time.

Section 2.2 explains that uncertainty, interpersonal, and intertemporal are special dimensions because separability can be defended there. For other dimensions it cannot be. I disagree because I think that only for uncertainty, separability has a special status (because of mutual exclusiveness of states of nature, explained on p. 96, Section 5.3 of Broome's book). Interpersonal and intertemporal do not have this; there an undesirably strong appeal will have to be invoked that the description of consequences contains everything relevant.

The coordinate value functions (as I would call it) are called "good at locations."

Section 2.2, near end, says that book argues for separability and utilitarianism, but that the case is ultimately inconclusive and that the arguments will contain gaps. John mentions that separability over time seems implausible to him.

Section 2.2, p. 28 bottom, gives precisely the same argument as Kahneman, I, & Sarin (1997) needed to defend that we assume instant utility measurement in intertemporal aggregation. John formulates it for interpersonal aggregation:

"For instance, between people, separability of income is implausible, but I think separability of good turns out to be an acceptable assumption. That is why my argument is conducted in terms of good rather than income. At places in this book the framework of the argument may seem contrived. *But if some artifice is required to gain access to the theorems, it is worthwhile.* It will reveal features of the structure of good that would otherwise remain hidden." [italics added]

Section 2.5, p. 33, points out that Broome thinks, like me, that completeness is the weakest of the EU axioms. However, he thinks it mainly because of incommensurability and I don't find that a good argument. Anybody who worked in a hospital will disagree with philosophers on this point. Philosphers can relax in their chair and argue that human lives and money are incommensurable. In the hospital, doctors do not have this luxury, but have to trade off human lives against money on a daily basis. My main counterargument against completeness is different: that many choice situations are too unrealistic to consider, which is related to Broome's rectangularity property.

Section 2.5, p. 36, "The conclusion is that general good can be represented by an expectational function that is the sum of expectational utility functions representing the good of individuals."

Chapter 3 is on a similarity argument by Harsanyi (1953) that Broome doesn't like too much.

Section 4.1, p. 60/61, discusses the Samuelson game where you don't want one gamble, you do like them when repeated often and only sum total matters, you don't want them maybe when repeated often but money is not transferable from one moment to the other.

Section 4.2, p. 70, states "second separability theorem" which has also been known as the "problem of aggregation" in the literature. The two-dimensional separability is called "crosscutting separability." For its proof, Gorman (1968) is cited.

Section 4.4 calls the assumption that the domain is a full product set the "rectangular field" assumption, and expresses interest in weakenings thereof.

Appendix to Chapter 4, p. 87/88, gives informal proof of Gorman's theorem in line with what I plan to do in the future. ("future" was written in

1998. Now, 2021, it is postponed until next life.)

Section 5.1, p. 91 (about EU): "It claims only that there *are* numbers p_1, p_2 and so on and a function u that allow the preferences to be represented in the manner of ... It says nothing about what the numbers and the function signify."

Section 5.1, p. 92/93: John repeates, for EU, that completeness is dubious.

P. 93 has reached additive separability for EU, and does not know how to make the last step to EU (the move from (5.1.2) to (5.1.1)); precisely here, my tradeoff consistency axiom would do the trick! Also, the intuition in the writing is precisely how I presented tradeoff consistency in my lectures in my young years.

p. 93 also points out the derivation of SEU from additive separability when there are equally-likely states.

independence/sure-thing principle due to mutually exclusive events: Sections 5.3 - 5.7 provide the best discussion I know in the literature of this issue. Section 5.3, p. 96, discusses the argument for independence, being the mutual exclusiveness of states of nature.
Broome describes an argument: "How can something that never happens possibly affect the value of something that does happen?"

Section 5.3, p. 98 (through endnote 15), mentions refs to people who explain Allais paradox. Always it's a kind of regret. Section 5.6, p. 107 etc., will discuss that in detail.

End of Section 5.3, p. 99/100, discuss consequentialistic trick of incorporating "everything relevant" into consequences (called "individuation," referring to separating consequences as different individuals), cites people on it, seems favorable to doing it, and says criteria for it should be developed. Cites Allais and ascribes to him that it should be monetary outcomes and cites Machina who said it should be "physically observable aspects."

Section 5.4 discusses "individuation" more, in the context of transitivity. It says that sometimes, when much appeal has to be made to individuation, transitivity becomes vacuous, but not violated. I fully agree with that.

P. 101 uses term "nonpractical" preference for what I describe as choice situations that are so hypothetical as to be useless.

P. 103, “principle of individuation by justifiers,” as formulated, does not help much, it is not verifiable but in a way circular. “Justifier” is a reason making it rational to have preference between two outcomes.

A nice point by Broome is that, even if one were to distinguish between an outcome with or without regret, it would still be irrational to have a preference between them. He says there is no “justifier” for the difference (justifiers should refer to “good” or “bad” features). This is Broome’s preferred viewpoint, he says with or without regret is different but should still be equivalent. (I prefer to put the difference at the statistical, not physical, level.) He writes: “Our principle for individuating outcomes has to be this: take one outcome as different from another if and only if it is rational to have a preference between them.” (this is written on p. 108.)

paternalism/Humean-view-of-preference: Section 5.5 discusses whether preferences can be just anything (that is in fact “consumer sovereignty”). It deepens the discussion, bringing in Humean considerations. “... it is a common opinion that rationality allows you to prefer anything to anything else” and says that that is part of a Humean tradition. It seems that the Humean view permits just any preference. (I: really???) Refers (footnote 23) to paper by Broome where the issue is discussed more.

Moderate Humeans: They restrict the above a little, by requiring internal consistency conditions, but nothing more. Then comes a strange step in Broome’s reasoning. He seems to think that internal consistency for *preference* does not impose any restriction for indifference. Probably, when John writes requirement of indifference, he means modeling requirement on degree of individuation. At any rate, I can surely appreciate his point that without any modeling restriction, consistency still is vacuous.

Broome writes (p. 106): “internal conditions of consistency require external criteria of goodness to give them meaning.”

p. 107: explains Allais-defenses as individuation through regret, and says there is no justifier for it.

p. 108: Here Broome states what I consider the paradigmatic interpretation of the sure-thing principle, that it shows how one defines consequences: “My only point is that Allais’s preferences are irrational if and only if we decline to distinguish outcomes that are given the same label in Table 14.” Critics might argue that in speaking of the preference for an outcome, separability is implicit?

P. 109/110, end of Section 5.6, on Machina who wants to consider only monetary outcomes, and then John's desire to individuate more: "For many purposes, this may not be the most convenient way of individuating. But it is the best way for the theoretical purpose of understanding rationality. Furthermore, because it preserves separability between states of nature, I hope to show in this book that it gives access to important discoveries about the structure of good."

Section 5.7 considers "dispersion of value between states," i.e., interactions between different states due to disappointment are to be incorporated in the consequences.

It also discusses that for fairness. Fairness is a bit different because it is more process-oriented, depending on the history of the act, and is not so easy to model as experienced emotion in the outcome such as is for instance regret. Several refs are given.

For Broome the special nature of fairness is not a big issue. He apparently does not want to distinguish much between act and consequence, and does not think that permitting the utility of an outcome to depend on the process leading to it is a big restriction. P. 114: "Any value an action or process possesses can perfectly well be counted into the value of its outcome. So that is not the real problem." I think that dependency is a more serious problem than Broome seems to think. I basically agree with Broome's discussion, but think the fairness thing makes the theory vacuous for too many preferences will become "inpractical." Later: that is exactly and entirely what he writes later in Section 5.8.

p. 114/115 discusses again relevance of counterfactuals. He says fairness is a genuine property of an outcome, based on a counterfactual conditional. Compares it to dispositional properties such as "inflammability" of ships, which also holds if they never catch fire. I would say that in such a case the dispositional property stands for nothing but the physical factors from which we derive the dispositional property. Ramsey (1931) wrote nicely about this for poison.

Section 5.8, I completely and entirely agree with every word of it. I think completeness is the major weakness in the EU axioms, exactly for the argument that Broome calls the "rectangular field assumption." Broome very very correctly points out that his individuation trick to save sure-thing principle, is at variance with the rectangular field property, and that in the latter lies the real problem. Only his one-before-the-last sentence suggests hope that the EU representation as is can be extended to incomplete product sets. That is not true, in such case conditions like continuity lose much of their force, finitistic axiomatizations must be considered which are well known to be hopelessly complicated.

Chapter 6 extends the EU defense, that was given in Chapter 5 for rationality/preference, to goodness.

Section 6.2, p. 132, argues that preferences do not always maximize good because we observe that empirically.

discounting normative: §6.2, p. 134, seems to assume, implicitly without further motivation, that discounting is irrational.

P. 137, footnote *: assumes, and I agree, that rational preference should be transitive and reflexive but not complete.

Section 6.5, p. 142, Bernoulli's hypothesis is EU with the "goodness" index as utility.

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): P. 146/147, first mentions that U of EU should be a strictly increasing transformation of the goodness index. But why should it be the goodness index, of the same cardinal class? It then argues that that is plausible by thinking similar to tradeoff thinking, and saying that it is reasonable that U is the goodness index. **This is the intuition of tradeoff thinking that I presented in lectures of my youth!** Broome agrees there is no definite proof, last sentence of this Chapter 6: "the hypothesis is defensible, but the defence is inconclusive." Later, e.g., p. 217, Broome will point out that if the cardinal index for EU and for utilitarianism is the same, then that strongly suggests that these actually *are* quantities of good.

The text also argues that the cardinal index should be the same for uncertainty as interpersonally. This follows formally from the mathematics of weak separability in both dimensions for matrices ("crosscutting separability," e.g. if row = person and column = state of nature), by Gorman (1968), leading to additive representability. (The same maths has been used by economists such as Van Daal & Merkies and others under the name "theorem of aggregation"). P. 146/147 (§6.5) will write, on distinctions between various cardinal indexes: "And it is natural to think this an empty distinction."

P. 149, footnote 19 says Bernoulli's hypothesis is implicit in vNM, and cites Ellsberg for it.

Chapter 7, p. 152, explains that Pareto cannot be satisfied under EU if persons have different probabilities.

Chapter 8 is on equity, I guess; I mostly skipped it.

Chapter 9 is on inequality.

p. 177 offers some funny citations of ancient writers who discriminated women.

Section 9.3, p. 186, explains that violation of separability due to equity can be removed by describing people's state not in terms of money, but in terms of "good."

Broome distinguishes equality within the utilitarian model, by concavity of individual utilities ("priority view," "individualistic egalitarianism"), and other kinds of equity ("communal egalitarianism") that lead to violation of separability.

Chapter 10, p. 202, summarizes the previous discussions in the "interpersonal addition theorem." General goodness is obtained by summing individual goodnesses and taking expectation over uncertainty.

Section 10.2 discusses how the problem of aggregation, applied to uncertainty and persons as dimensions, leads to identical utility for uncertainty as for persons. Then, Bernoulli's hypothesis also implies that the general good should be the sum of the individual goods.

P. 217: Same U for risk and interpersonal strongly supports it being goodness index. The utilitarianism custom of combining interpersonal addition with expected utility is nicely captured formally in this chapter.

p. 219/220, very correctly, points out that interpersonal comparability of utility is not a conclusion of Harsanyi (1955), but it is a presupposition, needed in the very definition of social welfare ordering.

Chapter 11 is on time preference. To aggregate within a person over time, the person at each timepoint is considered a separate unit. Broome puts in heavy machinery, "disuniting metaphysics," to justify it. The good of a life consists of the aggregate of the goods at each timepoint. A thought experiment where a person, halfway his life, is replaced by an exact copy, with identical memories etc., is used to support the claim. "The unifying relations must not be axiologically significant" is written (later, on p. 239) where "unifying relations" are wholistic (interaction) aspects of life time and axiologically probably refers to goodness in some way.

P. 228 mentions an example (from Parfit) that may be the hardest testcase for separability over time, i.e., a person who works all her life to save Venice. The example I always use to illustrate the point is of a person willing to sacrifice his life for a good cause, such as saving other people.

p. 239 repeats that incommensurability is the most serious gap in the normative theories. Broome then says he is inclined !not! to believe the disuniting metaphysics argument. A Dutch movie had an actor, a soldier going to die a heroic death, say in his goodbye letter to his wife: "I did not search for happiness but for meaning."

Book ends with: "The truth of the utilitarian principle becomes, in the end, merely a matter of meaning. It is a matter of choosing a metric for good." These sentences suggest to me that he takes the work in the same paradigmatic way that I am inclined to, where separability etc. only show how we intend to interpret the primitives of our model.

Reviews of this book:

Hausman, Daniel M. (1993) "The Structure of Good," *Ethics* 103, 792–806. Gives nice summary of Broome's arguments on separability, goodness, completeness, etc., with some own opinions added.

Hollis, Martin (1992) *Mind* 101, 553–554. Positive and presents main themes; doesn't try to be deep.

Sugden, Robert (1992) *Economica* 59, 253–254.

Pattanaik, Prasanta K. (1993) *Economic Journal* 103, 752–753.

Arneson, Richard J. (1993) *Journal of Economic Literature* 31, 1443–1445.

Temkin, Larry S. (1994) *Philosophy and Public Affairs* 23, 350–380. This review is superficial; in particular the listing of arguments against utilitarianism, at the end, is off because Broome's book discusses each of them extensively. %}

{% **paternalism/Humean-view-of-preference**: Humean viewpoint: no preference can ever be criticized for being irrational. Moderate Humean viewpoint: only internal consistency conditions (such as transitivity) can be imposed, no other criteria for rationality. Broome argues that the moderate Humean viewpoint cannot be maintained in the sense that it must necessarily reduce to the Humean viewpoint, as follows.

Violations of internal consistency can always be avoided by remodeling, by "finer individuation" of alternatives (e.g., incorporating context-dependence in the description of the alternative). Such finer individuation cannot be criticized on the basis of internal consistency and must necessarily be discussed on external grounds.

I personally think that both the Humean and the moderate Humean viewpoint are untenable, and that external criteria have to be invoked in rationality. The viewpoint that only the consistency axioms, and not for instance medical knowledge, is required for rationality, is surely not fruitful in medical decision making!

Probably Broome thinks the same, see end of §1: "I hope this will diminish the appeal of the Humean view as a whole."

P. 58 (on a book-making reasoning): "It is as though you stole his shirt and then sold it back to him."

P. 65: "a person's practical preferences are causally affected by her nonpractical preferences" %}

{% Propose a measure for how much information about unknown subjective parameters to be measured a set of decision problems gives. Such measures are used in recent computer-based adaptive measurements where the new stimulus offered to the subject is chosen to give optimal info given previous choices of the subject, as for instance in Cavagnaro, Gonzalez, Myung, & Pitt (2013, Management Science). But now the criterion is simpler and more tractable, and does not depend on previous choices. I expect that tradeoff-method based measurements do well. They apply their method to the measurement of PT (they write CPT; I mean the 1992 version of their theory). They then use power utility and the 1-parameter Prelec probability weighting family. Pp. 265 ff. show that variations/errors in observations contribute to the DFD-DFE gap, because of positive skewness and the lower bound of 0.

They find, surprisingly, that the stimulus set deliberately chosen by Stott

(2006) in fact has more overlap of data estimation than a randomly constructed set by Erev et al. (2002) (p 268 bottom).

Unfortunately, this paper follows the bad terminology of some papers in DFE to let "diminishing sensitivity" refer only to utility curvature and even equate the two.

This paper finds, again, that estimations of loss aversion are not stable. The authors add an argument to the many existing: that there often are not many mixed lotteries and only those contribute to the estimation (p. 269 3rd para). %}

{% Version of April '04:

inverse S: beginning has nice survey.

Paper discusses large and small probabilities without relating them to outcomes/rank-dependence.

Use range-frequency theory (RFT) of Parducci (1965, 1995) to explain inverse S probability weighing. According to RFT, we are extra sensitive to stimuli in regions where there are many observations/experiences, and insensitive in regions where there are few. Thus, if we more often encounter small and large probabilities, then we will be extra sensitive towards them. Difficulty is, what should we take as set of experiences? All probabilities we ever saw in our life, all probabilities occurring in the experiment we participate in so far, or only the probabilities occurring in the prospect now considered.

The theoretical discussion is nice, but testing these hypotheses empirically is not easy. The authors nevertheless try and, e.g., answer how frequent they think that probabilities appear. %}

concave utility for gains, convex utility for losses;
inverse S; find it using Goldstein & Einhorn (1987) family.
risk averse for gains, risk seeking for losses
reflection at individual level for risk: It is in their data but they do not report it.

Have no mixed prospects and, hence, model and measure no loss aversion.

For gains, Chinese students are less pessimistic and more likelihood insensitive than Swiss students. They also have more concave utility and, because CE data may not separate utility well from probability weighting (collinearity), it was not clear to me to what extent the higher concavity of utility drives the lower probability weighting.

The authors are happy about each subject clearly falling into one of the two categories (w, probability weighting, linear or nonlinear). I did not understand what else could happen than these two. There are few subjects of the "ambiguous type" (between the two categories, with p = 0.4 of being one catefory and p = 0.6 of being the other, as an example they give) but I don't know if their probabilistic models give much space to such types in, say, randomly generated choices for instance. %}

Bruhin, Adrian, Helga Fehr-Duda, & Thomas Epper (2010) "Risk and Rationality: Uncovering Heterogeneity in Probability Distortion," *Econometrica* 78, 1375–1412.

{% The authors test 1992 new prospect theory (PT) against salience theory (ST), using Allais paradox stimuli where lotteries are either correlated or independent. PT predicts equally many violations in each case, ST predicts some violations in the case of independent lotteries but not if correlated. There have been studies into this before, but this paper is way more thorough. The authors apply finite mixture models, finding that 28% of subjects to EU, 38% to PT, and 34% do ST. They also find that subjects doing ST have more preference reversals than other subjects.

An important point is how stimuli were presented, collapsed or not, correlated or not, and with common outcomes saliently visible or not. It has been found in the literature, in the 1990s, that the common consequence condition (sure-thing principle) is not violated much if common outcomes are saliently presented. It has then been argued that subjects may then ignore common consequences, thus satisfying EU, not because this is by true preference, but only because it is an easy heuristic to simplify the task. Unfortunately, I cannot produce references for this now.

The authors are more positive about salience theory than I am. Their implementation is as much regret theory as salience theory. %}

{% **questionnaire versus choice utility** %}

Bruni, Luigino & Francesco Guala 2001) "Pareto and the Epistemological Foundations of Rational Choice," *History of Political Economy* 33, 21–49.

{% **questionnaire versus choice utility**

The authors discuss Pareto's views on utility, and connect them to modern issues, in particular Plott's discovered preference hypothesis. To cite someone opposed to Pareto, they often cite Pantaleoni.

On a few points I disagree with the authors:

1. They assume that behavioral economists do not accept the revealed-preference paradigm but want introspective psychological inputs. The same claim is made by Angner & Loewenstein (2010). I think that the link is less strong, and disagree with both these teams. Behavioral economists point out problems for revealed preference, are often close to psychologists, and their work gives support to abandoning revealed preference. But behavioral economics does not necessarily abandon revealed preference. It is still essentially within the revealed preference

paradigm, showing there are more problems there than thought but yet to be resolved. For example, virtually all papers by Kahneman & Tversky use only revealed preference inputs.

2. I disagree much with the suggestion, on p. 152 ff., that part of diminishing sensitivity correspond to reference dependence. State-dependent reference points is a research interest of Sugden (e.g. his 2003-JET paper), but he/they got carried away thinking that Edgeworth's diminishing marginal utility be that. On p. 153 the authors write: "it is surely significant that he [Edgeworth] was aware of the reference-dependence of preferences, .." It concerns the point that if I ate 2 apples each of the last 10 days, then I like an apple less today than if I didn't eat any for 10 days, an aspect of diminishing marginal utility put forward by Edworth. Contrary to the suggestions of Bruni & Sugden, this is not reference dependence. It is simply intertemporal dependence, dependence on PHYSICAL CIRCUMSTANCES. It is completely standard in economic analyses. Reference dependence concerns only framing situations, where the physical circumstances are the same but the PSYCHOLOGICAL PERCEPTION is different, something which is not standard in economic analyses.

§6 criticizes the discovered preference hypothesis, arguing that (1) if preference converge after learning the limit need not be true preference but may be ad-hoc learned heuristic (the shaping hypothesis); (2) many choices in our life must be made without chance to learn from repetition; (3.a) even if people learn preferences, these need not be consistent or context independent; (3.b) in substantive justification of consistency, amounting to assumption that people maximize some (objectively measurable) index such as happiness, how justify this measure? Probably requires resort to psychology, exactly the thing that Pareto and many economists don't want. %}

{% In this paper, subjective probabilities (beliefs) can be chosen so as to maximize utility. For instance, in a prospect $100_{0.5}0$ you can believe that you get 100 with probability 1 and thus get the highest possible (expected) utility, so, this is what you then do. It is a Baron von Münchhausen way to get more utility. (He got himself out of a hole by very strongly, with his own hand, pulling his shoe leashes, thus lifting himself up, at least this is how his own story goes.) However, if decisions are to be taken then such misbeliefs can lead to suboptimal decisions. Then the optimal tradeoff between decision utility lost, and Baron-von-Münchhausen utility gained, has to be made. %}

{% The authors measure certainty equivalents of risky gambles with outcomes €5 and €25, or €15 and €20, and also of ambiguous gambles with those outcomes. Further, they play a complicated game, involving, to start, the following simple game:

	L	R
L	5^5	25^{20}
R	20^{25}	15^{15}

Each subject gets a role, say of row player. (This does not matter in the sense that the game is symmetric.) Then the subject has to choose between L and R, specify a belief, and choose two WTAs, one for L and one for R. Then the subject is paired with a randomly chosen other subject who gets the role of column player. Then the following, complex, payment follows.

(1) With probability 1/3 the simple game is played where the players receive the payment for their L/R choice made.

(2) With probability 1/3 the expressed belief is paid according to how close it is to the percentage of subjects who chose L, by a quadratic scoring rule, so that it is incentive compatible under expected value.

(3) With probability 1/3 a WTA is implemented. Then randomly WTA(L) or WTA(R) is chosen, say the former. Then a BDM implementation is done for this as CE of playing L in the simple game against what the other player chose of L or R.

The authors claim that, for *rational* (!) players, the choice of L or R is the same as playing the simple game. To me, who taught game theory for many years to master's students in economics and wants to be rational and Bayesian, this is not clear. I agree with the authors that my choice between L and R only affects MY payoff in Case (1) above, if the simple game is played. However, my opponent's choice of L and R impacts me differently, not only in (1) if the simple game is played, but also in (3), what I may get there. And, similarly, my choice between L and R impacts my opponent differently than only in the simple game. Thus, the payoffs are different than in the simple game, and I, experienced game theorist, find the game very complex to analyze. Comes to it that we should not see normatively how rational players should play this game, but empirically how real human beings play this game descriptively. These real human beings are assumed to not be ambiguity neutral, which greatly complicates the analysis of the above game, such as the conditioning on playing the simple game in (1). Further, the BDM mechanism is notoriously complex anyhow.

The authors claim to reveal how players play the simple game and also the certainty equivalents of the respective actions in that simple game, but I think it is way more complex, as explained above, and this is all unclear.

The authors claim, in particular p. 523 last para and p. 527 top, to be the first to separate strategic uncertainty and ambiguity (and risk). However, Li, Turmunkh, & Wakker (2020) also have such separations, with more sophisticated indexes.

The authors use a strange model where subjects derive direct utility from merely playing a game (may be negative). Thus, their utility can be above the maximum payoff in the game or below the minimum. The authors defend this on p. 533 2nd para by arguing for intrinsic utility, an argument used to justify many things in the literature. %}

{% **Newcomb's problem**: there is quite a bit of this, with nuances on different kinds of causality and causal decision theory.

Discusses preference axiomatizations, their normative and descriptive status, but also their interpretive status. The latter means that we interpret, for instance, subjective probabilities and utilities derived from decisions as reflecting the state of the agent, and as genuine beliefs and happiness. If deviation from EU, the descriptive approach will simply turn to other model. The interpretive view will

not do so, because beliefs and happiness are taken to be as in EU (almost by definition). They will rather search for alternative interpretations such as taking outcomes more complex. The interpretive view says that preferences deviating from EU (or whatever is taken as the appropriate theory) do not really reflect the preferences of the agent. They search for an idealized version of the agent. I am sympathetic to this view. %}

{% {% **tradeoff method**: is used in axiomatizations.

This paper proposes RAU (riskweighted ambiguity-resolved utility) theory. It is a special case of Choquet expected utility (CEU), so, prospect theory for gains. In CEU, a general nonadditive event weighting function W is used. This paper considers the special case where a subsigma-algebra exists where we have “local” probabilistic sophistication (i.e., where source theory holds), with a probability measure denoted small p. This is also assumed in the popular Anscombe-Aumann framework (AA). The author interprets these events as unambiguous. They can, for instance, be events with known objective probabilities. Unlike AA, the author also allows the unambiguous probabilities to be endogenous (subjective). However, unlike the AA framework, but like Sarin & Wakker (1992), this paper does not assume a two-stage framework, but allows any general framework. This is highly desirable, so as to avoid the problematic complications of nonEU in multistage optimization. Unlike AA and unlike Sarin & Wakker (1992), but like Sarin & Wakker (1994, in Machina & Munier (eds.)), the author does not assume EU for the unambiguous events, but Quiggin’s rank-dependent utility (RDU), called REU by her. It gives a probability weighting function applied to the unambiguous probabilities, usually denoted w. The author calls it a risk function and denotes it r. She then proposes the decomposition $W = r \circ v$, i.e., $v = r^{-1} \circ W$. She interprets r as risk attitude and v as ambiguity attitude.

The author can handle both risk and ambiguity/uncertainty together. This is not new but has been done before in prospect theory. Wakker (2010 p. 2) writes:

"At this moment of writing, 30 years after its invention, prospect theory is still the only theory that can deliver the full spectrum of what is required for decision under uncertainty, with a natural integration of risk and ambiguity." The novelty of the author is to give a precise place to risk and ambiguity, handling them in a unified manner but exactly separated and identified.

I disagree with the popular endogenous interpretations of unambiguity. But the author's concept can be taken as exogenous, as she writes, with objective probabilities. Then I agree with her composition and interpretation. Source theory in Baillon et al. (2025) studies the same decomposition $v = r^{-1} \circ W$ but only on subdomains where W is also probabilistically sophisticated. Wakker (2004) did consider the same decomposition, writing B for v, so $B = r^{-1} \circ W$ with W possibly not probabilistically sophisticated, and interpreted B as belief. B/v captures ambiguity attitude in full, and the general thinking in the field today (2025) is that that is more than belief. (My personal preference, not shown in my papers, is that all of ambiguity attitude is cognitive and is belief, coming from my collaboration with Tversky, but so be it.)

As written, I personally favor exogenous definitions of unambiguity. Many prefer endogenous definitions, and so does the author. Then there is a uniqueness problem that has plagued all endogenous definitions in the literature. There can be several sigma-algebras with probabilistic sophistication, but with different risk functions, say r and r´. Then also v in the composition is different, and there are different candidates for what risk and ambiguity attitudes are. The author has no real solution for it. Her §4 give two results that amount to all r's being the same, when, trivially, the problem does not arise. The author gives preference foundations. The author interprets the decision weights of the rank-dependent formula within a comon-cone derived from v (not W) as probabilities. They then depend on the comoncone and the author takes this as reflecting unknown probabilities, so, ambiguity. %}

{% $\alpha_E 0 \sim \alpha_p 0$, for $\alpha > 0$, defines objective probability p as the matching probability of event E. If a person does not do EU but weights probabilities, and does so the same way for objective and subjective probabilities, then the matching probability p still is the subjective probability of E. (P.s.: even, more generally, under all probabilistic sophistication.) However, if the weighting function is different for objective probabilities than for subjective ones (as in the source method of Abdellaoui et al. 2011 American Economic Review), then this is not so. This is what this paper points out. It calculates through many numerical examples with many weighting functions to illustrate this point again and again. This is what this paper does. %}

{% This paper gives a simple, but appealing, decomposition of vNM independence into betweenness and a condition that can be interpreted as homotheticity. Betweenness requires that every indifference class is an indifference set of an EU model, so, is linear in probability. Homotheticity requires that indifference classes are parallel. The two conditions together are equivalent to independence. Note that, given homotheticity, it is enough to require that one indifference class is linear, which then implies that they all are, so that the two conditions have considerable overlap. In an experiment, 1/3 of subjects violated homotheticity, 1/3 satisfied homotheticity but violated EU (so, assuming the technical axioms (which is a nontrivial assumption), they violated betweenness), and 1/3 satisfied EU. The author cites many ideas related to homotheticity.

Fo RDU (and PT for gains), homotheticity is equivalent to the weighting function being a power function. Accordingly, it cannot accommodate the common inverse S. Now consider the 1/3 of subjects that satisfy homotheticity but violate EU. (The author's discussion section at the end is on this.) Can we

conclude that they must violate betweenness? Can we conclude that RDU with inverse S probability weighting is violated? May seem so at first sight. But is not really so. The reason is that the axioms of completeness and continuity interfere. If we say that subjects satisfy homotheticity, all we can claim is that in the finite set of observations made we did not find a violation. We do not know if the condition is satisfied everywhere. This problem is of a more serious mathematical nature than first meets the eye. To explain, it may well happen that a finite number of observed preference neither violate homotheticity nor betweenness, but there is no way to extend these preferences to a preference relation that satisfies these two conditions and also completeness and continuity. That is, it cannot satisfy EU. There exist finite sets of observed preferences that satisfy all cancellation axioms of order 100 and lower, but still violate higher-order cancellation axioms, so that they violate EU. These are violations of a very complex combinatorial nature, not captured by simple axioms such as betweenness or homotheticity or anything else that is simple. Such finite sets cannot be extended to preferences that satisfy completeness and continuity and low-order cancellation axioms. %}

"Alias" refers to Wakker(1999) http://personal.eur.nl/Wakker//pdf/alias.pdf .
a' is like (a) in Alias, but for uncertainty, "born as a grown-up"

(This edition is the third, thoroughly extended; earlier editions were published in 1963 and 1964. In particular, the marvelous material on dynamic choice under uncertainty, Ch. 5, had not been published before.)

I read this book, and made extensive hand-written comments on it, between August 19, 1981, and September 4, 1981; My handwritten notebook p. 61.

Ch. 5 is fascinating. It precedes Hammond (1988) and is well written.

Burks studies dynamic choice under uncertainty and derives sure-thing principle from dynamic principles. A person "marks" decision trees, i.e., indicates his moves at every decision node. He does so a priori, all is a priori.

Thus we can, strictly speaking, not discuss forgone-event independence and DC (dynamic consistency). However, Burks does show how a sort of combination of those plus some more implies the sure-thing principle. The sort of combination is invariance (Axiom IVA), saying that choices in subtrees should not be affected by what happens in the rest of the tree. It comprises most of forgone-event independence and DC (it is Alias (a') $\Rightarrow$ (c)). The little more of DC's implications that is required to derive sure-thing principle. Is provided by normal form equivalence which, given restriction to prior choices throughout, is quite weak (Alias (c) $\Rightarrow$ (e)) and then gives the sure-thing principle because it also implies **RCLA.** Let me repeat that I am automatically assuming the logical equivalence axiom restricted to single nodes. In fact, logical equivalence regarding collapsing of subsequent chance nodes also implies RCLA.

In summary, invariance IV(A) does most of the job (Alias (a') $\Rightarrow$ (c)), being all of forgone-event independence that is needed and part of DC, normal form equivalence does the rest (Alias (c) $\Rightarrow$ (e)), so, the rest of DC and RCLA.

Burks deserves priority for the derivation of the sure-thing principle from dynamic principles over Hammond and others. Argument against it could be that invariance IV(A) is strong and comprises most of sure-thing principle. However, I feel that the essence of dynamic principles is present here. A further argument is that Burks discusses posterior choice on p. 307/308 when he explains why he violates EU in Allais paradox. Here he makes clear that he wants to preserve forgone-event independence (interpreting it, informally, as invariance IV(A)) thus give up DC.

Burks' work on these delicate issues is also accurate and free from the ambiguities found in so many other works on these issues.

Now follow detailed comments.

==================

!!!

It is important to note that all is done a priori, i.e., before the tree really unfolds and uncertainties get resolved. So, it can be considered prior planning in the being-commited-to-it sense. That appears, e.g., from p. 255 second paragraph ("he does not know").

!!!

Preface has said that Chapter V is new in this edition. Footnote at p. 251 says the theory was developed in a first version in the early 1960s and benefited from discussions with Savage.

P. 213, §4.4: a clear statement of the **Dutch book** argument.

P. 270 discusses conditional ordering of uncertainties axiom, similar to Epstein & Le Breton.

Work does not assume state space a la Savage but statements and logic, because the main subject of the book is inductive logic. (p. 302/303 discusses more) Does not formalize the complete set (algebra?) of atomic statements. For the decision under uncertainty literature it would have been easier if the book had formally defined an underlying state space and had related the events to that. Another reason why it would have been preferable if a state space or a complete set of atomic statements had been formalized is the following. As it is now, it is not clear if at all an event in one tree can be identified with another event in another tree or that, differently, in the description of events would be contained the dynamic context (tree) in which it appears. From the context it becomes clear that it is the former. Events are atemporal and in themselves do not contain information on sequencing or ordering.

p. 254 ℓ. –5: “sequence of statements” is as a partition.

p. 255: second move by adverse opponent is unfortunate assumption. It better be hypothetical.

P. 256/257: details about impossible events are best skipped at first reading. (Subjects are not required to mark decision nodes off the optimal path.)

p. 257, bottom, shows that trees are atemporal (given that events are atemporal). “An act in the most general sense is an assignment of consequences to logically possible universes. A choice tree represents a set of acts. In marking a choice tree by the rule just stated, a subject chooses one or more acts from this set.” P. 273 ℓ. 10/11 will repeat that, adding “The assignments are explicit in a normal form tree, implicit in other trees.”

p. 258 defines normal form act expression, assigning to each event of a partition a consequence. They do not refer to the decision tree they come from because it can be inferred from the context that events do not contain ordering/time information.

p. 258 ℓ. – suggests that events do not contain ordering/time information: “many logically equivalent normal form expressions that represent the same act “

p. 259: tokens of subtrees: The assumed prior information is formulated separately! Only with the same prior information, there is therefore reason to treat them the same.

p. 260: Universe description is a set of atomic statements. I'm not sure if it's really the overall total or if it's just restricted to some context (p. 261 ℓ.7 suggests "choice basis" is a kind of context).

p. 260, 4th paragraph: As does Savage, it considers all acts, i.e., all mappings from events to consequences, "since any consequence can be assigned to any universe." The paragraph also suggests further that Burks has a Hammond model in mind where decision trees serve no other purpose than illustrate normal-form acts. See also p. 308, second paragraph: "Now the value of an act or strategy should depend only on its assignment of consequences to possible universes, not on how the content of a universe description is distributed along a path through the tree."

p. 261 wants to put limit to (length of) decision trees to be made for a "choice basis," does that informally.

p. 262, ℓ. 3 "complete sets of choice trees" is Hammond-like set of decision trees

p. 262, Section 5.3.1, 2nd sentence of second paragraph, suggests that the whole analysis would best be restricted to one complete choice set.

p. 263, logical equivalence axiom: Within one chance node, propositions can be combined according to logic and the prior information that the chance node is conditioned on. In the state of the worlds model it means collapsing of events with common outcome.

p. 265 shows that logical equivalence axiom encompasses RCLA (merging successive chance nodes).

It also encompasses merging successive choice nodes.

P. 264 ℓ. −6 to −3: Later texts will show that Burks means here only same tokens of a subtree conditioned on same information !!and within the same tree!!, so at the same choice node. See also p. 265 lines 10-14. It is very explicit in the first sentence of the 4th paragraph of p, 265 (The second part of the axiom applies to a single tree.) and the footnote on p. 268. The condition might be dropped because it will be implied by invariance IV(A).

P. 266, subset axiom is IIA.

p. 268, Invariance is two parts, IV(B) (ordinal state independence), and then, the most crucial of all axioms, invariance IV(A). The latter is Alias (a') ⇒ (c). It therefore probably entails forgone-event independence (though Burks here did not commit to anything in Alias (b)) and the main part of dynamic consistency. Following the condition Burks writes: "requires the subject's choices in a subtree to be invariant through ... changes in the rest of the tree of which it is a subtree."

p. 273 formulates normal form acts. The fourth paragraph goes through some trouble so as to choose exactly one of the many logically equivalent versions. Readers not interested in logical equivalence issues can skip.

Section 5.4.1 on normal form equivalence is just Alias (c) ⇒ (e), because all choices are taken prior. So, it only says that a strategy in en extensive tree, valued a priori, can be identified with the corresponding single-stage act.

Section 5.4.2 gives the main result of the analysis, i.e., it derives Savage's sure-thing principle ("the partial act theorem") from mainly invariance and the normal form equivalence axiom. The derivation is presented on p. 279.

P. 299 compares to Savage's discussion of the sure-thing principle. But the informal (P2i) is none too clear and neither is Burks' discussion thereof, mainly because the decision-interpretation of the antecedent in it is unclear.

p. 303, bottom, introduces the mathematically trivial but conceptually useful notion of potential coherence, which for a finite set of choices means they can be extended to a complete infinite set satisfying structural richnesses, in short, it can be represented by SEU. (**desirable to extend preferences while satisfying/maintaining conditions**)

dynamic consistency: **favors abandoning time consistency, so, favors sophisticated choice**: p. 307-308

Section 5.6.2, p. 307/308, is very crucial. It is the only place where Burks discusses posterior choice, i.e., after receipt of information. Here he discusses Alias (b). So, here we can see whether he would rather give up forgone-event independence or DC. Burks in fact favors deviation from EU in the common consequence Allais paradox; he prefers sophisticated choice, i.e., giving up DC.

Section 5.6.4, p. 320, is a confusing sentence: "The very idea of a strategy of plan of action is to make choices before one is forced by circumstances to do so, and this involves deciding how one whould act in various situations."

It shows, first, that choices are assumed a priori indeed, as I have interpreted it throughout. But then it suggests that the choices are !not! committed, which is not at all like my preferred viewpoint. It might be interpreted as planned choice that is not committed, a notion that I do not like. Then it combines particularly bad with his text on p. 307/308 which suggests that after resolution of uncertainty he would deviate from prior plan.

The text is less troublesome if one interprets Burks' sentence as sophisticated choice, and "make choices" means "plan choices."

P. 534, §8.4.2: Pierce's dispositional-frequency theory of probability ("would-be"); i.e., that it refers to hypothetical situations. %}

Burks, Arthur W. (1977) "*Chance, Cause, Reason (An Inquiry into the Nature of Scientific Evidence)*." The University of Chicago Press, Chicago.

{% **cognitive ability related to risk/ambiguity aversion**: Measure cognitive skills, and risk aversion (fitting EU with power utility), intertemporal choice (quasi-hyperbolic) and two game situations (repeated prisoner's dilemma and job attachment). There is positive correlation between high cognitive skill, low risk aversion for gains, low risk seeking for losses, and small impatience regarding both parameters of quasi-hyperbolic. (Similar things for the two game situations.) Thus, nice evidence supporting rationality of expected value maximization.

For risky choices random incentive system (not clear if/how they implemented losses).

real incentives/hypothetical choice, for time preferences: for intertemporal **random incentive system between-subjects** (paying only some subjects) %}

{% Use introspective strength of preference measurements in addition to risky choices to fit data. I regret that the authors only cite Butler & Loomes (2007) (B&L)

twice for details, and not as regards the fundamental issue. B&L not only used preference, but two categories:

(1) I definitely prefer lottery A;

(2) I think I prefer lottery A but I am not sure;

The pesent paper uses four categories:

(1) A is very much better

(2) A is much better

(3) A is better

(4) A is slightly better

(Can say eight categories, as in the authors' terminology, if you add the four where B is preferred.)

B&L consider choice imprecision/confidence. The present paper considers strength of preference. These concepts are closely related and subjects will perceive them as about the same. B&L indeed write that their choice confidence refers to an underlying concept of strength of preference (e.g. their p. 283 bottom). The methodological discussion of using these concepts in economic choice is the same.

The authors shows that their strengths of preferences are responsive in sense of becoming stronger if an outcome of the preferred lottery is increased, for instance. They discuss to what extent strength of preference is related to choice error and gives new insights into it. It can give further insights into violations of independence and preference reversals. As always, salience interferes. If one lottery is almost identical to another but has stochastic dominance, then utility difference is small but the preference is completely clear. %}

{% **random incentive system**: used this for choices, but not for their strength-of-preference questions. P. 286 suggests that the latter cannot be incentivized.

error theory for risky choice; **real incentives/hypothetical choice**: discussed on p. 293. The authors use much introspective kind-of strength of preference judgments, discussed at length on p. 293. Do traditional strength-of-preference stimuli where certainty equivalents are derived from choice-list like questions. At each choice the subject not only expresses preference, but also the introspective question of whether the preference is sure or only probable. Use random-preference explanations for preference reversals. P. 283 explicitly interprets this as strength of preference. %}

Butler, David J. & Graham C. Loomes (2007) "Imprecision as an Account of the Preference Reversal Phenomenon," *American Economic Review* 97, 277–297.

{% One sample is some 1600 customers of an Italian bank. The other is some 1300 students recruited online.

correlation risk & ambiguity attitude: they find a positive relation between ambiguity aversion and risk aversion.

They measure risk aversion in two ways. First, they ask an introspective general question. Then they use the Barsky et al. (1997) question. Ambiguity aversion is measured using the usual Ellsberg two-color urns, but it is hypothetical. They control for suspicion by letting subject choose winning color. They ask for introspective strength of preference. They also have a measure for how much subjects do intuitive rather than deliberate thinking. The intuitive thinkers are less risk and ambiguity averse. %}

Butler, Jeffrey V., Luigi Guiso, & Tullio Jappelli (2014) "The Role of Intuition and Reasoning in Driving Aversion to Risk and Ambiguity," *Theory and Decision* 77, 455–484.

{% The authors consider the Bohnet & Zeckhauser (BZ) betrayal aversion experiment: A principal can do a job herself ("distrust"), giving (10,10), where the first coordinate denotes the principal's payoff, and the second an agent's. Or can pass the job on to the agent ("trust"). The agent then chooses between the selfish (8,22) or the fair (15,15). They measure MAP (minimally acceptable probability) as do BZ. The authors add two treatments (between-subject). Those consider variations in case of the trust decision (measured beforehand, by the strategy method). In each of the two, there are 17 cards and the agent randomly chooses one. In each, the card chosen determines whether it is (8,22) or (15,15), but the agent does not know at all which card gives which. In one of the two treatments (AxD), the agent knows that the cards imply one of those two, only does not know which card gives which, and in the other treatment (Axx) the agent known nothing about the cards at all when choosing. The authors replicate BZ although not as strong, with Axx in between.

social risks > nature risks in coordination games (here it is competitive game but then hamstrung effect … see below) Strangely, the authors find that principals like AxD much more (so, lower MAP). P. 2792 puts forward a hamstrung effect explanation. It is that the agent can see the conflict of interest, and could desire for it, but has no possibility to enhance it. So, those desiring to be selfish will feel disappointment. May be the principal enjoys this idea. A replication finds the result again but much weaker.

I did not find number of subjects in the first experiment specified in the main text, but p. 2792 2nd column 2nd para writes that the result may be an artifact of sampling because of small sample size (40). For the new treatments, it can be discussed whether this is human intentional influence because all the choice options (17 cards) given to the agent are informationally identical. P. 2790 describes this as "essentially a human randomizing device."

P. 2793: The authors are enthusiastic about their finding and write: "Our findings have broad implications for contract design in situations where the presence of social risk is a choice variable."

P. 2794 footnote 10: The authors follow Bohnet & Zeckhauser by using an EU backward induction type of analysis, in particular by conditioning on p* in the footnote. Li, Turmunkh, & Wakker (2020) criticize this analysis for being normative and not descriptive. %}

{% **correlation risk & ambiguity attitude**: finds a positive relation
This paper considers a game with a safe row C giving $18 for sure, and two rows A and B giving $25 or $14, depending on the column player's choice. Under risk neutrality, (0.5:A, .5:B) strictly dominates C, and C cannot be. But under considerable risk or ambiguity aversion, C can be. The paper separately measures risk and ambiguity aversion, and correlates it with choice C. A nice

thing is that, whereas risk and ambiguity aversion are measured the usual way using choice lists and Ellsberg ambiguity, they are still (somewhat artificially) related to the game situation, increasing validity. The paper uses EU and log-power utility fitting to measure risk aversion. It uses the nice Epstein-Halevy (RESTUD) method to measure preference while staying somewhat away from indifference. This is probably the reason that he finds only 25% ambiguity aversion.

The paper finds a positive relation between risk/ambiguity aversion and the choice of C. Subjects who knew they faced ambiguity/risk neutral opponents, acted accordingly and chose proper optimum. %}

{% **DC = stationarity**: intro first para and throughout.

If comparing constant discounters and hyperbolic discounters, the former can still be more impatient and, to the extent this is more irrational, thus be more irrational. The authors propose, comparing behavior and self-control problems, we should only do if the same degree of impatience in some average sense (“controlled comparison”). Difficulty is that this limits applicability. Also if people have different degrees of impatience, we can compare their degrees of DEVIATION from constant impatience and then (under time invariance) their vulnerability to control problems. Prelec (2004) and Bleichrodt, Rohde, & Wakker (2009 GEB) give such techniques.

Although time is continuous, it is not clear if consumption is discrete or continuous/spread-over-time. The authors do switch to discrete for quasi-hyperbolic. %}

Caliendo, Frank N. & T. Scott Findley (2014) “Discount Functions and Self-Control Problems,” *Economics Letters* 122, 416–419.

{% Vieider (2018 AER) criticizes this paper, showing that prospect theory with a plausible error theory can accommodate their findings well. The authors, indeed, ignore oceans of literature showing more risk aversion for probability equivalents than for certainty equivalents. See below.

real incentives/hypothetical choice: Did experiment in Afganistan. 1127 subjects (about half of the 2027 asked) filled out two hypothetical (real incentives with money carried around was too dangerous in Afganistan; p. 131) risky-choice matching tasks, giving q and q´ such that

$150 \sim 450_q0$ and (*)

$450_{½}150 \sim 450_q0$ (**)

Unit of payment is Afhani, and 450 is about three-day salary.

So, the first question is a probability equivalent (PE), also called standard gamble (SG). The second is a McCord-deNeufville (1986) variation (see Wakker 2010 §2.6, p. 59) with a 0.5 probability at 450 mixed in. They also do some priming of fear, and have info on exposure of subjects to violence. The main finding of the paper is that exposure to violence increases risk aversion. It is in itself a thin finding, but it is on a beautiful subject sample.

I consider risk questions more.

EU PREDICTION: q´ = ½+½q.

But the authors find that q´ is smaller, so, more risk aversion with the PE question, in agreement with the certainty effect. This is in agreement with the literature (not cited by the authors), which has found much risk aversion in PE, and also much trouble because PE questions usually perform poorly because of all kinds of biases. The keywords

PE doesn't do well and

PE higher than CE and

PE higher than others

in this file give such references. One difference is that most of this literature did direct matching, whereas the authors use a choice list, but the choice list will evoke part of the problems of matching. Bleichrodt (2002 HE) gives a good discussion.

The authors give a central role to the theory of utility of gambling (**utility of gambling**), also used in other Andreoni & Sprenger work, and which of course can accommodate the certainty effect well. Other theories with pessimism, such as Gul's disappointment aversion and RDU with convex w, can also accommodate the finding. PT *without loss aversion* and only inverse S probability weighting cannot. The certainty effect then overweights the lowest outcome similarly in both choices, but in the former effect the possibility effect is good for 450_q0, so that the prediction would be q´ bigger rather than smaller than the EU prediction. This is how the authors analyze PT. That they ignore loss aversion is stated in Footnote 10, in their words: "We abstract away from loss aversion …". Bleichrodt, Pinto, & Wakker (2001) did incorporate loss aversion, but with the difference that they considered matching rather than a choice list. Then they showed that PT does accommodate big risk aversion in PE. The choice list used here will to some extent work like matching, because the sure outcome is kept fixed and, hence, easily is taken as reference point.

The authors properly point out on p. 136 ff. that their data have great difficulties, with subjects not understanding. Thus, 63% of their subjects report q = q´ in Questions (*) and (**), which by transitivity gives150 ~ $450_{½}150$ violating stochastic dominance. It also explains why the authors find so much risk aversion in the question (*) with the sure option. %}

Cambridge Journal of Economics, volume: 45, issue: 5. 2021.

{% **SPT instead of OPT**: Pp. 74-75 really uses the right formula for 1979 prospect theory (Eqs. 17 and 18)! This is exceptional. Almost all other authors do this wrong, and instead do what is called separable prospect theory. The domain has only prospects with at most two nonzero outcomes, so, it is possible.

Paper tests gain- and loss prospects, but not mixed ones. For probability weighting, the paper allows for discontinuities at $p = 0$ and $p = 1$, capturing some insensitivity. In the interior, $0 < p < 1$, it only considers convex weighting functions, unfortunately (p. 75).

risk averse for gains, risk seeking for losses (p. 85, table 5 and p. 89); more subjects are risk averse for gains than risk seeking for losses.

real incentives/hypothetical choice: Done here (p. 81). Half of of the subjects were paid, half were not; no difference was found, neither in consistency, nor in risky choosing, nor in violations of independence. Discussed in §3.3 (p. 82 ff). P. 82 tests isolation of RIS by allowing subjects, after selection the choice to play for real, to change previously stated preference, with 80 subjects. Only 2 out of 80 subjects changed. They show that independence is massively violated, but isolation is not. This is a mild form of deception because experimental choices, announced to be consequential, in fact are not really so (**deception when implementing real incentivescrowding-out**).

losses from prior endowment mechanism: Said on p. 81; done for 96 subjects; p. 84/85 suggests that only part of subjects, not all, do isolation/integration of payment, but gives no very clear evidence on how many by using unclear overall tests.

P. 89: **risk averse for gains, risk seeking for losses** is found

P. 85 has nice discussion of within/between subjects and representative agent.

PT falsified: p. 94 describes dependence of probability weighting on outcomes in prospect theory. (**probability weighting depends on outcomes**)

reflection at individual level for risk: unfortunately the paper does not report this (Section 4.2). It only confirms reflection at average level (Section 4.1).

inconsistency in repeated risky choice: this paper has 31.6% %}

{% %}

Camerer, Colin F. (1992) "The Rationality of Prices and Volume in Experimental Markets," *Organizational Behavior and Human Decision Processes* 51, 237–272.

{% **survey on nonEU**; **time preference**;

P. 597: "methods for removing errors could be useful policy tools." Subjective fifty-percent intervals contain the true value about 30% of the time;

P. 603 refers to studies showing that mathematically sophisticated subjects, and also children who haven't yet learned the law of large numbers, are better at generating truly random numbers.

P. 619: **risky utility u = transform of strength of preference v**, haven't checked if he thinks that latter doesn't exist; Camerer is very explicit in his opinion on this issue.

P. 625, 2nd column, third line, makes the speculation that the value function in prospect theory was meant to be riskless. Although this interpretation seems to be a natural one and I like it, I think that, unfortunately, it cannot be found in any of the writings of Kahneman & Tversky, contrary to what Camerer suggests.

P. 627 points out that there is no clear way (I think, no way at all) to falsify the general Allais and Hagen risk theories.

P. 634 gives many refs on **real incentives/hypothetical choice**, several other places mention it. P. 635 seems to write: "The effect of paying subjects is likely to depend on the task they perform. In many domains, paid subjects probably do exert mental effort which improve their performance, but in my view choice over money gambles is not likely to be a domain in which effort will improve adherence to rational axoms."

P. 637 refers to several people who find that EU is not violated so much inside the probability triangle.

P. 637 says that nonlinear probabilities performance for many outcomes is empirical question;

is positive on future of nonadd. probability

P. 642 is, given Colin's disliking of EU, pessimistic on nonEU: "more general theories *fit* better than EU (since they have more degrees of freedom) but are no better in *predicting* new choices."

P. 643: "Maybe subjects do not induce divisions from preferences; instead, they regard money-splitting as akin to problem-solving and use a simple heuristic ... that generates allocations that are inconsistent with complete pairwise preferences."

Pp. 655-656 describes history of regret theory, where the inventors themselves later abandoned it because event splitting had driven their results, in positive terms: "The regret studies show the interplay of experimental studies, and the cumulation of discoveries, at its best. … This is a story of successful detective work."

P. 657: "Since ambiguity aversion is simply an application of the independence axiom,"

P. 659: "First, the BDM procedure only fails if independence is violated *and* reduction is obeyed." [italics from original] The sentence is not accurate, and should be: "First, the BDM procedure can be satisfied with independence violated but reduction also violated" where backward induction is satisfied.

P. 659 (on explanation of pref. reversal through BDM/nonEU): "the artifactual explanation may have received too much attention from talented researchers with better things to do."

P. 660 discusses several Loomes et al. papers that dispute the Tversky, Slovic & Kahneman (1990) explanation of pref. reversal as violation of procedure invariance rather than transitivity.

P. 661 supports the Slovic & Lichtenstein explanation of preference reversal that is often called contingent weighting.

P. 673: "suggest people use simple procedures to make choices, constructing their preferences from procedural rules rather than maximizing over well-formed preferences." %}

{% Neoclassical economists let utility represent introspective feeling of happiness. After the ordinal revolution, utility became related to revealed preference. Camerer studies currents in the brain. He equates, without further ado, the measurements of currents in the brain with the introspective feelings considered by the neoclassics. Thus, he comes to suggest that neuroeconomics can measure the introspective feelings (he sometimes calls it the black box) considered by neoclassical economists. Typical of this way of arguing is the last sentence on the first page, C26, continuing on p. C.27: "Pareto's view that psychology should be deliberately ignored was partly reflective of a pessimism of his time, about the ability to ever understand the brain well enough to use neural detail as a basis for individual economising."

Or p. C27, ℓ. 8: "The turn-of-the-century pessimism about understanding the brain … "

In neuroscience, the term "the hard problem" (Andreas Roepstorff) designates the big difficulty of relating objective measurements to subjective experiences. Camerer completely ignores this problem. The mind-body problem can't stop him either.

P. C27 brings up Friedman's positive economics, and criticizes its claim that a wrong theory A is OK if it gives right predictions P by assuming that the wrong assumptions must then have a hidden additional "repair" condition R. I disagree. It is well possible that wrong assumptions give right predictions without further assumptions. What is weak about Friedman's viewpoint is that we do not know, when using theory A, what predictions P' we want to derive from it in the future, and A being right on P does not exclude that it will be wrong on P'.

inverse S: pp. C33-C34, §3.3, refers to Hsu et al. (2005) for neuroeconomic evidence supporting inverse S probability weighting. P. C34 also explains the "three-valued logic" of probability weighting. %}
Camerer, Colin F. (2007) "Neuroeconomics: Using Neuroscience to Make Economic Predictions," *Economic Journal* 117, C26–C42.

{% A discussion of Levitt & List (2007, JEP). Camerer cites several people on the justified view that it is not clear whether, for predicting some field phenomenon, a lab experiment or another field experiment can serve better. Camerer several times argues that it is agreed among many experimental economists that external validity is not important for their studies, and this is hard to understand. For EVERY study it is important that finally external validity, with implications outside the walls of academia, will result. He may mean that some studies for a while focus on lab validity to first get things straight about lab findings, leaving external validity to others/later. He also raises an argument that experimental economics investigates general theories about links between factors and behavior, and from that concludes that "hence" external validity is not important. I do not understand. Some theory meant to be general may work well in the lab but not in the field, and this should always be a point of concern. He cites many studies that showed that lab findings usually extend to the field. Nicely, and no surprise for someone as broadly-read as Camerer, he cites psychological literature from the 1970s. I taught a module called quasi-experimental design to psychology students end of 1980s in Nijmegen in the Netherlands. Much of the discussions now going on in leading economic outlets on lab//field are discussed in better ways in first-year psychology textbooks of around the 1980s (e.g., Cook & Campbell 1979). %}

{% **PT, applications**: downward-sloping labor supply %}

Camerer, Colin F., Linda Babcock, George F. Loewenstein, & Richard H. Thaler (1997) "Labor Supply of New York City Cabdrivers: One Day at a Time," *Quarterly Journal of Economics* 112, 407–442.

{% The enthusiasm of the authors appears from the opening sentence: "The deepest trust in scientific knowledge comes from the ability to replicate empirical findings directly and independently." They apparently assume that scientific knowledge comes only from empirical findings, at least as far as deep trust is concerned, and then only from empirical findings that are replicable, excluding astronomy, archeology, macro-economic findings, and so on. It further appears from their sentence in the opening para: "Replication is now more important than ever."

They replicated all 18 experiments in AER and QJE of between-subject lab tests in 2011-2014, with always $\alpha = 0.05$ and power ≥ 0.90. They replicate about 70% of the findings, which, given publication bias, is a plausible finding. It is better than a similar study replicationg 100 psychological experiments, which found sme 40% replications. They advance as reasons that experimental economics has more rigor in view of real incentives and no deception. It is in general true that economics has more uniformity and less vagueness than psychology, which is broader and has less control. %}

{% **real incentives/hypothetical choice**: Paper considers, more broadly, effects of payment for achieving tasks such as probability matching, so, not just real incentives/hypothetical choice. I think, now in 2020 when writing this, that, in general, experimental economists exaggerate the importance of real incentives. This paper is balanced, i.e., in agreement with my views. ☺

Paper argues that, if real incentives are important, then other aspects such as give subjects right skills ("(cognitive) capital") should be equally important.

Abstract and p. 23: people are more risk averse under real incentives.

P. 8: "The extreme positions, that incentives make no difference at all, or always eliminate persistent irrationalities, are false. Organizing debates around those positions or using them to make editorial judgments is harmful and should stop."

P. 8: "In the kinds of tasks economists are most interested in, like trading in markets, bargaining in games and choosing among risky gambles, the overwhelming finding is that increased incentives do not change behavior substantially (although the variance of responses often decreases)."

Pp. 14-18 has Table 2 with references on use/effect of real incentives.

P. 11 mentions several other survey studies.

P. 21: effects result mostly from raising incentives from zero to small, not so much when raised from small to big.

P. 23: "It is worth noting that in many experiments, financial incentives might appear to have little effect because subjects are intrinsically motivated to perform well, so money adds little extra motivation. When subjects volunteer, for instance, they surely self-select for high intrinsic motivation." Then follows a warning about validity of volunteer-subjects results.

P. 24: "Overreporting purchase intention is quite familiar in marketing.":

P. 31: "For example, a search of the *American Economic Review* from 1970-97 did not turn up a single published experimental study in which subjects were not paid according to performance. Authors believe that referees will automatically reject a study which uses only hypothetical-payment data (and the authors are probably correct!)."

P. 34: "In … risky choices the most typical result is that incentives do not affect mean performance, but incentives reduce variance in responses."

P. 34 is, to my joy, harsh against people who dogmatically reject studies without real incentives.

P. 36: "Because …we do not know how earning money and losing mney differ." %}

Camerer, Colin F. & Robin M. Hogarth (1999) "The Effects of Financial Incentives in Experiments: A Review and Capital-Labor-Production Framework," *Journal of Risk and Uncertainty* 19, 7–42.

{% **paternalism/Humean-view-of-preference**: asymmetric paternalism: Paternalism by overruling individual decisions, or correcting for supposed biases, should never be such that rational individuals, who do satisfy normative theories, get harmed by it. Thus, if people on average overestimate utility of losses by a factor 2 in an irrational manner, then you cannot by way of best estimate divide all loss utilities by a factor 2, even if on average and for the majority of people you then get the best utility. The reason is that there will be some rational persons among the people concerned who did not overweight their loss utilities and who are harmed by this change. %}

{% A discussion and survey of neuroeconomics. The paper is written in the enthusiastic style of Loewenstein. The opening sentence of the abstract: "Neuroeconomics uses knowledge about basic brain mechanism to inform economic theory." The authors claim in several places that neuroeconomics is the next step after the ordinal revolution; i.e., that neuroeconomics can measure the classical cardinal utility that economics has been looking for for over a century now. On p. 556, when they discuss Jevons, the 5th para starts with: "But Jevons was wrong. Feelings and thoughts *can* be measured directly now, because of recent breakthroughs in neuroscience. …" Or beginning of conclusion, on p. 572: "Economics parted company from psychology in the early twenthieth century … Neuroscience makes this measurement possible for the first time."

P. 559 brings up that we can learn a lot about human beings from studying primates, and then informs us that they share more than 98% of our genes.

P. 568: Footnote 7: the animal can be Bayesian if exchangeability does not hold.

P. 569 2nd para gives support for sign-dependence. %}

Camerer, Colin F., George F. Loewenstein, & Drazen Prelec (2004) "Neuroeconomics: Why Economics Needs Brains," *Scandinavian Journal of Economics* 106, 555–579.

{% P. 9: "This pessimism was expressed by William Jevons in 1987: "I hesitate to say that men will ever have the means of measuring directly the feelings of the human heart. It is from the quantitative effects of the feelings that we must estimate their comparative amounts." … But now neuroscience has proved Jevon's pessimistic prediction wrong: the study of the brain and nervous system is beginning to allow direct measurement of thoughts and feelings." That is, the authors ignore the so-called "hard problem" of neuroscience, that we do not know how currents or whatever we measure in brains are related to feelings. I discuss it more at Camerer's (2007) paper in the Scandinavian Journal of Economics.

Typical statements are:

P. 32: economics assumes that time-preference is context independent, but neuroscience can discover context dependencies.

P. 35: economics thinks that the utility of money is indirect (as means to buy things), neurostudies suggest that it can have intrinsic utility. %}

Camerer, Colin F., George F. Loewenstein, & Drazen Prelec (2005) "Neuroeconomics: How Neuroscience Can Inform Economics," *Journal of Economic Literature* 43, 5–60.

{% Show experimentally that if a better-informed agent should predict actions of a less-informed agent, then the better-informed agent acts too much as if the worse-informed had the extra info that the better-informed has but the less-informed does not. Theory of the mind is about such things. %}

Camerer, Colin F., George F. Loewenstein, & Martin Weber (1989) "The Curse of Insight in Economic Settings: An Experimental Analysis," *Journal of Political Economy* 97, 1232–1254.

{% **survey on nonEU**;

P. 326 is, unfortunately, not aware of the difference between objective probabilities given beforehand and available as primitive, and subjective probability that is not given beforehand and is not available as primitive and is typically inferred from choice: "In SEU the distinction between known and unknown probabilities is pointless, because subjective probabilities are never unknown—they are always known to the decision makers (or inferable from their choices)." Thus, the authors cannot discuss the subtle issue of whether probabilistic sophistication and SEU can be absence of or neutrality w.r.t. ambiguity. P. 329 top repeats it. (**SEU = risk**)

P. 341 top & p. 353 top: the studies that they reviewed (all included in this annotated bibliography) find that risk attitude and ambiguity attitude are uncorrelated (**correlation risk & ambiguity attitude**);

universal ambiguity aversion: §2.3 says that ambiguity is "scary," and suggests as if universal that people are averse to ambiguity; also end of §2.5 (though as antecedent). This will be repeated on p. 347 following Eq. 6, saying: "Outcome dependence is important because people are ambiguity-averse for *both* gain and loss gambles. Models like Fellner's (1961), in which ambiguous events simply have a lower probability weight, fail descriptively because they predict *preference* for ambiguous bets on losses." [italics from original] One problem here is that the state of the art today (June 2011) finds prevailing ambiguity seeking for losses (**ambiguity seeking for losses**).Another problem is that rank-dependent weighting can combine underweighting of small events with ambiguity aversion for both gains and losses if sign-independent—and the Sipos integral (= PT) if sign dependent.

Footnote 37 suggests that EU is not normative;

Footnote 38 is weird; they argue !in favor! of forgone-event independence (often called consequentialism) for the special case of indifference, but refer to Machina (1989) who I think did not accept forgone-event independence if indifference; accepting forgone-event independence if indifference is close to betweenness.

§3.4 is nice, with the title: "The difficulty of establishing equivalence of ambiguous and unambiguous probabilities." That an unknown probability of 0.1 due to skewness may be overestimated, even by SEU.

probability intervals: P. 346 bottom writes that with probability intervals it is true that one need not give precise probabilities, but one then has to give precise boundaries of probability, an argument also advanced by Lindley (1996).

ambiguity seeking for losses: §5.1 discusses ambiguity in health (which means losses). Problem in health is that ambiguity will suggest that the health outcomes are less known, and will decrease the value of the outcomes. Still they report less ambiguity aversion for health than for money. P. 354 bottom: "These medical and health studies are a little discouraging, because they show less ambiguity aversion, and less reliable measurement of ambiguity, than is observed or assumed in laboratory experiments (and in theory)."

P. 359, 2nd full paragraph points out that a **Dutch book** example discussed before requires “isolation” (~ additivity). The next paragraph describes the “Dutch book” commonly advanced against violation of DC (dynamic consistency), in the Raiffa (1961) answer to Ellsberg, and calls it “less slippery.”

P. 361 has a nice text on the discrepancy between empirical and theoretical workers on ambiguity, still relevant in the year I copy this text (2015):

“The differences in researchers’ purposes sometimes limit communication and crossfertilization. For example, psychologists are sometimes annoyed that decision theorists rely on unrealistic axioms. But theorists see more realistic axioms as inelegant and difficult to work with. A review like this is meant to promote cross-fertilization by telling people with different purposes about other kinds of research, so they can draw inspiration and ideas from others. Since psychologists and decision theorists are not as curious about market implications as economists, economists who find the psychology described here inspiring must figure out its market implications and test those using market data, themselves. Similarly, pyschologists who are curious about the descriptive validity of new axioms, and theories based on them, must conduct tests themselves since most decision theorists are more interested in the mathematical properties of axioms than in their descriptive validity.”

{% **linear utility for small stakes**: §3.3 beginning: "The amounts of money involved in experiments are too small to trigger risk aversion relevant to life cycle spending. For that reason, Barsky, Juster, Kimball, and Shapiro, 1997, constructed a stated preference question that placed enough wealth on the line to introduce significant wealth swings. It involved a switch of job with a potentially large change in income. With the advantage again of being able to place these on the HRS, this form of question is now widely used and related to portfolio choice." This text also pertains to **real incentives/hypothetical choice**.

Argues that for economists to work with data, they have to produce much of the data artificially by themselves, using theoies, having to do for one with the central role of counterfactuals in decisions. (**conservation of influence**) From economic data we usually cannot separate preferences (utilities) from beliefs. Does the consumer really prefer this product, or have wrong beliefs? Argues that economists also have to reckon with perceptions of consumers, and not just with what was objectively offered to the consumer. This is an input in the development of stochastic choice theories.

End of §4.3 discusses what is in fact only the observability problem of indifference; i.e., the difficulty to falsify indifference empirically. %}
Caplin, Andrew (2016) "Economic Data Engineering," working paper.

{% Provide some preference axioms for predicted and experienced reward, which they interpret as dopaminenergic, to reflect dopamine neurotransmitters. Their application to belief elicitations consists of a speculation that dopamine measurements can help elicit beliefs, with learning and addiction idem dito. In this way the authors aim to help bridge the conceptual gap between neuroscience and economics, as they write in their abstract. %}

{% **value of information**: Different anxiety types have different needs for information. Let emotions such as anxiety enter as arguments into the utility function. Is a bit like the intrinsic **value of information** and early/late resolution of uncertainty. %}

Caplin, Andrew & John Leahy (1999) "The Supply of Information by a Concerned Expert," Dept. of Economics, New York University.

{% **conservation of influence;**

Agent receives physical prize z_1 in period 1, physical prize z_2 in period 2. There is uncertainty, so, probability distributions over prizes are involved. φ is a map that, at the end of period 1, maps the agent towards a psychological state. φ depends not only on z_1 but also on the lottery over the z_2's, and can reflect anxiety etc. There are decisions at both timepoints. This model generalizes Kreps & Porteus (1978) by permitting time inconsistency. Utility (from prior perspective) $V_1(y_1)$ is sum of expected utility $E(u_2)$ over second period and utility $u_1(\varphi(y_1))$ of psychological state $\varphi(y_1)$ at period 1, see Eq. (1) on p. 63. Decision making is assumed to be sophisticated, so, not resolute.

Under appropriate continuity, an optimal priori strategy exists if the set of options is compact. In several places, the authors state that anxiety will depend on possibility and will overestimate small probabilities (e.g. p. 56). §IV.B argues that what is often called risk aversion should have a dynamic aspect of anxiety and is not static.

The enthusiasm of the authors is reflected by sentences such as "More recently, these findings have moved out of the laboratory and into the field" (top of p. 60) or "One important advantage of our formulation over static nonexpected utility models is that the latter theories attempt to telescope a dynamic pattern of feelings into a single static utility function.” (p. 75) or the closing sentence of the paper.

information aversion: §II.B gives many refs where people, owing to anxiety etc., prefer not to receive info.

The model is general but, in return, it is not easy to see how to derive predictions from data. How can we measure its primitives from data? Are they identifiable? On p. 75 the authors explain that their model is very general indeed, incorporating everything relevant, with footnote 20 citing Machina on EU being normative then. As Machina added to this point, however, the problem then is that it is hard to derive predictions from data. %}

{% DM-Subjects can distribute risky prospects over other subjects (and also if self involved) before the uncertainty of the risks are resolved. Next the uncertainties are resolved. Next the DM-subjects can redistribute. So, this is about the interaction of fairness and risk, in Harsanyi-type models.

They find that ex ante considerations remain dominant over ex post, but there are some redistributions. They redistribute much more the differences resulting from different luck, than differences resulting from different decisions. Although being stakeholder or not matters, the same fairness views underly both cases. %}

Cappelen, Alexander W., James Konow, Erik O. Sorensen, & Bertil Tungodden (2013) “Just Luck: An Experimental Study of Risk-Taking and Fairness,” *American Economic Review* 103, 1398–1413.

{% The authors examine sources, i.e., collections of disjoint events. They are like different partitions of a state space, as are sources as I use them, but a difference is that the union of all elements of a source need not be the same for each source here, and can in principle be unrelated to each other. For each source, acts map the atomic events to outcomes, asssumed real-valued here. It is similar to the experiments in §1.1.6.2 of Luce's 2000 book. The authors do not impose many restrictions, besides weak ordering, mostly continuity and monotonicity. Thus, all acts have certainty equivalents. Within one source, acts can be compared through their certainty equivalents. But certainty equivalents are not evaluated the same for different sources. Thus, nonlinear transformations relate certainty between sources and, then, by transitivity determine all preferences.

The authors allow for several acts and their outcomes to be received at the same time. They may specify n sources of uncertainty and n acts, and the outcome of each act is received, giving a portfolio of n outcomes. The n sources may, for instance, refer to n timepoints. Then the aggregation of these is another topic to study. It requires consideration of (non)separability across different sources, and stochastic (in)dependence of the events of different sources.

The source method of Abdellaoui et al. (2011) is different because there different sources concern partitions of the same Savagean state space. The authors point out that their approach can be related to one common state space by taking a product of the n sources. However, this product loses information. For instance, in Abdellaoui et al. a union of some events of some source may be a superset of a union of some events of another source, but such set-theoretic info is lost if the mentioned product space is taken. Further, Abdellaoui et al. (2011) have the receipt of only one outcome, and not a portfolio of different outcomes. %}

{% I think that the term behavioristic in this paper means trying to get away from teleological approach to social scienes (verstehen) and trying to use tehnique f natural sciences.
Author discusses behavioral influences in economics with many points debated as much still today. Writing style is phenomenal, as is often the case with papers written before the 1930s, and in itself is enough reason to read this paper. The paper points out that behaviorists look at different phenomena, where there is less rationality. Nice final sentence, about new groups of scholars as they behave throughout every discipline of science:

"But if they think that they have built up a complete system and can dispense with all that has gone before, they must be placed in the class with men in other fields, such as chemistry, physics,

medicine, or zöology, who, because of some new observations, hasten to announce that all previous work is of no account."

This sentence may also reflect the intergenerational battle where young people rather claim novelty than credit predecessors, and where older researchers complain that they have seen it all before. The author was 63 in 1918, after a long life with prominent positions. He was president of the American Economic Association in 1916. %}

Carver, Thomas N. (1918) "The Behavioristic Man," *Quarterly Journal of Economics* 33, 195–201.

{% **standard-sequence invariance**: don't really use invariance axiom, but do use standard sequences to get sequences of outcomes that are equally-spaced in utility units.

Use the Gul-independence version of bisymmetry on all two-outcome acts, to get CEU (Choquet expected utility) for all two-outcome acts (proved in Lemma A.5, p. 54) (could also have been done by means of a variation of standard-sequence invariance, or tradeoff consistency as I call it, the more so as they introduce this concept later). Then use standard sequences as in Krantz et al. (1971) to define outcome-mixtures of acts. Use that to adapt constant-act independence and uncertainty aversion of Schmeidler & Gilboa (1989) and of Chateauneuf (1991) to continuous instead of linear utility, in their constant-independence axiom 6. Thus, this paper is the first to axiomatize maxmin EU with continuous utility. A valuable result! %}

{% Subjects can choose to precommit or not. If the usual violation of stationarity is due to intertemporal preference, subjects will prefer to commit (under some assumptions), but if it is instead uncertainty about future outcomes (receiving new info in between) then they will not want to commit. They also get options to increase flexibility. This is tested. %}

Casari, Marco (2009) "Pre-Commitment and Flexibility in a Time Decision Experiment," *Journal of Risk and Uncertainty* 38, 117–141.

{% **DC = stationarity**: This paper carefully distinguishes the three concepts and tests them separately, in particular, employing the longitudinal data required for testing time consistency (also known as dynamic consistency). It is very similar to Halevy (2015), but the two studies were done independently and do not cite each other. The three preference conditions are nicely displayed in Figure 1, p. 128. This paper cites several predecessors in the intro and Section 1. It uses nice terms for the three conditions, being absence of static choice reversal (Halevy: stationarity), absence of dynamic choice reversal (Halevy: time consistency), and absence of calendar choice reversal (Halevy: time invariance). The end of Section 3 properly explains that stationarity and time consistency can be equated only if we assume time invariance, a result stated formally by Halevy.

Unfortunately, p. 122, 2nd sentence of §1, unlike rest of paper, does confuse stationarity and time consistency. (**DC = stationarity**:)

Prospects to choose from are losses: (1) Listen to 20 minutes of unpleasant noise now; (2) do it in 2 weeks; (3) do it in 4 weeks. Subjects are asked for their preferences now, and after two weeks are again asked for their preferences at that moment over the remaining prospects. The stimuli are really implemented (subjects get paid for it to make up). Subjects have to attend all three sessions anyhow, so, no savings of transaction costs in that sense. Under discounted utility, the preferences are determined solely by whether there is impatience (then postpose the unpleasant thing) or negative impatience (then do it as soon as possible). So, whether discounting is exponential or hyperbolic or otherwise plays no role.

losses from prior endowment mechanism: this they do. For money there is the usual problem that subjects may integrate the prior endowment with the loss and, hence, not perceive losses, which is why they do money only hypothetically, something that I agree with. For the outcomes here, listening to unpleasant music, such integration is less likely because it is not so easily integrated with the prior endowment OF MONEY (they are paid for the unpleasant listening). This makes this paper a convincing implementation of real incentives, similar to Abdellaoui & Kemel (2014).

Big problem of longitudinal choice is that the intertemporal conditions such as time consistency make a big ceteris paribus assumption: in the time between the decisions, nothing relevant should have changed, with no new info received for instance. In reality this is hard to get implemented. For instance, not now but in two weeks the subject knows if he has a headache then. There thus is, more or less endogenous, uncertainty about own preference. The authors nicely put this point very central using the term stochastic utility for it (a term elsewhere used mostly for the uncertainty of the analyst, rather than the subject, about preferences). Subjects have an option to pay some for flexibility, which means that in two weeks they get the chance to revise their time-0 choice. If they do pay, then probably there is stochastic utility. Buying flexibility is through an auction, which may encourage subjects to pay (too) much.

Calendar choice reversals (so, violations of time invariance) are usually due to factors other than time preference (which makes it understandable that many intertemporal choice studies assume it explicitly-- many do it implicitly). This paper finds it and has to draw the somewhat negative conclusion that other things are going on. As for me, I usually like to get extra things, whether good or bad, over with as fast as possible, simply because then I can forget and need not plan about them anymore. This, rather than negative impatience, can explain why most subjects wanted the noise listening to be done righ away, as people often want to take negative consumptions as soon as possible.

Another nice aspect of the paper is that the stimuli used, nonmonetary, avoid the problem of saving money or getting interest rates from the market, because the stimuli purely concern consumption that cannot be transferred in time. (**time preference, fungibility problem**) It is discussed, for instance, on p. 123 bottom.

{% Subjects receive a card that is worth $2 (that they will later receive for it). Their subjective value of the card is then measured using BDM (Becker-DeGroot-Marschak). By any rationality standard, BDM should give the value $2. But this does not happen, and the measured value is usually higher. The authors argue that this is so fundamental that it should not be taken to reflect preference, but only that subjects do not understand the decision procedure. For the latter misunderstanding the authors use the strange term game form misconception. This term is strange because it suggests that the authors only think of game theory, and not of the many other preference situations. But so be it. This paper is part of a general direction of research by Plott, arguing that many biases found are too irrational to be taken as reflecting preference. The many biases such as framing are indeed of interest in decision making at low levels of rationality, as with marketing and consumers buying in supermarkets, which is what psychologists often study, but not if we are interested in higher-level preferences such as with financial traders, or if we have normative interests. In the same spirit as Plott, I usually study theories that satisfy transitivity, even if it is violated empirically.

Note that in the terminology of this paper, choice refers to descriptively revealed choice, and preference refers to some sort of true underling rational value system.

P. 1236 has a nice expression: "testing a scale by measuring a known weight."

P. 1237: "Many decision makers appear to confuse the second-price auction incentives of the BDM with a first-price auction."

The text is often verbose.

One problem I have with the experiment is that the amount, $2, is so small that subjects just for fun may deviate from the obvious. Another is that Fig. 2, p. 1244, may confuse subjects. Its left to says that subjects will sell the card, and have to name an offer price. This is suggesting to subjects that trading is to come. The bottom of the card explains the BDM payment system, but in no way makes clear that the suggestion of the upper left part will not happen at a later stage, and that this BDM payment is all there will be. The random prize has been determined beforehand, which is nice (the authors point out on p. 1244 that this excludes that the prize offered might depend on what the subjects do, which in fact excludes, in my terminology manipulation), and is tangible in the sense that it is below a covering card to be removed by the subjects, which is also nice. However, the randomization concerns the random prize only, and not the whole decision situation, which is a deviation from the Prince mechanism.

After a first round, subjects did it a second time. Subjects who in the first round had given a wrong value and lost because of it (the random prize between the stated and true value) did better in the second round, but not perfect.

The authors claim to exclude framing but their claim is incorrect. Subjects after a mistake in the first round usually improve their behavior in the 2nd round because of learning. The authors claim that framing would exclude such learning because the frame stays the same. This claim is incorrect. Nobody studying framing will think that learning cannot exist. %}

{% Assume M and m are maximal and minimal outcome, utilities 1 and 0. Then the graph of the utility function can be interpreted as the distribution function of a "benchmark" random variable. The expected utility of a random variable then becomes the probability of the rv exceeding the benchmark rv (assuming stochastic independence). This is nice. Known properties such as concavity of utility are reformulated for the new interpretation. %}

Castagnoli, Erio & Marco LiCalzi (1996) "Expected Utility without Utility," *Theory and Decision* 41, 281–301.

{% This paper considers a remodeling of utility as the probability of attaining some goal. In f ≽ β, β is the goal to be attained and β can be a random variable, f is an act, and the preference f ≽ β means that the goal has been attained. Goals may be something like obtaining enough money to pay all bills each month, enough food to survive, producing offspring, etc.

Assume U on [a,b], normalized to U(a) = 0 and U(b) = 1. U(12) = 0.7 now means that the probability of achieving one's goal is 0.7 if the outcome received is 12. Taking as benchmark a random variable β with distribution function U, the probability of 12 achieving the goal of exceeding the benchmark β is indeed 0.7. This is the basic idea of the model. The benchmark β, and its probability distribution, are taken endogenously. This remodeling of utility is interesting. It was introduced in earlier papers by the authors, such as Castagnoli & LiCalzi (1996, *Theory and Decision*). For more references, see Abbas & Matheson (2009).

The contribution of the present paper is to establish the re-interpretation of utility in a number of commonly used preference representations, primarily additive decomposability of Debreu (1960) and several of its extensions. For infinite state spaces, a complication is that the reinterpretations of utilities as probabilities must be combined with traditional subjective probabilities established in the "overt" state space, and this requires the derivation of nonelementary measure-theory results on the extension of measures from non-algebras to algebras. The authors resolve this complication, with a useful summary of known results in Appendix A.

{% Uses the statistically powerful adaptive technique to compare fit of several discount models. This is at the individual level. Unsurprisingly, quasi-hyperbolic and hyperbolic perform poorly because they cannot accommodate increasing impatience whereas this, even if minority, will still happens frequently and one can’t miss all those individuals. (P. 236: 25% of their subjects have increasing impatience.) Thus, the final sentence of the abstract writes: “specific properties of models, such as accommodating both increasing and decreasing impatience, that are mandatory to describe temporal discounting broadly."

P. 249: "Another significant result of the present study was the prevalence of increasing impatience (concavity of the discounting curve) in our sample. This phenomenon challenges the prevailing practice in the literature of modeling temporal discounting as exclusively non-increasing, while providing strong confirmation of the results from a small number of recent studies, notably by Attema et al. (2010); Abdellaoui et al. (2010); and Abdellaoui et al. (2013). Among the models we analyzed, only the Constant Sensitivity model can accommodate increasing impatience."

P. 250: "We believe the success of the Constant Sensitivity model demonstrates that increasing impatience and the extended present are likely to be relatively common behavioral variants, which reinforces the value of utilizing models that accommodate this behavior. The success of the neuroscience-inspired Double Exponential model … We anticipate that analysis of the unique characteristics of the Constant Sensitivity and Double Exponential models may yield important results in future studies. In addition, if increasing impatience, the extended present, and mixture are all important for describing discounting behavior, we propose that a mixture of Constant Sensitivity and Double Exponential would be a logical extension."

P. 250: "Several promising models have been developed in recent years that merit inclusion in future model comparison studies (Bleichrodt et al. 2009; Benhabib et al. 2010; Scholten and Read 2006, 2010)." It is useful to note here that the model of Bleichrodt et al. (2009) agrees with and extends Evert & Prelec's constant sensitivity model in the same way as negative powers extend positive powers for CRRA utility. Bleichrodt, Kothiyal, Prelec, & Wakker (2013) renamed the family "unit invariance." Bleichrodt et al. (2009) predicted, what this paper confirms, about their families: "They serve to flexibly fit various patterns of intertemporal choice better than hyperbolic and quasi-hyperbolic discounting can do, by allowing any degree of increasing or decreasing impatience. Thus, the CADI and CRDI [now called unit invariance] discount families are the first that can be used to fit data at the individual level."

P. 250: "In addition, it should be noted that all of the models tested assume linear utility, an assumption which has some support at the aggregate level, but could potentially introduce distortions if there is significant heterogeneity at the individual level (Abdellaoui et al. 2013). However, over the range of reward magnitudes involved in our experiment, any effect of nonlinear utility would likely be small." (**linear utility for small stakes**) %}

{% The authors propose a new risk model that assigns to $X = (p_1{:}x_1,\ldots,p_n{:}x_n)$ with expected value EV the value $EV + 2[\lambda E(X-EV)^+ + (1-\lambda)E(X-EV)^-]$. Here Y^- is defined as ≤ 0, as is often done in decision theory (especially if Y concerns nonquantitative losses for which $-Y$ is not defined) but not in mathematical probability theory or measure theory, where Y^- is usually taken ≥ 0. $\lambda = ½$ gives back EV. A pessimist will have $\lambda < ½$. I note that the model could have been rewritten as $EV + (2\lambda-1)E(|X\text{-}EV|)$, showing it's an analog to mean-variance. A behavioral foundation is in Blavatskyy (2010 Management Science), something the authors are not aware of.

They further generalize by replacing EV by $(g(p_1)x_1 + \cdots + g(p_n)x_n)/(g(p_1) + \cdots + g(p_n))$. Wakker (2010 Exercise 6.7.1) showed that this violates stochastic dominance whenever g is nonlinear. So, I would have preferred that the authors had cost-effectiveness done using rank-dependent probability weighting. The authors show how the model can accommodate all kinds of phenomena. They do not provide a behavioral foundation or empirical test.

Rieger (2017) comments, pointing out for instance that the model is close to Guls' (1992) disappointment aversion model, treating EV the way Gul treats certainty equivalents. %}

{% **biseparable utility violated**;
The cautious expected utility model takes not one utility function, but a set $\mathcal{W}$ of such. Each lottery is evaluated by the, for that lottery, most risk averse utility function in $\mathcal{W}$ in expected utility. That is, the certainty equivalent CE of lottery x is $V(x) = \inf_{v \in \mathcal{W}} CE_v(x)$, where $CE_v(x)$ is the CE of x under EU with utility function v. It is dual to maxmin EU for uncertainty, with linearity in probability rather than in utility (maxmin EU has linear utility in the Anscombe-Aumann sense). Cautious EU can be risk averse if all functions in $\mathcal{W}$ are concave, and risk seeking if all those functions are convex. One can increase risk aversion by applying a concave transformation to all functions in $\mathcal{W}$, and increase risk seeking by applying a convex transformation. Thus, the model itself does not very directly speak to risk aversion. But what it adds to EU is entirely in the direction of risk aversion. For comparison, RDU can add risk aversion to EU by adding a convex probability weighting function to EU, but it has the flexibility of

adding other attitudes through other weighting functions.

One can readily formulate α maxmin generalizations of cautious EU. The model shares with Chew's (1983) weighted utility (and with the smooth ambiguity model although that is for ambiguity), the spirit of getting the action/variance-in-data from the outcomes, and will not work well to accommodate the fourfold pattern of risk attitude with risk aversion depending on the probabilities considered. (**event/outcome driven ambiguity model: outcome driven**, though here it is risk and not uncertainty). For instance, if we face an outcome interval where the utility functions in $\mathcal{W}$ differ much from each other, then the nonEU part of the formula will add much risk aversion. If we then go to another outcome interval where the utility functions are all equal, then there the formula satisfies EU. The outcomes we deal with, and not the events/probabilities, determine risk attitude. This is different for RDU or prospect theory, where the relevant probabilities determine how we deviate from EU.

The cautious model will not be very tractable for calculations, just as with maxmin EU, because for the very evaluation of a single lottery already a minimization problem, minimizing over a set of utility functions, must be carried out.

Whereas for most lotteries the model adds a layer of risk aversion, it does not do so for riskless lotteries. These get a kind of privileged treatment. Thus, a necessary axiom is negative certainty independence (NCI):

$$x \sim \alpha \;\Rightarrow\; \lambda x + (1-\lambda)c \succcurlyeq \lambda\alpha + (1-\lambda)c$$

for all lotteries x,c, sure outcomes α, and $0 < \lambda < 1$. A way to see this: If, in $\lambda x + (1-\lambda)c$, I could for x take the most aversive utility function for x, and for c the most aversive utility function for c, then I would have indifference. In reality I cannot minimize for both x and c at the same time. Putting NCI differently, and assuming RCLA, replacing any sublottery in a multistage lottery by its certainty equivalent always worsens the case. Put yet differently, and very nicely, any conditional CE (recommended to be used by McCord & de Neufville 1986) exceeds the unconditional CE. Thus, the model can be taken as a nice new insight into McCord & deNeufville: It characterizes when M&d ALWAYS find lower risk aversion. (This point gets a displayed elaboration below.) In combination with the RDU model the condition is very restrictive because it is imposed irrespective of the ranking of the outcomes and, indeed, it cannot be reconciled with RDU (unless EU). Loosely speaking, as soon as there is rank dependence, we can always arrange the conditional CE to come out relatively favorable but also relatively unfavorable and the latter violates NCI.

NCI implies convexity (also called quasi-convexity or quasi-concavity; it means:mixing with something good is always good) w.r.t. probabilistic mixing: if $x \sim y \sim \alpha$, then $\lambda x + (1-\lambda)y \succcurlyeq \lambda x + (1-\lambda)\alpha \succcurlyeq \lambda\alpha + (1-\lambda)\alpha \sim x$. That is, in $\lambda x + (1-l)y$ we twice substitute conditional CEs (p.697 footnote 8), each time worsening the lottery. So, there is a general preference for probabilistic mixing.

Theorem 1 p. 698 shows that under usual monotonicity/continuity/weak ordering, the condition (NCI) is not only necessary, but also sufficient, for cautious EU. Here is again the duality with maxmin EU, with convexity meaning that we have a minimum over dominating linear functions but a certainty independence needed extra because we have ordinal inputs. The negative certainty independence axiom of the authors nicely combines these two conditions. $\mathcal{W}$'s closed convex hull is unique up to redundant utilities (giving too high CEs to ever be minimum, as resulting for instance from any convex transform; they get some sort of Kannai-type minimally concave utilities); see §2.5 p. 701. It is a very, incredibly, appealing mathematical result connecting simple concepts in a way never noticed by anyone before. I elaborate on this point:

======================================

BEGINNING OF ELABORATION OF LAST SENTENCE

McCord & deNeufville (1986) had a nice idea. About utility measurement for EU under risk. Let M be the best outcome and m the worst. Normalize U(M) = 1, U(m) = 0. Then

x ~(p:M, 1-p:m)

implies U(x) = p, and was the common method. But M&d argued that such measurements are too much distorted by the certainty effect, and give too much risk aversion. They recommended mixing in another lottery C with weight (probability) 1-a, and use indifferences,

ax + (1-a)C ~ a(p:M, 1-p:m) + (1-a)C

to avoid the certainty effect and its excessive risk aversion. To me, this idea is about the same as negative certainty independence (NCI), the axiom that Dillenberger was the first to write. Nice idea.

Now for another nice idea: of multiple utility models.

Surprisingly, this paper shows that the two above nice ideas, that I have known longtime, are in fact the same. One axiomatizes the other. Nice surprise!

END OF ELABORATION OF LAST SENTENCE

==

I disagree with many empirical claims in the paper though.

(1) Pp. 694-695 mentions Quiggin's RDU and betweenness as the most popular alternatives to EU, overlooking the Nobel-awarded prospect theory whose 1979 introduction is the second-most cited paper ever in an economic journal. (**Prospect theory not cited**; although these authors are not experimental economists.) P. 712 writes that the NCI model, like betweenness and RDU, is not designed to distinguish between gains and losses. Here it is strange again that PT is not mentioned. Kahneman & Tversky's papers are only cited for particular empirical facts and in the definition of RDU it is just mentioned as comprising. Cautious utility can capture sign-dependence well in one way: It can let the set of utility functions for losses be very different than for gains. It cannot capture sign-dependence in the sense that its deviation from EU is always to take the minimal EU, both for gains and losses. A sign-dependent generalization could be to take the max for the loss-part, or do α maxmin with α different for losses than for gains.

(2) P. 695 claims "Third, our model is consistent with the main stylized facts of preferences under risk as surveyed in Camerer (1995) and Starmer (2000)." As most theoretically-oriented economists, the authors are not well aware of the common empirical finding of the fourfold pattern. They show no awareness of risk seeking for small-probability gains. They do explicitly point out that they do not seek to accommodate sign dependence (p. 712), and they do point out that they can accommodate risk seeking for losses (by having all utility functions in $\mathcal{W}$ convex for losses), but what their NCI adds for losses goes in a risk averse and I think wrong direction for losses. Whereas RDU adds layers to EU that can be risk averse or risk seeking and, importantly, can do so depending on probabilities considered, cautious EU only adds a layer of risk aversion to EU that is outcome-

oriented and not probability-oriented.

(2a) Problems for losses: People have a special aversion to sure losses, contra to NCI. The common finding is

$$-100_{½}0 \succ -50 \text{ (risk seeking)}$$

but, mixing it fifty-fifty with a sure 0, I predict

$$-100_{¼}0 \prec -50_{½}0$$

violating NCI.

(2b) Problems for low-likelihood gains: People will dislike certain outcomes if they compete with small-probability-high-gains (leading to inverse S under RDU). Thus, the common finding is

$$10^6{}_{10^{-6}}0 \succ 1 \text{ (risk seeking)}$$

but, mixing it fifty -fifty with a sure 10^6, I predict

$$10^6{}_{½+10^{-6}/2}0 \prec 10^6{}_{½}1$$

violating NCI.

NCI implies universal convexity of preference, but I expect it to be violated in many instances. Wakker (2010 Theorem 7.4.1) shows that under RDU (= PT for gains), convexity of preference ($p \sim q \Rightarrow \lambda p + (1-\lambda)q \succcurlyeq q$; a condition called quasi-concavity by Wakker) is equivalent to concavity of probability weighting. However, most empirical evidence suggests the opposite for gains: Convex probability weighting (under inverse S usually for moderate and high outcomes, although weak in the interior). This gives counterevidence to convexity of preference (modulated by violations of RDU). The authors mention this difference between their model and RDU in footnote 37, p. 713. I expect that neither convexity nor concavity of preference holds very generally (for gains or losses), depending on configurations of lotteries as with inverse S.

P. 713 suggests that betweenness is more restrictive (= parsimonious) than the NCI model, and that the latter is permissive (= less parsimonious), but then suggests that RDU is even more permissive (although staying vague by saying that "there are instances"). I see this differently. The set $\mathcal{W}$ of utility functions (also when modulo closed convex hull, redundant utilities, and affine transformations) is of higher dimensionality than RDU's (1 utility function + 1 weighting function). The NCI axiom, only imposing some inequalities and not symmetric in left- and right-hand side of preference, is more permissive than comonotonic independence or betweenness. The latter are symmetric in the left- and right-hand side of preference, amounting to invariant preferences and to preserving indifferences. This is the same as convexity being more permissive than linearity.

Related to the above point of cautious utility being permissive, elicitiation will be problematic. The elicitation discussed at the end of section 2 (p 702 bottom) confuses empirical observation with identifiability. It only shows how observations exclude some utility functions, and writes that if we know the whole preference relation than the set $\mathcal{W}$ must be identifiable (up to its degree of uniqueness of course). Such observations hold for every model satisfying the minimal requirement of identifiability, and give no clue on how much a finite number of observations narrows down the set $\mathcal{W}$. As always, one can do parametric fitting. But then one should not only restrict the utility functions considered, but also the *set of* utility functions considered. If this is done to a high degree, then cautious EU can become sufficiently parsimonious to be empirically tractable for data fitting and predicting. But it will take creativity to find empirically satisfactory parametric subfamilies.

P. 707 ℓ. −5 claims that RDU has a continuous (onto) weighting function, but this is not common because there is much interest in discontinuities at p = 0 and p = 1.

EVALUATION:

Cautious EU and its axiomatization are mathematically highly appealing and esthetic. In full generality the model is way more general (less parsimonous) than other models and, hence, less tractable. But more restricted (parsimonous) subfamilies can be developed and, in particular, the complexity of solving a minimization problem for every lottery to be evaluated can be made tractable this way.

Empirical problems are that, whereas RDU imposes an extra layer on EU that can give both extra risk aversion or extra risk seeking and, in particular, can have that depend on probabilities which is empirically and psychologically desirable, this model only imposes an extra risk aversion layer (cure: could easily be modified by α maxmin generalizations) that is outcome-oriented (no cure conceivable for this). %}

{% First I present a misleading reasoning that mispresents this paper, and then the correct reasoning. Imagine an implicit equation F(x) = G(x). I define H(x) = F(x) – G(x). Then x = $H^{-1}(0)$. Now didn’t I turn an implicit equation into an explicit one, using function inversion? Isn’t this trivially always possible if one can use function inversion? Of course, the above rewriting is trivial and not of any use. (As an aside, my little Pascal program, written 35 years ago, to obtain function inverses has helped me throughout my life to solve any equation I want, turning it into the most useful thing I ever did. I still use it today (2021) on my 20 year old computer - it doesn’t run on modern computers.)

A problem of Gul’s disappointment aversion model and, more generally, betweenness models, is that they only give implicit equations for functional values and certainty equivalents. This paper gives explicit rewritings of disappointment aversion and many other betweenness preferences using function inverses, but in particular useful manners that give good insights and facilitate computations (though they can remain difficult). They need the NCI preference condition for it, leading to infimum operations. The term explicit representation is to be taken in this sense. %}

{% This paper introduces cautious utility, a new theory for decision under risk, or, a generalization of their 2015 theory. It generalizes the 2015 theory to multiattribute outcomes, and adds a central role to a reference point. The authors assume that the first attribute concerns money. The theory assumes a set of utility functions and then, for DUR, assigns the minimum expected utility to each lottery. This adds extra risk aversion (worse certainty equivalents), beyond expected utility. The pessimistic minimum taking already brings extra pessimism and loss aversion when choosing between riskless outcomes, cautiousness, which can better be interpreted as endowment effect, already bringing WTP-WTA discrepancy. More, extra, cautiousness, risk and loss aversion, can come when risk comes in. The model can thus deliver a distinction between a riskless endowment effect and risky loss aversion. Cautiousness is one factor jointly inducing extra endowment effect, extra loss aversion, and extra certainty effect (and other deviations from EU for risk). I interpret it as follows. Cautiousness is a new thing. One can distinguish some subcomponents of it, where one brings an *extra* CE effect, another brings *extra* endowment effect, and one brings *extra* loss aversion. Cautiousness gives a new way to add to those phenomena. Thus, it gives a new way to add to risk aversion. But it absolutely does not fully capture those phenomena, let be unify them.

The authors interpret cautious riskless preferences as uncertainty about what the proper tradeoffs are, processed in a very pessimistic way. For a mug and trading off the first attribute of money against the second attribute of mug, because of pessimism in WTP you take the lowest value of the mug, and in WTA the highest, giving WTA > WTP.

For multi-attribute outcomes, one can first specify a utility function that captures preference over all (riskless) outcomes, and from there on apply any risk model such as prospect theory. This is the more common approach and the one I am most familiar with. An alternative route is to do a sort of component-wise risk modeling. This is what cautious utility does, and it brings more novelty. Especially because it gives a new way to capture the endowment effect.

EXAMPLE [where cautious utility would not bring real novelty]. Under prospect theory, loss aversion is commonly modeled through an asymmetric utility function, steeper for losses than for gains with a kink at 0. Cautious utility theory can readily incorporate this by letting all functions in the set of utility functions be asymmetric and have the same kink at 0. □

Cautious utility has a way to capture extra loss aversion differently than in the example, and really new. That is, to bring in a new component to loss aversion. To maximally clearly bring out this novelty, the paper focuses on symmetric utility functions, so that prospect theory's way of modeling loss aversion is entirely ruled out.

P. 2072: "The most popular model to study our behaviors of interest is Cumulative Prospect Theory (Tversky and Kahneman (1992))" (**Prospect theory/Rank-Dependent Utility most popular for risk**).

The authors interpret cautious utility as a new theory distinct from prospect theory, capturing uncertainty about tradeoffs between attributes. Here is a way to bring back prospect theory: In cautious theory, there are two stages of uncertainty, one about the tradeoffs between attributes, and the other about the probabilistic risk through the lotteries. The uncertainty about tradeoffs between attributes is treated in a totally pessimistic manner, giving all weight to the worst case. I expect that modeling that stage of uncertainty using PT with loss aversion (yes: loss aversion!) will work better than the cautious model for what they call endowment effect. %}

Cerreia-Vioglio, Simone, David Dillenberger, & Pietro Ortoleva (2024) "Caution and Reference Effects," *Econometrica* 92, 2069–2103. https://doi.org/10.3982/ECTA21748

{% **quasi-concave so deliberate randomization**; This paper considers an interval [w,b] of monetary prizes and the set of lotteries over them (need not be simple). Subjects choose from finite sets A of lotteries, but they can randomize and thus choose from all probability distributions over A. It means that in fact they choose two-stage lotteries. Reduction of compound lotteries is assumed, meaning that in fact subjects choose from co(A), the convex hull of A. They assume single choices, so, if there is a set of indifferent best ones then one is selected one way or the other.

Theorem 1 gives two equivalent ways of describing the above model.

Randomization between indifferent optimal elements need not be "real" randomization, but just arbitrary selection. There is real randomization, roughly, if $\lambda p + (1-\lambda)q \succ r$ even though $p \prec r$ and $q \prec r$ (the paper does it a bit differently by bringing in stochastic dominance). Theorem 2 (p. 2432) shows that regularity is violated if and only if real randomization occurs, which holds if and only if there is some strict convexity of preference somewhere. Proposition 1 shows, under continuity, that this is equivalent to a violation of strict stochastic dominance. The intuition of Theorem 2 is explained on p. 2427: "Possibly the most well-known property of stochastic choice, widely used in the literature, is Regularity (also called Monotonicity): it posits that the probability of choosing p from a set cannot decrease if we remove elements from it. It is often seen as the stochastic equivalent of independence of irrelevant alternatives (IIA), and it is satisfied by many models in the literature, most prominently, models of Random Utility, albeit it is well known that it is often empirically violated. We show that our model of deliberate stochastic choice will necessarily lead to some violations of Regularity (unless the stochastic choice is degenerate, i.e., there is no stochasticity). Intuitively, our agent may choose from a set A two options that, together, allow her to "hedge." But this holds only if they are both chosen: they are complementary to each other. If either option is removed from A, the possibility of hedging may disappear and the agent no longer has incentive to pick the remaining one, which in turn generates a violation of Regularity. The key observation is that the agent considers all the elements chosen as a whole, for the general hedging they provide together. By contrast, Regularity is based on the assumption that the appeal of each option is independent from the other options present in the menu or in the choice."

Luce (1959) also had a probabilistic generalization of independence of irrelevant alternatives, but if I remember right it was more restrictive than regularity, imposing conditional probabilities (I am not sure).

Details:

- P. 2425 Footnote 2 writes that Tversky (1969) was the first to write on stochastic choice. But there is much preceding literature. For instance, in Luce, R. Duncan & Patrick Suppes (1965) "Preference, Utility, and Subjective Probability." In R. Duncan Luce, Robert R. Bush, & Eugene Galanter (eds.) *Handbook of Mathematical Psychology*, Vol. III, 249–410, Wiley, New York, Chs. 19.5-19.8, pp. 331-402 are on it.

- P. 2426 writes: "Crucially, convexity is a property shared by many existing models of decision making under risk, and it captures ambiguity aversion in the context of decision making under uncertainty." I view this differently. Convexity is an absolute property, reflecting pessimism. Ambiguity aversion is a relative property, reflecting more pessimism for ambiguity than for risk (Wakker 2010 §11.6).

P. 2429 Axiom 1: Unfortunately, the authors use the term "rational" for a mathematical property, amounting here to stochastic dominance. This is OK in math where one has much liberty to use everyday language to define abstract concepts and, for instance, is often done in theoretical game theory, but is unfortunate in economics where we want to use the word in its natural-language meaning. %}

{% This paper illustrates how many representation theorems of Choquet integrals can be applied in finance.

In finance, we consider a finite state space $S = \{s_1,\ldots,s_n)$, and financial assets x are maps from S to $\mathbb{R}$. So, what Savage calls an act. V(x) is the market price of x, at which you can buy or sell x. Whereas economists usually take a preference relation $\succcurlyeq$ over acts as primitive, finance takes V as primitive, as does the risk measure field (and, for instance, production and price theory in economics also do). I assume, for simplicity, that all payments are done at one fixed time, say tomorrow. A call option at strike price k ($k \in \mathbb{R}$) is the asset $x \vee k$, giving k whenever $x(s) \le k$ and x(s) whenever $x(s) \ge k$. A put option at strike price k ($k \in \mathbb{R}$) is the asset $-(x \wedge k)$, giving $-k$ whenever $x(s) \ge k$ and $-x(s)$ whenever $x(s) \le k$. It readily follows that

$$x \vee k - (-(x \wedge k)) - k = x.$$

The put-call parity requires that the market price V, to avoid arbitrage, should respect this equality and satisfy

$$V(x \vee k) - V((-(x \wedge k))) - V(k) = V(x) \quad (*)$$

where it is understood that $V(k) = k$.

Avoiding arbitrage everywhere is equivalent to as-if risk neutral pricing, i.e., maximizing subjective expected value. This is the “fundamental theorem of finance.” It was essentially first proved by de Finetti (1931), in individual choice theory, not very well known in finance. In economic terms, it implies linear utility.

This paper considers the condition that arbitrage is not avoided everywhere, because of frictions, but that the put-call parity (*) is still satisfied. It shows that this holds, under regularity conditions, if and only if the market price is a Choquet integral. In economic terms, it still implies linear utility. It uses a theorem by Greco (1982) that provides most of the maths needed for this. As these annotations indicate at Greco’s paper, Anger (1977) preceded it with a more general theorem. As Anger (1977) is more general than Schmeidler (1986) and also preceded it. Hence, the axiomatization in this paper essentially follows from Anger. Wakker (1989 Fuzzy Sets and Systems) used Anger’s condition in a preference axiomatization and used the term maxmin relatedness for it. %}

{% This paper revives the local utility analysis by Machina (1982), connecting it with the valuable generalization of vNM EU by allowing for incompleteness by: Baucells & Shapley (2008) and Dubra, Maccheroni, & Ok (2004) (two papers written independently and simultaneously, using sets of vNM utilities and unanimous agreement). It further shows that prospect theory with risk aversion and prudence must reduce to EU. I conjecture that pospect theory can be reconciled with risk aversion and prudence if prudence is taken in a comonotonic cosigned way, and not in the traditional way as done here. The authors define prudence in terms of the 3rd derivative of utility in EU, but this is just in that definition of EU and does not refer to the utility actually used, so, it does not require the utility actually used to be differentiable. %}

{% This paper assumes the Anscombe-Aumann framework, with linearity of the vNM utility function. Then it gives a general representation for quasi-convex functionals; i.e., it characterizes quasi-convexity of preference, interpreted as uncertainty aversion. For the special case of RDU for uncertainty (also known as CEU), because utility is linear, their quasi-convexity will be equivalent to convexity of the weighting function.

To explain the model, I first discuss concave functionals. (It would be more convenient if the weakening of concavity, called quasi-convexity, were called quasi-concavity here, but I stick with the terminological conventions of this field.)

Assume the usual Anscombe-Aumann framework with n states of nature and prize set X. Take u(x), the vNM utility of prize x, as unit of outcome. Take a functional V that now is nothing but a function from $u(X)^n$ to $\mathbb{R}$. It is well known that V is concave if and only if it is the minimum of the dominating linear functions. In the presence of monotonicity and normalization, we can take those dominating linear functions as EV functionals determined by the subjective probabilities assigned to states. Because EV in u units is usually called expected utility in the Anscombe-Aumann framework, I will do so too henceforth. So, a functional then is concave if and only if it is a maxmin EU model, which is nice to know.

Gilboa & Schmeidler (1989) characterized maxmin EU by imposing concavity of preference (uncertainty aversion), which amounts to quasi-convexity, rather than concavity, of the representing functional. They mainly added certainty independence to go from quasi-convex to concave.

The present paper drops concavity of the functional (and certainty independence), imposing only quasi-convexity. Then the functional is not the minimum of a set of dominating EU functionals, but of a quasi-concave G transform of those EU functionals. Here G depends not only on its u(x) input, but it can also entirely depend on the EU functional; i.e., on the subjective probabilities p chosen on the state space. Its quasi-convexity concerns both mixing in u(x) and in p. We need not consider a subset of dominating EU functionals, but can just use all EU functionals, by letting G take value infinite for all the EU functionals to be ignored. The functional is of course general, depending on all subjective probabilities over S. But it is a convenient way to unify many models.

The paper describes for many models what they mean in terms of their G function, such as the variational model (G is additively decomposable), the Chateauneuf-Faro (2009) model (G is multiplicatively decomposable), the smooth model (for φ concave), and probabilistic sophistication.

P. 1284 $\ell\ell$. 3-4 below Proposition 6 writes: "The function G can thus be properly interpreted as an *index of uncertainty aversion*." [italics from original] The authors here only mean that the partial pointwise-dominance ordering of G is compatible with the Epstein-Ghirardato-Marinacci definition of more ambiguity averse than, because this is all that Proposition 6 shows. It does not mean that other orderings derivable from G would reflect more ambiguity aversion.

{% The authors define a statistics model, and a common decision theory model, which assumes Anscombe-Aumann. They define a mechanism to relate the statistical model to the decision theory model, and then show how all kinds of ambiguity models can be related to statistical techniques.

Theorem 6 characterizes the smooth model, but has the two-stage setup exogenous. (See footnote 31.) %}

Cerreia-Vioglio, Simone, Fabio Maccheroni, Massimo Marinacci, & Luigi Montrucchio (2013) "Ambiguity and Robust Statistics," *Journal of Economic Theory* 148, 974–1049.

{% The authors take Savage's SEU model, with state space S and subjective probability P, as point of departure. They assume an additional set M, interpreted as possible models of which we do not know which one is true, and apparently taken to be a set of subjective probability measures m on S. The beginning of the paper carefully explains that S is outcome relevant, and M is only instrumental. They assume that P is a μ weighted average over M, so, μ is the 2nd-order distribution over S. As a Bayesian I am happy to see that the authors are exemplary Bayesians here! P. 6755 middle of 2nd column writes: "The first issue to consider in our !!normative!! approach" [exclamation marks added], suggesting that the authors consider their approach to be normative.

A necessary and sufficient condition for P to be derivable from M is that if $m(A) = m(B)$ for all $m \in M$ then $1_A 0 \sim 1_B 0$ ($1_A 0$: get $1 under A and $0 otherwise) (p. 6756 Proposition 1).

A question addressed in this paper is when the 2nd stage μ can be recovered from P. Without further info about M it obviously cannot. The main case is if all in M is orthogonal (with which the authors indicate disjoint supports) or, more generally, if the elements of M are linearly independent. The authors cite Teicher (1963) for this result on p. 6756 1st para following Proposition 1. Note that this is an extreme case, where the different models considered are completely different. The authors add results referring to supports and absolute continuity. They give a mathematical intertemporal example, stationary and ergodic, where the condition is satisfied.

It is encouraging for theoreticians that PNAS took this mathematical paper. The authors relate to many important ideas, such as Hansen & Sargent's robust approach, Wald, Marschak, model uncertainty, with much knowledge of history. %}

{% The authors reveal incomplete preferences for choice under ambiguity in their Experiment 1 (§3.1). To this effect, they measure a matching probability of an ambiguous Ellberg 2-color bet, using choice lists (prizes €15 and €0). But, in each choice in the choice lists the authors have a third option, besides the risky or ambiguous bet, and that option is described as "I am indifferent between the two urns." to the subjects, and called option mix in the paper. Then a 50-50 lottery would choose the option for subjects. By classical theories, if a subject is not indifferent between the two bets, she should surely choose the one preferred. If she is indifferent, she may choose the mix, but need not, and may as well choose any of the two options. Hence, there will at most be few indifferences. And, by stochastic dominance and transitivity, each subject will in each single choice list have at most one indifference. The data show the opposite. Many subjects choose indifference, and even several times in single choice lists: 40% does it for the most critical choices. 23% never chooses mix, 29% chooses it exactly once, 13% twice, and 35% three or more times (p. 555; replicated pp. 557-558).

Several explanations other than incompleteness of preference under ambiguity can be considered. But the authors have a nice second experiment (§4) to halfway counter. Here they replace the ambiguous bet by a sure €7.5, so that they measure the probability equivalent. And here they find only few indifference choices. This does not fully rule out the alternative explanations, but at least gives a good counter. The alternative explanations will have to distinguish ambiguity from risk.

I think that a plausible explanation (not contradicting incompleteness, but giving it background) is that people want to avoid responsibility for a choice. The authors do not discuss this, although p. 582 in the appendix shows that subjects could choose an explanation "I don't like to have the responsibility of handling a situation that requires a lot of thinking" among 31 other ones. This may only happen for complex decisions involving ambiguity, and not for more clearcut decisions such as involving only risk.

A plausible explanation that is alternative is experimenter demand: The subjects think that the indifference option hasn't been put there for no reason, so the experimenters must be hoping that they will use them and, then, so they do. An alternative explanation can also be trembling hand, if stronger for ambiguity than for risk (the latter counters the authors' counterargument on p. 560). Such alternative explanations are hard to ever rule out.

The authors in the middle of p. 551 point out that they avoid connotations of incomplete preference or randomization to subjects, but are too optimistic in suggesting that, therefore, there could be no experimenter demand.

Some nonEU theories for risk allow strict preference for mixing lotteries. (**quasi-concave so deliberate randomization**) That is, if P ~ Q, then still 0.5P + 0.5Q can be strictly preferred to both P and Q, a violation of betweenness. For instance, this happens under RDU with concave (optimistic) probability weighting. Something similar could happen when ambiguity is present (violating certainty independence). This would then be an explanation alternative to incompleteness. But I do not believe that such singlestage preferences play any role here, because such things are too complex to be conceived by subjects. §5 (pp. 556-559) describes an experiment to see if subjects were willing to pay a positive amount (0.05€) so as to mix, to see if there is a strict preference for mixing. No very clear results come, with some willing to pay and some not. The conclusion (p. 560), hence, says that 30% may prefer randomization and 50% may be incomplete.

P. 551 1st para: ambiguity was implemented by letting a colleague compose the urns.

P. 551 (**suspicion under ambiguity**): they let subjects choose the winning colors.

P. 552 bottom: The authors apply RIS to each separate experiment. But, to my regret, they do several payments to each subject, one for each task. Empirically this will not matter much, but strictly speaking one does get income effects and one looses the theoretical incentive compatibility of RIS.

P. 554 2nd para: The "identifying assumption" entails that choosing indifference (mix) means indecisiveness, i.e., incompleteness. Subjects use whole regions of indifference but only when ambiguity is involved. %}

{% **losses from prior endowment mechanism**; RIS for each individual. N = 85; very bright students; use 4 choice list, for gains, losses, known and unknown probabilities (Ellsberg urns), always first with known probabilities, so order effects can be (p. 206 bottom).

They consider the smooth model, with a risky $x_{0.5}0$ equivalent to an ambiguous 100_E0, and the 2nd order probability of E is 0.5. Under the smooth model this implies

$\varphi(0.5U(x)) = 0.5\varphi\big(U(100)\big)$. (*)

Unfortunately, as a colleague pointed out to me, the paper uses a different, incorrect, equation:

$0.5U(x) = 0.5\varphi\big(U(100)\big)$. (**)

That Eq. ** cannot be correct can for instance be seen directly because replacing φ by $\varphi/2$ should not affect preference, which goes wrong in Eq. **.

The authors are not clear and do not write Eq. ** explicitly, but still it can be seen that they use it because:0: (1) it is suggested on p. 204 top; (2) a colleague of mine could exactly reproduce their Table 2 using Eq. **, and not using Eq. *. (3) their repeated claims that risk attitude cancels when measuring ambiguity attitude (assuming that U and φ are power functions) only follows from the incorrect Eq. **, and not from the correct Eq. *.

suspicion under ambiguity: subjects can choose color to gamble on, controlling for suspicion.

risk averse for gains, risk seeking for losses & convex utility for losses & ambiguity seeking for losses: They find risk aversion for gains, risk seeking for losses, ambiguity neutrality for gains, and weak ambiguity seeking for losses. Importantly, note that ambiguity is what is MORE than risk attitude, so that weak ambiguity seeking for losses means somewhat MORE under ambiguity than under risk (**uncertainty amplifies risk**). Find risk and ambiguity aversion positively correlated for gains, but unrelated for losses (p. 214) **correlation risk & ambiguity attitude**).

reflection at individual level for ambiguity & **reflection at individual level for risk**: They find the opposite, both for risk- and for ambiguity attitudes. Subjects risk averse for gains are also mostly risk averse for losses, and risk seeking for gains then mostly so for losses. Subjects ambiguity averse for gains are also mostly ambiguity averse for losses, and ambiguity seeking for gains then mostly so for losses. Unfortunately, they only report preference patterns and no correlations (of utility parameters that can serve as risk/ambiguity aversion parameters). They also find no relation between reflection for risk and reflection for ambiguity at the individual level, but it is not very clear.

They use the KMM (Klibanoff, Marinacci, & Mukerji) model. In their theory, they also allow for "subjective probability" at the extreme outcome as a subjective variable, which amounts to **biseparable utility.** In their data analysis they, however, do not do this and just take subjective probabilities as 50-50 (pp. 215-216). %}

{% I like the basic philosophy underlying this paper, as several others by these authors, that we should develop results assuming finitely many choice observations. The result of this paper is mathematical. The authors assume a finite number of observations of binary choices. Under continuity, if the domain is not too large (mainly, compact), then, if the finite set of choices is large and dense enough, we can infer the true preference relation from it to any desired degree of precision. A version is given for deterministic choice and for stochastic choice. This is the result of this paper. It is intuitively self-evident, but takes maths to get exact. They only consider cases where the finite set of choice situations has been randomly drawn (p. 1637).

criticizing the dangerous role of technical axioms such as continuity: This paper does the opposite, and uses bluff whenever the issue arises. For instance, end of Footnote 4: "continuity is a necessary regularity condition; without it, no meaningful inferences can be made with any finite amount of data." This latter claim is, of course, very incorrect. Most that the authors can say is that their approach cannot be used without continuity. Bear in mind that continuity means absolutely nothing without restrictions on the topology specified. Assumption 1 (1639), making topological assumptions, continues in the same style, when the authors write, below it: "Assumption 1 puts a necessary structure on the set of alternatives." Again, "necessary" can mean no more than that the authors need it for their approach, but the authors write ambiguously as if it is general. Same style at Assumption 3, below which the authors write: "The importance of having a dense set of alternatives is clear: without it, the characteristics of the preference remain unobservable on an open set, and for general classes of preferences, knowledge of the preference outside this set does not suffice to infer those unobservable characteristics." Here they seek to exploit the ambiguity of the term "general." In the para below Corollary 2, p. 1645, the authors themselves gives a counterexample, where knowing EU preferences on a small subdomain can determine them on the whole domain. %}

Chambers, Christopher P., Federico Echenique, & Nicolas S. Lambert (2021) "Recovering Preferences from Finite Data," *Econometrica* 89, 1633–1664.

{% This paper assumes that the empirical content of a theory is (at most) what it can predict for a finite data set (p. 2304 penultimate para). UNCAF (universal negation of conjunctions of atomic formula) axioms such as the weak axiom of revealed preference and transitivity are falsifiable and UNCAF, but continuity is not (**criticizing the dangerous role of technical axioms such as continuity**:a bit but not really) and completeness, under some assumptions about choice, neither is. The paper introduces formal terminology and results for the assumption, referring to mathematical logic and model theory.

P. 2305 has nice citation from Carl Sagan; "Absence of evidence is not evidence of absence."

P. 2308: two theories are observationally equivalent (Thom Bezembinder used the term data equivalent) if they have the same implications for finite data sets.

P. 2308: "The empirical content of a theory is the most permissive observationally equivalent weakening of the theory." It is next formalized in Definition 3.

The authors say on p. 2311 2nd para that decision theorists often call continuity technical. I discussed the dangers of continuity, of not just being technical, on several occasions, such as Wakker (1988 JMP pp. 432-433). This was also argued by Adams et al. (1970) and Pfanzagl (1966), and it is nice to see that the authors cite these works (on p. 2314). (**criticizing the dangerous role of technical axioms such as continuity**)

While not formalized, I used similar criteria of observability/empirical content in some works. I use it for instance to point out the dangerous empirical status of completeness. My book Wakker (2010 p. 38 penultimate para) writes: "A third argument against completeness concerns the richness of the models assumed, that constitute continuums, with choices between all prospect pairs assumed observable. We will never observe infinitely many data, let alone continuums (Davidson & Suppes 1956). Here completeness is an idealization that we make to facilitate our analyses. Although it has sometimes been suggested that completeness and continuity for a continuum-domain are innocuous assumptions (Arrow 1971 p. 48; Drèze 1987 p. 12), several authors have pointed out that these assumptions do add empirical (behavioral) implications to other assumptions. It is, unfortunately, usually unclear what exactly those added implications are (Ghirardato & Marinacci 2001b; Krantz et al. 1971 §9.1; Pfanzagl 1968 §6.6; Schmeidler 1971; Suppes 1974 §2; Wakker 1988)." The topic is central in Wakker (1988 JMP p. 422 and Example 7.3 and what follows), Köbberling & Wakker (2003 p. 410 last three paras." Further references criticizing continuity for not properly separating observable and non-observable conditions include Fuhrken & Richter (1991, p. 94) and Luce et al. (1990 p. 49).

P. 2315 2nd para presents Samuelson's counter to Friedman, where Samuelson very strictly separates falsifiable and nonfalsifiable. If the readers can bear another self-reference, Wakker (2010 p. 3 middle) counters in an opposite direction, by arguing that usually we do not know what will be falsifiable and what not.

It seems that this paper discusses in detail that we can never really falsify indifference from revealed preference unless we add assumptions such as nonsatiation. Wakker (1989 §1.1.5) discussed this calling it the preliminary choice problem. %}

{% Propose a generalization of mean-variance where the combination of mean and variance can be anything monotonic (so, only weak separability in the two) and, the main contribution, it goes for uncertainty/ambiguity rather than for risk. Assume Anscombe-Aumann, although as often these days they just take a mixture space (p. 616). They mention Anscombe-Aumann as one case, but explicitly also consider the case of monetary outcomes and linear utility, referring to "finance applications" for its interest. Assuming the Anscombe-Aumann framework, the mean is mean Anscombe-Aumann-EU. Instead of variance they take a generalized dispersion measure, satisfying conditions specified below.

A probability measure π on the state space S is derived subjectively à la Savage (or Anscombe-Aumann). The model is very general and encompasses Siniscalchi's (2009) vector utility, variational, multiplier, and many other models. The authors share with Siniscalchi (2009) a complementarity axiom (here taken objectively rather than subjectively as by Siniscalchi: P. 619 footnote 8) that rules out likelihood insensitivity/inverse S, slo that I think the model will not be suited to fit empirical ambiguity attitudes. There may be interest in finance though, and the paper is targeted to that. They generalize Grant & Polak (2013) JET mainly by giving up the additive decomposability in mean and dispersion, but only have weak separability and some other (in)equalities there (complementarity independence, common-mean certainty independence, and common-mean uncertainty aversion).

P. 613: a measure of dispersion is the subjective EU an agent would be willing to give up to achieve constant EU over the state space.

P. 613: they argue that ambiguity aversion need not always be constant as in Grant & Polak (2013), which motivates the generalization.

P. 614: the general form is

$V(f) = \varphi\big(E_\pi(U \circ f)\ ),\ \rho(U \circ f)\big)$ where φ is bivariately weakly separable, $E_\pi(U \circ f)$ denotes the subjective Anscombe-Aumann EU, ρ captures dispersion about $E_\pi(U \circ f)$, and $\varphi(y,0) = y$. P. 615: $\varphi(\mu,0) - \varphi(\mu,\rho)$ is the absolute uncertainty premium in utils.

P. 617b lists axioms, including subadditivity $\big($3(b)$\big)$ and symmetry $\big($3(d)$\big)$, each ruling out likelihood insensitivity. Symmetry is captured by Axiom A5, complementarity independence (p. 619). Axiom A.6 (p. 620) is common-mean uncertainty aversion and also rules out likelihood insensitivity. Axiom A.7 (p. 620) is common-mean certainty independence, imposed only for acts f and g that have a common “mean” (π-EU). Axioms A.1-A.7 are necessary and sufficient for their model (Theorem 2, p. 621).

P. 623 penultimate para: their A.7 is not weaker than weak certainty independence of Maccheroni et al. (2006 JET), but common-mean translation invariance is weaker than the translation invariance property implied by weak independence.

Pp. 625-626: they can handle Machina’s examples. Pp. 627: relations to CAPM. %}

{% This paper is a rewritten version of the working paper Frick, Iijima, & Le Yaouanq (2019) "Boolean Representations of Preferences under Ambiguity."

The authors assume the Anscombe-Aumann framework.

Any sufficiently smooth function (absolutely continuous/bounded variation) can be written as a sum of a strictly increasing and strictly decreasing function. In the same spirit, one can, by properly combining max and min, generate almost every function, in a similar way as one can generate almost every kind of set by properly combining union and intersection. This is, if I understand well, underlying several papers by Efe Ok, e.g., the appealing Hara, Ok, & Riella (2019), cited in this paper. This paper presents a result in this spirit in the Anscombe-Aumann framework.

We throughout assume Axioms 1-4 (weak ordering, monotonicity, nondegeneracy, and Archimedeanity w.r.t. probabilistic mixing, and Axiom 11 (mixture independence, i.e., expected utility for lotteries). Theorem 4, p. 1048, shows that in this almost complete generality the representing functional W can be written as resulting from a maxmin operation:

$$W(f) \;=\; \max_{G\in\mathcal{G}}\inf_{\mu\in\Delta(S)}G\big(\mathrm{Exp}_{\mu}[u(f)],\mu\big)$$

where u is the EU ("vNM") utility function, $\Delta(S)$ the set of all probability distributions (called beliefs) over the finite ("horse") state space S, G from $\mathbb{R}$ ×

$\Delta(S) \to \mathbb{R}\cup\infty$ increasing (don't know if they mean strictly increasing or nondecreasing) in first argument and $\mathcal{G}$ a set of functions G that are quasiconvex and such that W(a) = a for all constant functions f with f(s) = a for all s. It reminds me not only of the general Hara, Ok, & Riella (2019), but also of the very general functional in Cerreia-Vioglio, Maccheroni, Marinacci, & Montrucchio (2011, JET).

Theorem 3 specifies the preceding result by reinforcing independence for lottery mixtures to weak certainty independence, which amounts to constant absolute ambiguity aversion in utility units. Then the representation specifies the function G and becomes

$$W(f) = \max_{c\in\mathcal{C}}\inf_{\mu\in\Delta(S)}\big(\mathrm{Exp}_{\mu}[u(f)] + c(\mu)\big)$$

$\mathcal{C}$ denotes a set of convex cost functions c: $\Delta(S) \to \mathbb{R} \cup \infty$.

Theorem 2 specifies Theorem 3 further by reinforcing weak certainty independence into full-force certainty independence, which amounts to adding constant relative ambiguity aversion in utility units. Then the representation is further specified into the dual-self expected utility model (DSEU) (called Boolean expected utility in their 2019 working paper) assigns to act f the value

$$W(f) = \max_{P\in\mathcal{P}}\min_{\mu\in P}\mathrm{Exp}_{\mu}[u(f)]$$

where P is a usual set of priors over the state space (horse race) of the Anscombe-Aumann framework, and $\mathcal{P}$ is a collection of sets of priors. This model is put central by the authors. It satisfies Savage's P4 (**event/outcome driven ambiguity model: event driven**).

In all the above, the same class of models results if we interchange max/sup and min/inf. The model can be interpreted as a zero-sum game between a maximizating and a minimizing agent, so, between an optimist and a pessimist.

The DSEU model had been considered before, by Ghirardato, Maccheroni, & Marinacci (2004; invariant biseparable), as the paper points out in the abstract and intro.

As nonadditive measures in Choquet expected utility have too high cardinality to be very useful in general, thus sets of priors in multiple prior models have even more (Basu & Echenique 2020) too high cardinality to be very useful in general. The above model has yet drastically higher generality, because the set $\mathcal{P}$ has very high cardinality, indeed, leading to an almost completely general model. But this general model is useful in appealingly organizing and unifying models, and providing starting points for specifications. The model readily captures general preferences and hence, readily represents basic preference properties.

If $\mathcal{P}$ has exactly one element (surely no power for the maximizing agent), then the model is maxmin EU. If all P are one-element (surely no power for the minimizing agent), then the model is maxmax. Schmeidler's uncertainty aversion, i.e., preference for probabilistic mixing, i.e., preference for all hedges, holds iff all options available to the optimist are identical (up to irrelevant changes) so that the optimist is powerless. The sets available to the optimist have nonempty intersection if and only if there is preference for complete hedges (mixtures that give a lottery for sure). One can readily see that the pessimist always has an element of the nonempty intersection available, she can just always choose that and hence can do expected utility and be uncertainty neutral. So, there is an EU upper bound to her evaluation. It implies (I don't know how to prove but the authors do) that her real preference relation then in fact satisfies preference for complete hedging.

The authors consider k-ambiguity aversion: If $f_1 \sim \cdots \sim f_k$ then every convex probabilistic mixture $\lambda_1 f_1 + \cdots + \lambda_k f_k$ that is a complete hedge $p \in \Delta(S)$ is preferred to them. It means, roughly, that all unions of elements of k-fold partitions are relatively underweighted. 2-ambiguity aversion gives source dispreference relative to SEU: For every event E we can take convex weights α, $1-\alpha$ such that, denoting outcomes in utility units, $f_1 = \alpha_E 0 \sim 0_E(1-\alpha) = f_2$ and then $(1-\alpha)f_1 + \alpha f_2$ gives the preferred complete hedge that under rank-dependent utility implies $W(E) + W(E^c) \leq 1$. For k ambiguity aversion, I focus on a k-fold partition $E_1,\ldots,E_k$ that is uniform, i.e., with all events exchangeable, so that we have local probabilistic sophistication, and I assume rank-dependent utility for ambiguity, i.e., Choquet expected utility, with weighting function W. Then k-ambiguity aversion holds here if and only if $W(iE) \leq i/k$ for every disjoint union of i elements of the partition. (We can take 1/k probabilistic mixes of k such events giving a complete hedge with the sure outcome utility i/k.) Proposition 3 (p. 1040) shows that k-ambiguity aversion is equivalent to every k-tuple of collections for the optimist being nonempty. It implies that for every k-tuple of acts and every assignment of a choice set to each act by the optimist, the pessimist has an SEU representation available. In α maxmin, k-ambiguity aversion is equivalent to $\alpha \geq 1-1/k$.

Insensitivity gives overweighting of unlikely events. If in the aforementioned k-fold partition each single event is overweighted, then k-ambiguity aversion cannot hold. In this sense, the model can accommodate insensitivity by not imposing k-ambiguity aversion for large k. It is crucial here that DSEU is event driven. (**event/outcome driven ambiguity model: event driven**)

k-ambiguity aversion, or its exclusion, do not come close to insensitivity because the characteristic property of insensitivity is overweighting of unlikely events *together with* underweighting of likely events. k-ambiguity aversion concerns underweighting of all events involved, likely as much as unlikely.

For a fixed event E, we have source preference of SEU over $\{E,E^c\}$ i.e., with M denoting matching probability, $M(E) + M(E^c) \leq 1$ (local ambiguity aversion), if and only if for every pair of collections that the optimist can choose the pessimist can choose from that pair such that the same P(E) results. So, there is a dominating SEU available to the pessimist regarding $\{E,E^c\}$. Under α maxmin this holds iff $\alpha \geq 0.5$. The DSEU model can accommodate local ambiguity aversion together with local ambiguity seeking by letting the sets of priors and their collections behave differently for different sources of uncertainty. The α maxmin model cannot accommodate it. The end of §3.1 (p. 1043) points out that the smooth model neither can.

The authors also propose formulas for updating and relate them to the DSEU model (**updating under ambiguity**). %}

{% Measure usual behavioral attitudes, 21 in total, for representative sample of 1000 people. There are 8 indexes of social behavior, 9 of risk/uncertainty, 3 of overconfidence, and 1 of time preference. Principal components analysis reveals six factors: generosity, punishment (impulsivity), inequality/WTP (inequality aversion & bit risk aversion), WTA (risk aversion), uncertainty (ambiguity aversion and RCLA)

correlation risk & ambiguity attitude: they find unrelated.

They find a high relation between violations of RCLA and ambiguity aversion.

They find a negative relation between loss aversion and the endowment effect, which is strange because one would expect it positive. Well, the endowment effect, difference between WTP and WTA, has components other than loss aversion, such as bargaining (mis)perception.

cognitive ability related to risk/ambiguity aversion: there is a positive relation between cognitive ability and both risk and ambiguity aversion, significant but very weak (0.03 or so). %}

Chapman, Jonathan, Mark Dean, Pietro Ortoleva, Erik Snowberg, & Colin F. Camerer (2018) "Econographics," working paper.

{% %}

Chapman, Jonathan, Mark Dean, Pietro Ortoleva, Erik Snowberg, & Colin Camerer (2022) "On the Relation between Willingness to Accept and Willingness to Pay," working paper.

{% Version of 4 Sept 2018:

RIS: They pay each subject TWO randomly chosen choices. I regret that they did not do only one (say for double stakes), losing all the good theoretical properties, and I think also confusing subjects.

They measure preferences where computer program, after each choice of an individual, determines which next choice stimuli will be most informative. So, indidivually dependent adaptive. Pro is that the esatimation per individual is more efficient, but con is that the stimuli are different for every subject so that we cannot do within-stimulus-between-subject analyses. A similar technique was used by Cavagnaro and co-authors in various papers, e.g., Cavagnaro, Pitt, Gonzalez, & Myung (2013). If I understand right, DOSE has extra facilities of correcting mistaken choices in the beginning of the experiment.

The authors take a representative (N = 2000) US sample. Choices are between

(0.5:x, 0.5:-x) and 0 or between (0.5:2x, 0.5:0) and x. The authors assume loss aversion but no probability weighting. The use the gain questions to estimate utility curvature with power utility and the same power for gains as for losses (finding average power 0.69), and then the mixed choices to estimate loss aversion. Because of symmetry of utility about 0, utility curvature will not affect loss aversion much. They also estimate a discount factor for each subject, where the present effect plays no role in their stimuli and is found not to play a role in the results. They use the risky utility function in analyzing discounting. For the gain choices the authors use WTP and WTA formulations, which may generate rerference dependence and perceptions of losses.

Their DOSE performs well in having little noise, good stability (they replicated within-subject half a year later), and better relations with other variables. They find on average no loss aversion, even a bit of gain seeking. There is, surprisingly, a positive relation between cognitive ability and loss aversion (**cognitive ability related to risk/ambiguity aversion**). I conjecture that this is because low cognition subjects are not less loss averse, but have something like joy of gambling.

Men/young people and stock owners are most loss averse. There is a weak positive relation between cognitive ability and doing expected value maximization (**cognitive ability related to risk/ambiguity aversion**).

Strangely enough, the authors find that loss aversion is as stable over time as utility curvature. I conjecture that this may be because the WTA/WTP formulations of gains generate reference dependence and loss aversion. %}

Chapman, Jonathan, Erik Snowberg, Stephanie Wang, & Colin F. Camerer (2018) “Dynamically Optimized Sequential Experimentation (DOSE) for Estimating Economic Preference Parameters,” working paper.

{% In big representative samples (in total, N = 3000), they find that half the subjects are the opposite of loss aversion, what I often call gain seeking and what the authors call loss tolerant. This goes contrary to may other studies that report prevailing loss aversion. The authors suggest that this may be because most studies used student subjects, and that loss aversion occurs only for students but not for representative samples.

I have a different opinion. I think that in general loss aversion is prevailing

and is one of the strongest phenomena regarding risk attitudes. But at the same time it is very volatile and hard to predict, and changing one word may as well double it or rule it out entirely. Thus, different studies find different things.

What may play a role here is that the authors use many 50-50 lotteries, where the opposite of loss aversion and risk aversion is often found. See the keyword "**risk seeking for symmetric fifty-fifty gambles**" in this bibliography, giving many such findings.

The authors also find no correlation between loss aversion and the endowment effect. Again, I belief that those will be positively related. An explanation for the mentioned finding can be that this is H0 due to noise. There can be expected to be much noise here. Thus, the authors do find a relation for subjects with good cognitive ability (**cognitive ability related to risk/ambiguity aversion**). An impressive data set Gächter, Johnson, & Herrmann (2022) also found a positive relation. %}

{% **social risks > nature risks in coordination games**

Measure CEs (certainty equivalents) in game situations. CEs are higher in coordination game (which is cooperative) than in matching pennies (which is competitive). These things are moderated if "opponent" is random computer. Neuroimaging is used to find correlations with brain activities.

A difficulty is that the measurement of the CEs in this paper interferes with the games. What happens is, first, players are asked what they play if they have to play a game. Next, some players are given the choice to either play the game, or instead get a sure outcome for themselves (and then the same sure amount for their opponent). This impacts the game by forward induction. If your opponent had the choice between the game and the sure amount, and chose the game, then this signals that she wants to get more money from the game than the sure money amount, which for instance may rule out some equilibria. In the coordination game it makes it extra safe to also enter there and go for a high amount. Thus, it makes coordination games extra attractive. %}

Chark, Robin & Chew Soo Hong (2015) "A Neuroimaging Study of Preference for Strategic Uncertainty," *Journal of Risk and Uncertainty* 50, 209–227. https://doi.org/10.1007/s11166-015-9220-9

{% Use real incentives.

Use front-end delay: Choices between receiving money after 2 or 9 days (proximate), after 31 and 38 days later (intermediate), and after 301 versus 308 days (remote). They find decreasing impatience when going from proximate to intermediate, but not when going from intermediata to remote. %}

Charness, Gary, Uri Gneezy, & Alex Imas (2013) "Experimental Methods: Eliciting Risk Preferences," *Journal of Economic Behavior and Organization* 87, 43–51.

{% Survey belief measurements. Adding my opinion: the results of introspective measurements are hard to interpret, especially for use in normatively justified decisions. What the authors call simple methods pay probability estimates according to whether they are close to true probabilities, but, then, can only be used in the uninteresting case where the experimenter already knows the true probability distribution. %}

Charness, Gary, Uri Gneezy, & Vlastimil Rasocha (2021) "Experimental Methods: Eliciting Beliefs," *Journal of Economic Behavior and Organization* 189, 234–256.

{% **updating: testing Bayes' formula**: a refinement of the Charness & Levin (2005) design gives violations of stochastic dominance. The larger the groups to decide and the more transparent the stimuli, the fewer the violations of stochastic dominance. %}

Charness, Gary, Edi Karni, & Dan Levin (2007) "Individual and Group Decision Making under Risk: An Experimental Study of Bayesian Updating and Violations of First-Order Stochastic Dominance," *Journal of Risk and Uncertainty* 35, 129–148.

{% They study the Linda conjunction fallacy of Kahneman & Tversky (1983). In the replication they find 58% rather than the 85% (note the reversal of digits …; typo!?) that K&T did; here subjects received a flat $2 payment. Then they redid, telling the subjects that there was a correct answer, and paying $4 to who gave the correct answer. This reduced the error rate to 33% (**real incentives/hypothetical choice**; p. 554). They also let groups of 2 and also of 3 answer. The groups, especially of 3, had much lower error rates, both with answer-contingent payment and with flat payment.

Note that paying for the correct answer versus flat is a way of rewarding different than the real-hypothetical decisions distinction. Here it is not a decision

the outcome of which is real or hypothetical, but just a different payment for an effort. In the hypothetical treatment there is no reference to any hypothetical payment. %}

Charness, Gary, Edi Karni, & Dan Levin (2010) "On the Conjunction Fallacy in Probability Judgment: New Experimental Evidence Regarding Linda," *Games and Economic Behavior* 68, 551–556.

{% Consider three-color Ellsberg urn with 36 balls (slips in envelope but I write balls), with a known number X of red balls, and 36−X black and yellow balls in unknown proportion. They find the switching value X, which is similar to matching probability but not the same because the number of black/yellow also changes. Subjects who switch between 11 and 13 are ambiguity neutral. Then choosing known or unknown for X = 12 are both taken as ambiguity neutral. The latter is for 60% (n = 164) of their subjects. Subjects who for X = 12 choose risky are categorized as ambiguity averse in most other studies but as neutral in this study; if there are many such subjects, it explains much of their finding. Further, 20% is inconsistent, 12% is ambiguity seeking, and only 8% is ambiguity averse **(ambiguity seeking**). Strange that so few of the latter. One might conjecture that many subjects are very weakly ambiguity averse, choosing red in classical Ellsberg experiments and also here when X = 12, in which case the majority of the subjects categorized as ambiguity neutral would choose to bet on red. This did not happen. Footnote 15 (p. 11) points out that only 50% of these subjects (82 of 164) chose red. Given the outstanding nature of red versus the other two colors, this can be taken as roughly ambiguity neutral.

suspicion under ambiguity: §2 discusses an experiment where they did not control for suspicion, then finding 25% ambiguity aversion. In the beginning of the paper the authors suggest that they deviate from most other studies, and find less ambiguity aversion than those others, because they, supposedly unlike the others, control for suspicion. However, as my keyword shows, most other studies have controlled for suspicion also in the past.

They also study subjects who try to convince each other of their preferences, with an incentive for them to convince each other. Ambiguity neutral subjects can convince ambiguity seeking and inconsistent, but less so ambiguity averse.

For both the first part, individual choice, and the second part (convince others), one choice was paid for real, which entails a mild income effect.

P. 20: "ambiguity aversion by no means seems as prevalent as some studies have suggested." %}

Charness, Gary, Edi Karni, & Dan Levin (2013) "Ambiguity Attitudes and Social Interactions: An Experimental Investigation," *Journal of Risk and Uncertainty* 46, 1–25.

{% **updating: testing Bayes' formula**: Considers case where Bayesian updating means CHANGING successful strategy, so that the former can be distinguished from heuristic-like continuation of strategies that were successful in the past, more or less a myopic version of CBDT, as follows. A coin has been flipped, giving H or T, unknown to an agent. There are an upper and lower urn, containing B and W balls, where the distribution of H will always be more extreme than of the lower. One ball will be drawn from an urn, where B gives a valuable prize and W not, and sometimes you can choose from which urn this is to be done, upper or lower. H is more favorable because, if H, then the upper urn contains 6 B balls and 0 W balls, and the lower urn contains 4 B and 2 W, whereas if T then the upper urn contains 0 B balls and 6 W balls, and the lower urn contains 2 B and 4 W.

H	T
{B,B,B,B,B,B}	{W,W,W,W,W,W}
{B,B,B,B,W,W}	{B,B,W,W,W,W}

A first draw is done from the lower urn, and the agent sees its result. The agent can then choose from which urn the second and last draw should be made. If the first draw from lower is favorable and gives B, then Bayesian updating recommends to switch and 2nd draw should be from the upper urn. If the first draw is unfavorable and gives W, then Bayesian updating recommends not to switch and 2nd draw should again be from the lower urn. Myopic continuation of successful strategy, and changing of bad strategy, would suggest opposite.

In experiment the authors find about fifty-fifty of the two strategies. No payment in first draw reduces error rate. Error rates are also reduced if higher prizes, presence of affect for first draw (if they know before first draw whether B or W will be favorable) and being male do so too (**gender differences in risk attitudes; gender differences in ambiguity attitudes**). %}

{% **ordering of subsets**: This paper gives necessary and sufficient conditions, in full generality, for existence of probability measure representing qualitative probability relation. The ultimate result!

Assume that $\succcurlyeq$ is a preference relation on an algebra of events (subsets of a state space S, also called universal event). We call P *agreeing* if P is a finitely additive probability measure on the algebra, and

$E \succcurlyeq F \Rightarrow P(E) \geq P(F)$.

$E \succ F \Rightarrow P(E) > P(F)$.

This amounts to the usual $E \succcurlyeq F \Leftrightarrow P(E) \geq P(F)$ if and only if $\succcurlyeq$ is a weak order, but it is nicer because it also covers the practically realistic case of incomplete observations. 1_E denotes indicator function. The condition necessary and sufficient for comparative probability (existence of agreeing probability) is, besides well boundedness ($S \succ \varnothing$ and $S \succcurlyeq E \succcurlyeq \varnothing$ for all E):

For all $A \succ B$ there exists $\varepsilon > 0$ such that:

$E_j \succcurlyeq F_j$, $j = 1,\ldots,n$, $m > 0$, $k \geq 0$

&

$$m \times 1_A + \Sigma 1_{E_j} + k1_\varnothing = m \times 1_B + \Sigma 1_{F_j} + k1_S$$

& $k \leq m\varepsilon$

cannot be.

For finite S the condition is equivalent to excluding $k \leq 0$ (or, $\varepsilon = 0$) and was demonstrated by Kraft, Pratt, & Seidenberg (1959). It then amounts to the well-known necessary and sufficient condition for solving linear inequalities. The general way of turning this into preference conditions was explained beautifully by Scott (1964). For infinite S we have to ensure Archimedeanity, and the ε condition ensures it. Substitution of P shows that ε reflects $P(A) - P(B)$. %}

Chateauneuf, Alain (1990) "On the Use of Comonotonicity in the Axiomatization of EURDP Theory for Arbitrary Consequences," CERMSEM, University of Paris I; extended abstract presented at Fifth International Conference on the Foundations and Applications of Utility, Risk and Decision Theory (FUR-90).

{% Theorem 2 characterizes the maxmin EU model just as Gilboa & Schmeidler (1989, JME) did, but with linearity of utility referring to money-addition and not to the mixing of probabilities as in G&S. Chateauneuf and Gilboa & Schmeidler obtained their results independently, although at a late stage Gilboa helped Chateauneuf to correct a mistake in Chateauneuf's theorem, acknowledged in Footnote 9 of Chateauneuf's paper. The "fundamental lemma" on p. 623 of Chateauneuf (1988) stated the same result. Although it referred to a 1986 working paper of Gilboa & Schmeidler's 1989 paper, the results were obtained independently.

Theorem 1 provides an alternative to Schmeidler (1989), again with monetary outcomes and linear utility. It uses a nice weakening of comonotonic independence building on Anger (1977). Chateauneuf uses mixing independence and not addition independence.

{% **tradeoff method**: Axiom A4 is a weakened version of tradeoff consistency (if the latter were imposed on all events and not just states of nature). It is used jointly with something like tail independence, and suffices to imply proportionality of the additive value functions.

A4 says for, say, outcomes always ordered from best to worst, so, a ≽ c and b ≽ d:

(1) (p_1:x_1, p_2:a, p_3:a) ~ (p_1:y_1, p_2:b, p_3:b) and

(2) (p_1:x_1, p_2:c, p_3:c) ~ (p_1:y_1, p_2:d, p_3:d) imply

(3) (p_1:x_1, p_2:a, p_3:c) ~ (p_1:y_1, p_2:b, p_3:d).

(1) and (2) imply ab $\sim^*_c$ cd, and so do (1) and (3). So, this is a nice weakening of tradeoff consistency. It kind of implies, loosely speaking, that V_{p1+p2} is proportional to V_{p2}. A reformulation: if replacing the tradeoff ab by the tradeoff cd on an event A does not affect indifference, then neither should it do on any subset of A.

Additionally nice is that it also is a weakening of vNM-probability-mix independence. %}

{% **event/outcome driven ambiguity model: event driven**

Neo-additive means: non-extreme-outcome additive.

The simplest and most well-known version of the neo-additive model is **EU+a*sup+b*inf**. (My 2010 book defines it this way, explaining in Footnote 3, p. 319 that details about null events are ignored.) The authors write it as (1−δ)EU + αδsup + (1−α)δinf. The authors consider somewhat more general models, first explained intuitively: A subjective probability measure P is given. All events E with positive probability P(E) > 0 are possible and P-nonnull. However, there may be nonempty P-null events E with P(E) = 0 that are still considered to be possible. "Possible" thus is an additional category, broader than P-nonnull. A person maximizes EU w.r.t. P but assigns some extra weight to the infimum and the supremum POSSIBLE outcomes. Given P (in fact, for each P), the maximal set of possible events that can be considered is all nonempty events, leading to the aforementioned well-known model **EU+a*sup+b*inf**. Given P, the minimal set of possible events that can be considered is only all P-nonnull events. This leads to the RDU model with W(.) = w(P(.)) with w a neo-additive probability weighting function (w linear on (0,1) under the most common case of a ≥ 0 and a+b ≤ 1). This is the probabilistically sophisticated version of the neo-additive model. The authors allow for intermediate cases between these two extremes. In the notation of the authors, the weight for the supremum possible outcome is αδ, and the weight for the infimum possible outcome is (1−α)δ. δ indexes distrust in the beliefs P, α designates optimism beyond EU, and 1−α designates pessimism beyond EU.

Both α and δ are from [0,1], and are allowed to take the extreme values 0 or 1. $\delta = 1$ and $\alpha = 0$ indicate maximal pessimism, going by the infimum possible outcome (most extreme is if all nonempty events are possible, when acts are evaluated by their infimum outcomes, as in the opening formula above).

We can infer possibility from preferences. Event E is possible if and only if $x_Ey \nsim y$ for some outcomes x,y. x_Ey denotes the binary act in the usual way. There is a small inaccuracy in the paper regarding null/possible events, explained later. I first explain the paper's terminology and some other things. The paper uses the term null for impossible, which, as explained, is broader than P-null. Hence, nonnull is possible (including both what the authors call universal and what they call essential). They denote the set of null events by $\mathcal{N}$.

For the preference foundation, the authors use a subjective midpoint operation defined by Ghirardato, Maccheroni, Marinacci, & Siniscalchi (2003). This is somewhat complex to observe, especially because it needs many certainty equivalents, but it is possible. The authors, properly, do it only for 50-50 mixtures which, as just explained, are reasonably well observable. They do not use general mixtures as GMMS do and which is not really observable (for instance for a 1/3-2/3 mixture GMMS need infinitely many observations).

P. 544: They interpret δ as index of confidence in the EU probability, $\alpha\delta$ as index of optimism, and $(1-\alpha)\delta$ as index of pessimism (the authors there confuse optimism and pessimism). The authors do not explicitly commit to risk attitudes, but their interpretation of δ as disconfidence in P strongly suggests that they assign all deviations from EU to ambiguity and assume EU for risk. If this assumption does not hold, then their parameters reflect a general uncertainty attitude that captures both ambiguity and (part of) risk.

§4.1 shows how neo-additive can accommodate the coexistence of gambling and insurance, deviating from EU under risk.

nonadditive measures are too general: they may argue for this, but I am not sure if they do.

EXPLANATION WHY NULL EVENTS ARE NOT TREATED COMPLETELY CORRECTLY, FORMALLY (end indicated by open box □)

Given monotonicity, E is possible if and only if:

===================

[either

there exist outcomes $x > y$ with $x_E y \succ y$ (betting on E) (*)

or

there exist outcomes $x < y$ with $x_E y \prec y$ (betting against E) (**)]

In the neo-additive model,

===================

Given $\alpha > 0$, (*) is necessary and sufficient for possibility.

Given $\alpha < 1$, (**) is necessary and sufficient for possibility.

Given $0 < \alpha < 1$, (*) and (**) are equivalent.

In their preference condition on p. 548 ℓ. −6, the authors, unfortunately, relate the nullness of events only to bets on events (Eq. *), and not to bets against events (Eq. **). This is incorrect for the pessimistic case of $\alpha = 0$. Relatedly, the Hurwicz capacity in Definition 3.2 need not be exactly congruent for $\alpha = 0$ (then nonnull events may still have capacity 0), contrary to what the authors claim. In Theorem 5.1, null event consistency (Axiom 6) is not a necessary condition for the representation, contrary to what is claimed there. For instance, assume $\delta = 1$, $\alpha = 0$, and $\varnothing$ is the only null event. Thus, acts are evaluated by their infimum outcome (which is the minimal outcome in the paper because all acts are assumed simple there), implying the most extreme pessimism there is. The weighting function/capacity, which I denote W, has $W(E) = 0$ for all events except the universal event S. W is not exact because $W(E) = 0$ for many nonnull events. For each $\varnothing \neq E \neq S$ and $x \succ y$ we have $x_E y \sim y$, which according to the definition on p. 548 ℓ. −6 would mean that E is null. By Axiom 6 (null event consistency) it should imply $y_E x \sim x$, but this is not so, because $y_E x \sim y \prec x$. So, the representation does not imply null event consistency, contrary to what Theorem 5.1 claims. Their preferential definition of null and universal events (p. 548) does not imply that the latter are complements of the former, contrary to what is assumed throughout the paper. In the proof the authors incorrectly claim sufficiency of all their conditions on p. 565, not giving a proof.

It often happens under RDU that researchers relate likelihood interpretations only to the weighting function W (= capacity). Under RDU, likelihood is better related to the rank also and is better assigned to ranked events (as, you guessed it, in my 2010 book). In the neo-additive model, the best and the worst ranks play special roles, and besides best-ranked events the authors should also have considered worst-ranked events. □ (END OF EXPLANATION) %}

{% **biseparable utility violated;**

This paper provides the multiplicative analog of the variational model of Maccheroni, Marinacci, & Rustichini (2006, Econometrica). The latter generalized maxmin EU by imposing only the additive part of certainty independence (constant absolute ambiguity aversion in utility units) and not the multiplicative part (constant relative ambiguity aversion in utility units), leading to an extra term c(p) depending on the prior probability p. The present paper takes only the multiplicative part and thus generalizes maxmin EU by adding a nonnegative factor 1/φ(p) depending on prior probability p. Both generalizations have their pros and cons. P. 541 discusses the variational model but only in general terms, not referring to the additive/multiplicative analogy. Seems plausible that factor 1/φ(p) added to maxmin is attitude.

This paper writes the representation first in a more complex manner, with a threshold α_0 added, in the beginning, but φ can always be redefined to get rid of this α (Corollary 5). More preference for certainty à la Yaari (1969; the authors refer to Ghirardato & Marinacci for an interpretation as ambiguity aversion) is equivalent to pointwise domination by φ, but only if identical utility and set of priors.

To take the multiplicative part of certainty independence, the paper needs a zero point, and for this a worst consequence x_* is assumed, in their axiom 5 (worst independence). $u(x_*)$ will be 0. %}

{% My annotations below concern the version of mid 2020.

The authors present variations of theorems as in Köbberling & Wakker (2003 *Mathematics of Operations Research*). All results below remain valid if the domain is a comoncone rather than a whole product set, and all results extend to biseparable utility, so that many ambiguity theories are covered.

K&W used tradeoff consistency conditions. Those imply the sure-thing principle, and the hexagon condition for two dimensions, giving additive representation $V_1 + \cdots + V_n$. To get EU, the V_js should be proportional. Tradeoff consistency gets that by implying consistency of orderings of utility differences across states. These results can be generalized by imposing the sure-thing principle separately, and then weaker conditions to give proportionality. This paper does so. The latter weaker condition is a consistency, across events, of a tradeoff-based endogenous utility midpoint operation, imposed only on binary acts. The latter implies the hexagon condition, so that also the case of two states gives additive representability and, hence is covered. Thus, whereas TO consistency has all ideas into one, this paper separates them, with all the pros and cons.

Two results underlie this paper:

(1) It can be seen that if one has additive representability, and EU on all or

sufficiently many two-dimensional subsets (with EU entirely depending on that subset), then one gets EU on the whole domain, so that EU must be independent of the subsets after all.

(2) If for three or more states, and everything nonnull, one has SEU (= CEU) on every comoncone, then one gets CEU overall. Main reason is that comoncones have intersections of dimension two or more, so that the representations on those overlaps are cardinal. It implies same utility functions and agreeing weighting functions on common events, so that it can all be patched together consistently into one overall representation. If there are only two states, then the comoncones (there are only two such) have a one-dimensional overlap, with the representation only ordinal there, and then the representations can really have different utility functions, and no overal CEU representation exists, as examples in this paper show. %}

Chateauneuf, Alain J., Fabio A. Maccheroni, & Horst Zank (2021) "On the Separation of Utility and Beliefs," working paper.

{% Present a beautiful result under CEU (Choquet expected utility): Preferences are convex (w.r.t. outcome mixing) if and only if utility is concave and the capacity convex. This beautiful result is somewhat "hidden," and follows from equivalence of (i) and (iv) in Theorem 1 (Choquet functional is concave iff it is quasi-concave which is iff U concave and W convex) plus Proposition 1.

They also show that preference for sure diversification (the same as convexity, only restricted to the case where the mix of acts is a constant act) implies a nonempty core, and is equivalent to that nonemptiness under concave utility.

They also show that convexity of preference restricted to comonotonic sets of acts is equivalent to concave utility. For the special case of SEU this result has been known before, but has not been well known.

Unfortunately, they only obtain their results under the assumption of differentiable utility. %}

{% Considers languages that do not (Chinese), sometimes (weak-FTR; e.g. Dutch), or always (strong-FTR; e.g. English) use future tenses for future actions. Sometimes is called weak, always is called strong. Empirically examines how this impacts saving and other intertemporal actions, using data of 76 countries. Finds strong effects with weak-FTR 31% more likely to have saved in a given year, 31% more savings at retirement, 24% less likely to smoke, and so on (p. 692 top). Incredibly strong results. One may worry that these effects are generated by confouding factors other than the linguistic cause considered. But the author controls for cultural values, even for "deep" cultural values as he pompuously calls it. This daunting task is implemented by one and only one control question, being how important people think it is to teach children to save. It did take me some thinking to see in which sense this one question be controlling for "deep cultural values" or other confounds. The author's reasonings, and claims of causality as derived from this one question (no lack of optimismm here), are typically stated in the 2nd para of the conclusion:

> "One important issue in interpreting these results is the possibility that language is not causing but rather reflecting deeper differences that drive savings behavior. These available data provide preliminary evidence that much of the measured effects I find are causal, for several reasons that I have outlined in the paper. Mainly, selfreported measures of savings as a cultural value appear to drive savings behavior, yet are completely uncorrelated with the effect of language on savings. That is to say, while both language and cultural values appear to drive savings behavior,

these measured effects do not appear to interact with each other in a way you would expect if they were both markers of some common causal factor."

The author has collected an impressive data set, where he must have consulted the linguistic literature a lot, which is the more impressive as it is a single-author paper.

One explanation offered is about time perception: People not using future tense will distinguish less between present and future and, hence, discount the future less, which then enhances rationality. This has some plausibility.

A second explanation offered is about beliefs. Although the author is not explicit, when analyzing beliefs he assumes probability distributions over waiting time for one reward. A formal proposition is provided. Imagine one reward R is received at some timepoint t, and the timepoint is risky, with distributions $F_W(t)$ for weak-FTR and $F_S(t)$ for strong-FTR. Weak-FTR will have more uncertainty, less precision, about timings. P. 697 writes: "we might expect $F_W(t)$ to be a mean-preserving spread of $F_S(t)$." Because time is valued by discount functions that are usually convex, people will (assuming EU and, crucially, $U(R) > 0$) be risk seeking regarding delay-time and prefer future more under $F_W(t)$ than under $F_S(t)$. (Makes sense because sure receipt of reward in one year and a day is preferred less than fifty-fifty either tomorrow or in 2 years and a day.) The author cites Kacelnik & Bateson (1996) and Redelmeier & Heller (1993) for similar risk seeking.

There is a mathematical mistake here in Chen's analysis. U(R), a factor in a multiplication, is a ratio scale and it matters whether it is negative, 0, or positive. The more so as in intertemporal choice, with the normalization $D(0) = 1$, the total weight distributed over all timepoints is not constant (unlike with probability), further showing that utility is not cardinal but is a ratio scale. The neutrality level of utility is empirically meaningful. If D(T) is convex, then D(T)U(R) will be convex for $U(R) > 0$, but the opposite, concave, for $U(R) < 0$. Because of this, Chen misinterprets the literature. Redelmeier & Heller find a small majority of common positive discounting and convex discounting D(T), but they have this for aversive outcomes (health impairements), being worse than neutral. Hence, they have risk aversion rather than risk seeking. I did not check Kacelnikov & Bateson on positive or negative outcomes. There is a nice study on risk about delays with gains, being Onay & Öncüler (2007), but they find the opposite of Chen's claim, being risk aversion. In O&O this gives the paradoxical implication of concave discounting. O&O nicely point out that the risk aversion found should probably be ascribed to probability weighting rather than to concave utility (= discount function), pointing out that the EU assumption in Chen's analysis is also problematic.

The author's claim "we might expect $F_W(t)$ to be a mean-preserving spread of $F_S(t)$" (p. 697) set me thinking. Why are $F_W(t)$ and $F_S(t)$ the same regarding expectation of waiting time t (arithmetic mean) and not of ln(t) (geometric mean) or of exp(t), or of anything other? Another complication is infinite waiting time (not getting the object). $F_S(t)$ may be sure to receive reward R in one year, and to never receive reward R´ ($t = \infty$). $F_W(t)$ may think that for both R and R´ it is fifty-fifty: Either receive them in one year or never. Here we have infinity coming in and the usual maths does not work. $F_S(t)$ is not a mean-preserving spread of $F_W(t)$. Another complication in this analysis is that intertemporal utility may be cardinally different from cardinal risky utility, being a nonlinear transform; risk attitude may be different than what intertemporal utility suggests under EU. A third complication is that if $F_S(t)$ has different beliefs over t than $F_W(t)$, then this will affect the discount function and it cannot be assumed the same.

P. 720 2nd chunck of text: I did not understand how the described similar development paths exclude innate cognitive or early cultural differences, a claim central in the 3rd para of the conclusion (p. 721). Pp. 720-721 discuss the grand topic of why similarly-situated societies differ so greatly in economic development and health, illustrating the broadness of the author. P. 721 gives three causes: (1) geography and (2) climate (which are apparently not included in "similarly situated "), and, (3) ecology of animal domestication. Then some more are discussed later. For cause (3) would have been good to indicate that this holds for mankind many thousands of years ago, but not today. %}

{% N = 5 capuchin-monkeys were given tokens, and learned that they could trade them with experimenters in exchange for apples, at rates different for different experimenters. First it was verified that the monkeys satisfy elementary versions of GARP (generalized axiom of revealed preference).

Then the monkeys were in two treatments. In treatment one, one apple was displayed, the monkey could pay tokens, and then either received the one apple displayed or that one with one added (a bonus), so, two apples. Essentially, they received a fifty-fifty prospect yielding one or two apples. In treatment two, two apples were displayed, the monkey could pay tokens, and then either received the two apples displayed or one was removed and only one apple was received (a loss). Essentially, they received a fifty-fifty prospect yielding one or two apples, as in treatment one. In each treatment, the monkeys spent some time doing repeated choices, until their choices stabilized.

The monkeys exhibited loss aversion in trading more in treatment one, and preferring treatment one to treatment two if they could choose. The authors conclude that loss aversion is innate and not learned, because these monkeys had no chance to learn it from others.

The authors next used a parametric model, with linear utility with a kink at zero (loss aversion), and developed a probabilistic-choice model and regression to fit the data. They got the best fit if they take loss aversion parameter 2.7. %}

{% **natural sources of ambiguity**: the authors do so. They use the source method, with a-neutral probabilities for each source and a source-dependent probability weighting function (what I call the source function).

Subjects do real-effort task where they only get paid for it conditional on some natural uncertainty event, bringing in ambiguity. The natural events concern a digit of a stockprice in the future, so that there is symmetry and the a-neutral probabilities are readily available, similarly as they are in unknown Ellsberg urns, and no elicitation of a-neutral probabilities is required. They consider a-neutral probabilities 0.1, 0.5, and 0.9. There are familiar stocks and unfamiliar ones. Such experiments with digits have the interesting feature that probabilities are not really unknown and that emotions other than unknown probabilities are driving the differences.

They find natural things such as source preference for familiar sources. They also confirm the gain-part of the fourfold pattern of Trautmann & van de Kuilen (2015), i.e., more insensitivity for unfamiliar sources. %}

Chen, Yiting & Songfa Zhong (2024) "Source Dependence in Effort Provision," *International Economic Review* 65, 1499–1517. https://doi.org/10.1111/iere.12698

{% In an online experiment, there are six numbered boxes, where n contain a high prize h (say h = $30) and 6-n a low prize $\ell < h$ (say $\ell = \$10$). Subjects know n, h, and ℓ, but not which of the six boxes contain which prize. One of the six boxes, randomly chosen independently of everything else, receives an extra amount, say $4. Next I describe the acts to be done by the subjects, and which info they have at their act. Subjects first choose a number between 1 and 6 at their choice, and then write it on a piece of paper unverifiable by the experimenter or anybody else. They do not know which boxes contain h or which one contains the extra $4 at that stage and in this sense they have no reason to prefer any of the six boxes. Then they get informed about which box has the extra $4. Then, knowing this, but not knowing which boxes contain h and which contain ℓ, subjects should make public which number between 1 and 6 they chose. The content of that box they will get, as they know. They can now lie or tell truth here. For any single subject one cannot know if he lied or not. But much more than 1/6 report the box with the extra $4, so that we can statistically, significantly, prove that many must be lying. The main finding of this paper is that, if there is uncertainty about the boxes ($0 < n < 6$), then subjects lie less than if there is no uncertainty (n = 0 or n = 6). A plausible explanation is magical thinking, where subjects think that the risk about h versus ℓ will work out unfavorably if they lie (this may also be suspicion about the experiment), or quasi-magical thinking where they do not express magical-thinking beliefs but still behave as if. (Karmareasoning.) There are several treatments precluding several alternative explanations.

Remarkable is that, with subjects prefering not to lie if the sure outcome $h + 4$ versus h is involved ($n = 6$), so $h \succ h + 4 + \text{lying}$, and also if the sure outcome $\ell + 4$ versus ℓ is involved ($n = 0$), so $\ell \succ \ell + 4 + \text{lying}$, they still prefer the opposite if there is uncertainty ($0 < n < 6$), which can be taken as a violation of stochastic dominance if we take the four outcomes h, $h + 4 + \text{lying}$, ℓ, $\ell + 4 + \text{lying}$ as sure outcomes.

The finding can have many implications such as in cheating with banks, tax, auditing. %}

{% **restrictiveness of monotonicity/weak separability**: This paper replicates experiments by Andreoni & Sprenger (2012) and Andersen et al. (2008) for choices that are both risky and intertemporal. When dealing with time and risk, A&S implicitly first aggregated over timepoints (conditioning on risky events). This implies a sort of weak separability, i.e., separability of each single risky event which, in particular, precludes hedging considerations across different timepoints. It also requires correlated lotteries for different timepoints, and A&S’s mistake was that in their experiment they instead implemented the lotteries stochastically independently.

This paper changes correlations/dependencies to correct for hedging possibilities, and also considers choice lists instead of the convex choice sets of A&S. Then differences in utility curvature are reduced or disappear. It implies that this paper uses EU to analyze risky choice (p. 2249b 3rd para says it implicitly), which is empirically problematic. Epper, Fehr-Duda, & Bruhin (2011) used PT for this purpose. Several papers by Ayse Öncüler also considered interactions between intertemporal and risk, showing that the effects of either are reduced in the context of the other.

Related comments were made by Epper & Fehr-Duda (2015 AER) and Miao & Zhong (AER 2015). %}

{% **real incentives/hypothetical choice, explicitly ignoring hypothetical literature**: states that he does so in footnote 3. %}

Cheung, Stephen L. (2016) "Recent Developments in the Experimental Elicitation of Time Preference," *Journal of Behavioral and Experimental Finance* 11, 1–8.

{% One choice list for risky choice, and six choice lists for intertemporal preference, were presented to N = 122 student subjects. EU (expected utility) and RDU (rank-dependent utility) with utility and probability weighting as free parameters are used to fit risky choice, and DU (discounted utility) with utility and discounting as free parameters is used to fit intertemporal choice. CRRA utility is always used. For risk, probabilities and not outcomes were varied in the choice list, and for time, timepoints and not outcomes were varied in the choice list.

Although it should be trivially obvious that one can directly measure utility of DU from intertemporal choices, there has been confusion in the field, mainly by the confused paper Andersen et al. (2008 Econometrica), that this might not be possible (or not desirable?). Fortunately, in the mean time there have been some papers doing it, and so does this paper. The author overstates the case on p. 494 when writing: "Unfortunately, until quite recently there were essentially no known methods to elicit the curvature of utility outside the domain of risk." Not only I, but many people have known this as standard knowledge for many decades. Here, and in other places, the author is too much focused on the confused Andersen et al. (2008 Econometrica).

The main question considered here is whether utility for risky and intertemporal choice is the same or not. The paper finds more concave utility for risk (**risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**).

I am puzzled that only one choice list is considered for risky choice, essentially giving only one indifference there. It is not only problematic for reliability, but even for identifiability. P. 515, §3.7, writes: "Since there is only a single risk preference choice list, it is not possible to estimate probability weighting parameters at an individual level." So it is! You can't get two parameters (probability weighting and utility) from one data point! Most of the paper uses a representative-agent analysis, but then I think the same problem remains, contrary to what the paper suggests. The computer will generate output, but it is problematic. Therefore, I have difficulties with the risky utility estimated here.

Section 3.4 considers the interesing joint estimation of risky and intertemporal choices. It only does so when assuming a common utility function and, unfortunately, gives no statistics on how allowing different utility functions compares to not doing so.

Section 3.5 considers the interesting discounted incremental utility model of Blavatskyy, and finds that it better fits data than regular discounted utility. %}

Cheung, Stephen L. (2020) "Eliciting Utility Curvature in Time Preference," *Experimental Economics* 23, 493–525. https://doi.org/10.1007/s10683-019-09621-2

Cheung, Stephen L., Agnieszka Tymula, & Xueting Wang (2022) "Present Bias for Monetary and Dietary Rewards," *Experimental Economics* 25, 1202–1233. https://doi.org/10.1007/s10683-022-09749-8

{% **biseparable utility violated**: his weighted utility violates it.

event/outcome driven ambiguity model: outcome driven: although this paper is on risk and not uncertainty, weighted utility does have the spirit of being outcome driven.

This paper axiomatizes weighted utility. This paper explains how the mathematical theory of generalized means (quasilinear means), part of functional equations, can be applied to decision under risk by letting certainty equivalents be such generalized means. P. 1066 end of 1st para: "In general, the received expected utility hypothesis is equivalent to adopting the quasilinear mean as a model of certainty equivalence."

It then characterizes the certainty equivalent of weighted utility.

P. 1068 Property 3 shows that vNM independence (in the form of substitution), the condition of decision theory, is essentially the same as quasilinearity of functional equations, as indicated in the last lines of p. 1068.

P. 1070 propagates continuity just by restating its definition.

Theorem 1 axiomatizes the quasilinear mean, being the certainty equivalent of EU, citing Hardy, Littlewood, & Polya (1934) for it. It is sloppy in not stating any continuity (axiom 4) of the functional. Continuity is restrictive because it refers is continuity in distribution, which imposes restrictions both in the probability dimension and in the outcome dimension.

P. 1077 2/3: quasilinear mean well defined iff utility (often denoted U; denoted φ in this paper) is bounded.

P. 1080 1/5 nicely cites Hardy, Littlewood, & Polya as preceding Pratt on more risk aversion iff utility is convex transformation. %}

{% They assume different sources of uncertainty. For each source, they assume (subjective!?) expected utility maximization, but different sources use different utility functions. There is source preference for a first source over a second if and only if the second has a more concave utility function.

The model doesn't stay as simple as just written. The authors assume that the probabilities (that need not be objective so I will call them subjective) for each source are given, available, and can be used as primitives, which I find an unfortunate assumption for subjective probabilities. They thus use them to define mixture operations. $x\lambda_s y$ is a mixture of x and y, interpreted as follows. One receives x under event E and y otherwise, where E is an event from source s (the authors denote a source by a small s) with subjective probability λ_s. The result of this mixture depends on source s. They justify EU by assuming the Hernstein-Milnor (1953) axioms, which uses the subjective probabilities as inputs.

Something that complicates things is that x and y in the mixture $x\lambda_s y$ need not just be riskless outcomes but can be any act or gamble available in the domain. We thus get multistage gambles, n-stage gambles for every $n \in \mathbb{N}$. The authors assume recursive CE substitution. If the mixtures in several stages all involve the same source then we have EU and RCLA also holds. If the several stages involve the same source then in applications for subjective probabilities I expect learning to take place, but the authors do not assume that and assume that the subjective probabilities remain the same and are not impacted by learning. (Same as in Luce, 2000, who in the footnote

on p. 10 acknowledges me for pointing this learning out to him in a similar multistage setup.) %}

{% Point out that Ellsberg's ambiguity aversion is a special case of source preference. Abstract, very erroneously, writes that rank-dependent utility (= CEU for uncertainty), PT, and multiple priors satisfy probabilistic sophistication. Would imply that these models cannot accommodate Ellsberg, which of course is completely untrue. If extended to the Anscombe-Aumann framework and imposed on the whole framework there, it would imply full subjective expected utility there, thus negating the existence of Schmeidler (1989) for instance.

Paper lets subjects bet on whether a digit for some source is odd or even (suspicion is avoided because subjects can themselves choose to gamble on odd or even), and find source preference for the best-known source. (**natural sources of ambiguity**) Because the probabilities about digits can be taken as objective, this in fact is: **violation of risk/objective probability = one source**

Very very unfortunately, do ranking from bottom to top and not from top to bottom for the RDU-functional definition.

event/outcome driven ambiguity model: outcome driven:

source-dependent utility (pp. 186-187): This paper most clearly has this idea. It proposes a SDEU (source-dependent expected utility) model where they have expected utility within each source, but different utility functions. This is much in the spirit of KMM, but without the multistage complications of KMM.

losses from prior endowment mechanism: Random incentive system but for gains and losses both so that there can be income effect. Find source preference for both, and related differences in neural activities.

reflection at individual level for ambiguity: Although they have within-subject data, they do not report it in the main paper. Because they have N = 16 and there can be expected to be few ambiguity seekers for gains, the data will not give much info on it anyway. %}

{% This paper deserves to be a classic, with many valuable results on mean-preserving spreads. I conjecture that the, then young, Chew wanted this to be his master piece and so it is.

Their Theorem 2 (p.415) shows that, under continuity, elementary risk aversion is equivalent to aversion to mean-preserving spreads. A useful result! Elementary risk aversion concerns only simple equally-likely lotteries ($1/n{:}x_1$, …, $1/n{:}x_n$). It says that moving a small amount espsilon from a "high" outcome to its lower neighbor, without affecting their ranking, always is an improvement. It is obviously weaker than aversion to mean-preserving spreads, and also than outcome-convexity. Table II (p.418) displays that, for RDU, this is equivalent to convex w and concave U. (The paper writes g instead of w for probability weighing. Unfortunately, it does bottom-up integration for RDU rather than the nowadays (1992-2023) common top-down integration, so, it uses probability weighting in a dual manner, and its concavity is equivalent to modern convexity.)

Unfortunately, the paper does not make well clear what differentiability assumption is made in Table II. The introduction p. 404 suggests Gateaux differentiability (which under RDU is equivalent to differentiable w). P. 418 ℓ. 2-3 suggests that for RDU not any smoothness is assumed. However, the derivations on occasions assume marginal rates of substitution that are not infinite and that need ratios with denominators > 0 (p. 416 the formula between Eqs. 4.8 & 4.9), and that there are points p where the derivative g´(p) is > 0 (p. 429 last line of displayed formula in the RDU proof). This need not hold for a continuous strictly increasing continuous g (which is almost everywhere differentiable but may have derivative 0 whenever it is defined, if it is not absolutely continuous; Paradís, Viader, & Bibiloni, 2001 Theorem 3.1 give an example.), contrary to frequent confusions in the literature.

Ebert (2004, Theorem 2), unaware of this paper, with the principle of progressive transfer the same as elementary risk aversion, proved the above result for RDU without assuming any smoothness. This completely generalizes Chew, Karni, & Safra (1987) to the nonsmooth case. %}

{% This paper considers multiple priors in three ways. The set of priors, with a deck of 100 cards, and n describing number or red (winning) cards, so that objective probabilities are multiples of j/100: (1) interval ambiguity: [50-n, 50+n]; (2) disjoint ambiguity: [0,n] u [100–n,100]; (3) two-point: {n, 100–n}. Subjects consider bets on such events and, using price lists, certainty equivalents are elicited. This means that all bets considered have at most one nonzero outcome. I haven't seen implementations of multiple priors with nonconvex sets of priors before, and this is a useful phenomenon to investigate.

They also do the same stimuli but with 2nd order uniform objective probabilities given over them, which is risk and RCLA to be tested. Figure 2, p. 1251, is best to see the results.

They find strong correlations between ambiguity attitudes and RCLA violations. This comes as no surprise because the two kinds of stimuli are similar. In general, multiple prior implementations of ambiguity are a kind of two-stage already (may I add: unlike natural ambiguities), which explains much of the correlations found in the literature.

It is not easy to draw inferences about existing ambiguity models because most have no clear predictions. The only clear finding comes from the smooth ambiguity model together with ambiguity aversion (concave 2nd-order utility transformation function φ), if it is assumed that the 2-stage decomposition exogenously specified by the experimenters is the subjective one of the smooth model—but this assumption is made in all tests of the smooth model that I am aware of. The authors use the term "recursive EU" for it. Anyway, then the stimuli of this experiment are targeted so much towards this model, that predictions can come. Here they seem to find a violation: key Finding 1 (p. 1242) goes against the smooth model (recursive EU) to the favor of recursive rank-dependent utility (always assuming ambiguity aversion), as mentioned in ℓ. –7 of §1 when coupled with the common assumption of ambiguity aversion. This Key

Finding 1 is: aversion to increasing number of possible compositions for interval and disjoint ambiguity, and aversion to increasing spread in two-point ambiguity except near the end-point.

No predictions for existing (general) models:

(1) Choquet expected utility (CEU-I will use this term the authors' term (introduced by Wakker 1990, Theory & Decision) instead of my own preference, RDU) is (too) general because nonadditive measures can accommodate anything here.

(2) Multiple priors with α maxmin (needed empirically because maxmin EU is too pessimistic) is also (too) general. The authors, by the way, do not mention α maxmin and only maxmin EU but do not analyze it, grouping it with CEU instead.

(3) Source dependence is also too general because it is only one completely general idea, and not a theory.

(4) Recursive RDU is considerably more general than recursive EU and there are, again, (too) many nonadditive weighting functions.

Hence, the authors add assumptions to the theories, but their assumptions are, unfortunately, not empirically plausible (e.g., van de Kuilen & Trautmann 2015). Whereas on p. 1246 2nd para the authors point out that CEU in general ("Savagian [Savagean] domain") gives no predictions, they throughout assume that CEU is coupled with the Anscombe-Aumann framework. For example, see p. 1241 3rd para, using vague implicit words. I think that this is unfortunate and empirically invalid (e.g. my Wakker (2010) book §10.7.3). Comes to it that they then add the assumption of RCLA, which drives most of their predictions, but even under the EU assumption of Anscombe-Aumann RCLA need not hold. Anscombe-Aumann assumes backward induction which, if anything, goes against RCLA when deviations from EU are desirable. (Backward induction + RCLA imply vNM independence.) This point becomes especially problematic if combined with the authors' unfounded claim on p. 1247 top, that two-stage models would not distinguish between objective and subjective stage-1 priors.

Whereas on p. 1258 bottom they cite evidence for ambiguity seeking for unlikely (they call it preference for skewness), for all models they throughout assume ambiguity aversion. Van de Kuilen & Trautmann's (2015) survey cites violations, as does the keyword **ambiguity seeking** in this bibliography.

In their discussion of empirical performance they only consider fit and not parsimony; i.e., they do not correct for number of parameters. Thus, the "source perspective" as the authors call it is a general property (rather than a model; it is similar to commodity dependence of utility) that can accommodate any finding, which is why it comes out positively in Table IV on p. 1256.

Note also that, contrary to what is sometimes weakly and sometimes strongly suggested (p. 1241 middle: "Multiple prior models such as Choquet expected utility"), Choquet expected utility (CEU) is different than multiple priors—these two models only have overlap, but are not nested. It is true that for the stimuli considered here, bets with only one nonzero outcome, CEU and α maxmin coincide.

correlation risk & ambiguity attitude: find strongly positive relation but this is because both are coupled with a similar two-stage structure.

P. 1240 footnote 3: contrary to the claim there, source preference was first axiomatized by Tversky & Wakker (1995, Econometrica, §7).

P. 1244 top: subjects can choose winning color so as to avoid suspicion. (**suspicion under ambiguity**)

P. 1246 $\ell\ell$. 3-5 equate convexity of nonadditive measure with ambiguity aversion, which only holds if EU is assumed for risk. Without that, empirically failing, assumption, I qualified it as a historical accident in Wakker (2010 p. 328 penultimate para).

P. 1247 top claims that two-stage models do not distinguish between objective and subjective stage-1 priors. I am not aware of this point, only knowing the explicit deviation of it by the smooth model (which the authors mention in footnote 10). The claim is repeated on p. 1258 top.

As I wrote above, CEU is too general, as are most other existing theories. Developing good specifications is desirable. Unsurprisingly, I like Abdellaoui, Baillon, Placido, & Wakker's (2011) specification of the source method. We can consider a recursive version here. It would be like the recursive RDU considered in this paper, only the weighting function of the prior stage would capture ambiguity. However, for empirical purposes it would be desirable to take inverse S weighting functions rather than the convex weighting functions considered by the authors, because inverse S is empirically better. It would fit the data well. For instance, for two-point ambiguity with n = 0 we'd just have risk transformation of 0.5, giving the high 0.8 in Figure 2 (left), and for n = 50 we'd only have uncertainty of the prior stage, i.e., ambiguity transformation of 0.5, being lower than the 0.8 of risk. For n = 25 we'd have transformations at both stages, giving the worst result. As for transformation in the 2nd stage, the probability 0.75 is underweighted by the certainty effect and the probability 0.25 is a bit overweighed by the possibility effect but the latter is much less.

testing color symmetry in Ellsberg urn: they seem to confirm it.

I next discuss the reference Wakker (1987) on p. 1246.

It is downloadable from

https://personal.eur.nl/Wakker/pdf/nonaddprobs_der.str.prfs1987.pdf

In those days, Chew and I, young, were among the very few to know about maths of nonEU. He was almost the only human being I could communicate with on many topics. The paper cited there was finished as first draft on Dec. 31, 1986, and I consider it one of the best I ever wrote. I then sent it to Chew and Yaari, asking for comments. Chew and I communicated frequently, stayed in each others' houses, where he conquered my heart by taking me to Vietnamese restaurants in Toronto and later in Los Angeles, and so on. It is nice to see that Chew still remembers it. My paper has been taken apart and rewritten into several different papers after, and my 2010 book is close to it but, à la, more up to date.

☺ ==========================%}

Chew, Soo Hong, Bin Miao, & Songfa Zhong (2017) "Partial Ambiguity," *Econometrica*, 85, 1239–1260.
https://doi.org/10.3982/ECTA13239

{% They compare ambiguity aversion/source preference for Ellsberg known urns, RCLA, and trailing digit of foreign vs. home city being odd or even ("natural uncertainty"), finding strong relations between all. N ≥ 2000 subjects!

Funny start of paper: "The proverbial urn …"

Footnote 3 criticizes Smith (1969) who suggested that utility for the known Ellsberg be higher than for the unknown, arguing that both functions are interval scales so that their absolute levels are meaningless. I disagree with the authors' criticism. The two functions will be unique up to a joint unit and scale, so that Smith's comparisons are meaningful still. I do not find Smith's idea very valuable, e.g. when applied to constant acts, but it is meaningful.

P. 1140, as usual in many papers, treats KMM's smooth model as recursive expected utility. %}

Chew, Soo Hong, Bin Miao, & Songfa Zhong (2023) "Ellsberg Meets Keynes at an Urn," *Quantitative Economics* 14, 1133–1162.
https://doi.org/10.3982/QE2253

{% %}

Chew, Soo Hong & Naoko Nishimura (1992) "Differentiability, Comparative Statics and Non-Expected Utility Preferences," *Journal of Economic Theory* 56, 294–312.

{% N = 3,583 subjects collected online. This paper presents Ellsberg 2-urn choices in a somewhat complex manner, using matrices. It uses a test question to see if subjects understand the matrices. Those who do, exhibit the usual ambiguity aversion. Those who don't, are close to fifty-fifty. A naïve interpretation would be to say that not-understanding subjects are less ambiguity averse and, maybe, even more rational. This is of course an incorrect interpretation. The not-understanding subjects are just behaving randomly. Their data is not ambiguity neutrality but mere noise. Funny.

The authors also distinguish between ambiguity-minded subjects, reluctant to assign probabilities to the unknown urn, and probability minded, who are willing to. The former are extremely ambiguity averse (84%!) and the latter not at all (31%). Remarkably, the ambiguity-minded are younger, and more educated, analytic, and reflective, suggesting that they are more rational which would be bad news for Bayesians like me. But my interpretations are very different. Being ambiguity minded or probability minded is measured through the following questions Qk and Qu:

"Qk- the subject is asked to quantify the probability of drawing a red card from 'Deck no. 1', which contains exactly ten red cards and ten black cards. The six available response alternatives include: 0%, 25%, 50%, 75%, 100%, and 'Cannot be determined'. The only satisfactory response is '50%'.

Qu– the subject is asked to quantify the probability of drawing a red card from 'Deck no. 2', which contains exactly twenty *red* [cards] with an unknown mix of red and black cards. The six available response alternatives are the same as in Qk. Satisfactory responses are '50%' or 'Cannot be determined'." [italics added here and is a typo]

Answer 50% to question Qu means probability minded and answer "Cannot be determined" is ambiguity minded. Main problem is that the authors' term probability here makes subjects think of objective probability related to composition of urn. I as 100% Bayesian would answer "Cannot be determined" because I think the experimenters have in mind not my subjective probability but an objective one. The more so as the multiple choice framing suggests that there may exist a correct objective answer, and subjective probabilities can deviate from the categories offered (e.g. if I (think to) know about experimenters' color preferences). So, subjects categorized as ambiguity minded need not at all be so. A second problem is that these questions prime subjects to dislike unknown objective probabilities, generating false ambiguity aversion. This explains the extreme 84% ambiguity aversion found among the ambiguity minded. %}

Chew, Soo Hong, Mark Ratchford, & Jacob S. Sagi (2018) "You Need to Recognise Ambiguity to Avoid It," *Economic Journal* 128, 2480–2506. https://doi.org/10.1111/ecoj.12541

{% The original 2003 working paper contained nice ideas about **small worlds**—what Tversky would call sources of uncertainty—and their comparisons. Unfortunately, Econometrica had the authors take out these interesting ideas, reducing the paper to a, nice indeed, definition of exchangeability, but other than that a technical generalization of probabilistic sophistication to the case of no stochastic dominance and with continuity weakened somewhat by replacing it by solvability, along the well-known techniques of Krantz et al. (1971). The move from continuity to solvability is discussed in more detail by Wakker (1988, Journal of Mathematical Psychology). Econometrica let the authors take out the most valuable idea, and made the main theorem and the main intuition become disconnected! The second part of the paper, with the valuable idea of variable source, thus only appeared in their 2008 JET paper.

Basically, the authors define two events as equally likely if they are exchangeable in the sense that their outcomes can be switched without affecting preference. Monotonicity need not be brought in separately because it automatically follows from set-inclusion. Thus, an event is more likely than another if the former contains a subset exchangeable with the latter. The general idea of using the set-theoretic structure on the state space because it is automatically there is discussed in more detail by Abdellaoui & Wakker (2005, Theory and Decision). %}

Chew, Soo Hong & Jacob Sagi (2006) "Event Exchangeability: Probabilistic Sophistication without Continuity or Monotonicity," *Econometrica* 74, 771–786. https://doi.org/10.1111/j.1468-0262.2006.00682.x

First version (which was later split up into the above paper and their 2008 JET paper): Chew, Soo Hong & Jacob Sagi (2003) "Small Worlds: Modeling Attitudes towards Sources of Uncertainty," Haas School of Business, University of California, Berkeley, CA.

{% %}

Chew, Soo Hong & Jacob Sagi (2006) "Small Worlds: Modeling Attitudes towards Sources of Uncertainty," Haas School of Business, University of California, Berkeley, CA; version of June 2006.

{% They consider subdomains of the event space, sources, the concept first advanced by Amos Tversky, with which Tversky influenced not only me but also Chew (and Craig Fox) in the early 1990s (see Chew & Tversky 1990). So, this is a paper in the right spirit and I like it much!

I think that Savage's **small worlds** is too much a different idea than source so that I disagree with the authors linking with small worlds. Savage's small worlds serve for cases where the grand-world is too complex, and then the agent takes a small world, the best modeling of reality he can. So, there is only one small world. If different small worlds then Savage surely would not want inconsistent probability assessments between them, but he would treat the small world as consistent with the grand world. Savage wants whatever can be considered to consistently satisfy his axioms.

The authors take sources not as partitions of the whole state space, but as partitions of subevents of the state space, taking the overall subevent as a conditioning event. They call it conditional small world event domain. I regret this move because it confounds the source concept with issues of conditioning and dynamic decisions. (Even if conditioning is important, one does not want to mix it in with every static concept.) Probably the authors made this move so as to have something easy to say on the Ellsberg's 3-color paradox.

They also define a collection of events as a conditional small world event domain only if probabilistic sophistication holds there. On their conditioned events they call probabilistic sophistication homogeneous, where Wakker (2008, New Palgrave) used the term uniform for the unconditioned-source concept of probabilistic sophistication.

They derive their representation of probabilistic sophistication on λ-systems, which is more general than the conventional algebras. Abdellaoui & Wakker (2005, Theorem 5.5) derive probabilistic sophistication for the more general mosaics of events, like Chew & Sagi using also solvability instead of the more restrictive continuity. Chew & Sagi are more general in considering conditionings and in relaxing monotonicity.

In §4 they call events of (homogeneous) conditional small world event domains EB-unambigous, where EB abbreviates exchangeability-based. Argue that if there are more EB unambiguous sources, as in the Ellsberg 2-color paradox, then we need extraneous info to determine what is really unambiguous, so that EB unambiguous need not really be unambiguity. (I think that we ALWAYS need such extraneous info.) I regret, if it is not unambiguous, that the authors still use this term unambiguous. In §4 they have to spend much space on discussing the, I think wrong, definition of Epstein & Zhang.

Unfortunately, the authors ascribe source dependence to risk attitude, and write that the risk attitude depends on the source of ambiguity, which is something like a contradictio in terminis. Abdellaoui et al. (2011 American Economic Review) used a source function to reflect ambiguity attitude. %}

Chew, Soo Hong & Jacob S. Sagi (2008) "Small Worlds: Modeling Attitudes toward Sources of Uncertainty," *Journal of Economic Theory* 139, 1–24. https://doi.org/10.1016/j.jet.2007.07.004

{% Consider inequality with risk, and one-parameter extension of the generalized Gini mean, with a quadratic term for inter-personal correlations (in spirit of

quadratic utility of Chew, Epstein, & Segal 1991), accommodating “shared destiny,” preference for probabilistic mixtures over unfair allocations, and for fairnes “for sure” over fairness in expectation. They essentially use an Anscombe-Aumann framework, reinterpreting the horses in a horse race as people in society. %}

{% Use Chew’s weighted utility, instead of RDU or PT, to model the coexistence of gambling and insurance. Analyze economic implications and refer to experimental findings.

§1, p. 1011, top para, suggests that RDU (Called RDEU here) cannot accommodate longshot preference behavior under tractable functional forms (“we have not been able to …”). I am puzzled about this claim. All common functional forms, such as in Tversky & Kahneman (1992), were primarily developed to do so, and can qualify as tractable. The same para, and also §2.3 (including footnote 6) point out that RDU cannot combine global risk aversion for small stakes with some risk seeking for large stakes. This is very true. There is empirical evidence for risk seeking (fourfold pattern). Now, had the authors also had empirical evidence for global risk aversion for small stakes, then they had had a point. But they don’t mention any such evidence. When choosing between 1 cent for sure, or a 1/1000 chance at $10, will people be risk seeking? Problem is that the choice options are too small to be of interest to anyone. There may be risk seeking for joy of gambling.

For limits as in Chew & Tan’s p. 1016, it is well known that the probability-weighting function of T&K’92 does not exhibit the desirable subproportionality. Tversky was enthusiastic about the families developed by Prelec that can satisfy this. %}

{% Under the state-dependent generalization of Savage's (1954) SEU, subjective probabilities are nonidentifiable, as is well known. This readily extends to general betweenness nonEU models. For the extension to rank-dependent models, a delicate question is how one takes the rank-ordering of outcomes, at least if outcomes are money. By their utilities or by the money amounts? This paper only considers the latter, without discussing it. Chiu (1996, *Geneva Papers on Risk and Insurance Theory* 21) did it the other way, getting real generalizations. This paper shows that we cannot do the linear rescaling of utility/probability underlying the nonidentifiability in SEU in rank dependence. So, in that sense state-dependence is not possible under rank-dependence. However, more general forms of state-dependent utility with nonidentifiable weighting functions are possible, as for instance in Chew & Wakker (1996 JRU). They have a state-dependent utility or, equivalently, an outcome-dependent weighting function. %}

{% They show that distributions of individual risk attitudes can be recovered from market data, more precisely, horse race betting, without individual data needed, if enough assumptions: That sufficiently many market equilibria can be observed (sufficiently many probabilities and corresponding odds), that individual risk attitudes satisfy a single-crossing condition, that individuals bet a fixed amount (p. 22), that they satisfy the rational expectations assumption (p. 12) of going by true probabilities (even if in reality they don't know them), and that they do not change between different markets. They apply their technique to a dataset of 25,000 races. The abstract writes: "We estimate the model on data from U.S. races. Specifications based on expected utility fit the data very poorly. Our results stress the crucial importance of nonlinear probability weighting."

P. 2: under risk neutrality, betting odds would be proportional to winning probabilities.

P. 4: besides rank-dependent utility (RDU) - the authors write the inefficient RDEU - also something called NEU works well, but the authors never define what NEU means.

P. 12: "We could also incorporate ambiguity-aversion in the "exponential tilting" form introduced by Hansen and Sargent (e.g., in their 2007 book, or Hansen (2007)). However, in our very simple choice problems with static decision-making, it is observationally equivalent to increased risk-aversion." This is useful for the source method!

P. 24: they do not even commit to the very general HARA family because it predicts a fanning out not holding in the data.

P. 28: unfortunately, the authors follow the tradition of finance of letting "preference" refer to utility.

P. 30: "We could, of course, resort to parametric specifications, but this is precisely what we have tried to avoid in this paper." I guess that they take every point in the domain as a separate parameter? Not clear to me. %}

{% Savage (1954) (casually, just to simplify maths) and de Finetti (1974) (very deliberately), used finitely additive and not countably additive probabilities in expected utility. By Yosida & Hewitt (1952), the finitely additive probability can be decomposed into a countably additive measure, and a purely finitely additive measure. For example, the latter can be ℕ (natural numbers) with every finite set having measure 0 but yet ℕ having measure 1. For the latter measure, all mass

seems to have escaped to infinity.

The author of this paper considers models as just described. She refers only to Arrow (1971), who gave an adaptation of Savage (1954) with countable additivity. She then presents the finitely additive case of de Finetti and Savage as different than Arrow, but presents it as new, unaware that de Finetti and Savage already did **finite additivity**. She interprets the purely finitely additive part as extreme event. Problem is that an extreme event is to be qualified by an exteme *outcome*, obviously depending on the act chosen, and this is not captured by the model of the author. %}

{% **game theory can/cannot be viewed as decision under uncertainty**:

I read a preliminary version of January 2018.

This paper follows up on Heinemann, Nagel, & Ockenfels (2009 RESTUD), HNO henceforth, and Nagel, Brovelli, Heinemann, & Coricelli (2018), NBHC henceforth. They consider a stag hunt game, an entry game, and risky lotteries determining their certainty equivalents (CEs), as described in my annotations of

NBHC. In addition, and this is the novelty relative to NBHC, they measure a CE for an ambiguous lottery, coming from an Ellsberg urn generated by a two-stage lottery after the first stage has been implemented but not revealed. They find that the CEs of stag hunt are highest, then risk, then ex aequo ambiguity and entry game. As did NBHC, they find more choice switches in the (unconventional) choice lists for the entry game. In the version that I read, they did not report correlations or regressions and based their conclusions solely on compared CEs. %}

Childs, Andrew M. (2010) "On the Relationship between Continuous- and Discrete-Time Quantum Walk," *Communications in Mathematical Physics* 294, 581–603.

{% Pp. 3-4 summarizes explanations of WTP/WTA discrepancies. In my terminology, the 1st (p. 3 2nd para) is the rational basic utility (fitting within neoclassical theory), the 2nd (p. 3 3rd para) is the irrational framing/loss aversion of prospect theory, and the 3rd (p. 3 4th and last para) is a bargaining attitude of the subjects when answering.

4th (p. 4 1st para): subjects may guess favorable market prices rather than their value. (I add: if you do not buy for a given price, can always buy it 5 minutes later in the next store.)

This paper really addresses the interesting question whether utility is really kinked at the reference point, or only in general is very concave. This is not very relevant to the main question claimed in the paper. If utility is not kinked but still very concave about the reference point, then still the MRS (marginal rate of substitution) between money and life years changes much around the reference point and we have no clear MRS.

P. 4 last para suggests that marginal utility of wealth can be assumed constant for the small stakes they consider. But then how can the WTA/WTP ratio still change as stakes get smaller?

They use the nice Cherry et al. (2003) idea of first making subjects rational in an (incentivized) experiment, hoping for spillover to their real experiment.

The negative weights in Table 7 are hard to understand. Do they support the claimed weight 1? %}

{% The first two pages discuss in detail that probabilities are often unknown. However, the author does not use it to show that Savage's (1954) subjective expected utility, and its axioms, are violated. He only uses it to argue that choices are not deterministic but probabilistic. He does an experiment, with 10 subjects and real incentives, with unknown probabilities but only to test stochastic choice and stochastic choice he also analyzes mathematically in some detail.

ambiguity seeking for unlikely: Subjects can gamble on an event with known probability p and on event with unknown probability but with observed relative frequency of p. For p ≥ 0.5 they prefer the known distribution but for p < 0.5 they

prefer the unknown event. Note that this finding need !not! designate ambiguity seeking and in fact can be explained by SEU because the subjective probability depends not only on the observed relative frequency but also on the belief prior to the observed frequency.

It was real payment with the possibility of losses. If paricipants lost too much then they were offered favorable gambles. This procedure constitutes a mild form of deceiving subjects. (**deception when implementing real incentives**) Funnily, p. 80 writes that if subjects had won an "unduly large amount of money," unfavorable gambles were presented to them.

Pp. 87-88: the two paras there, under the heading "bias towards one-half," write briefly, interestingly, about ambiguity attitudes. P. 87 writes,: "One of the most striking features shown by the data is a tendency for individuals to bias unknown probabilities towards one-half." (**inverse S & uncertainty amplifies risk**) It also describes ambiguity aversion for events that are revealed-as -likely as their complement. %}

{% Study choice between two-outcome prospects, not binary choice, but from a budget set, taking one commodity as payment under one state and other as payment under the other state. Subjects can thus choose from budget sets using a mouse (**revealed preference**). Giving money to subjects to invest optimally in a project consisting of an event-contingent payment has been done before, by Frans van Winden for one. But the way presented in this paper, as choices from budget sets, is new in decision under uncertainty/risk. It is easy to present to subjects and each choice of a subject gives much information. They test revealed preference axioms (i.e., whether choices are generated by a transitive preference relation), something which they do more elaborately in their follow-up paper in American Economic Review.

They write, in Eq. (1) (p. 1929) and elsewhere, that they do Gul's disappointment aversion theory. However, in reality it is **biseparable utility**, agreeing with virtually any nonEU theory presently existing, including RDU and prospect theory. Indifference curves have a kink at the certain (safe) prospect.

Boundary choice is if subjects maximize outcome for one state, taking it 0 at the other. Safe choice is if taking same payment under both states. Intermediate choice is any other. Under expected value subjects would always choose boundary (or be completely indifferent). Under biseparable utility there will be quite some at the kink of safe choice. Under virtually all theories there will be little intermediate choice. I expect (too) many such because of the compromise effect: subjects think that the truth is in the middle and, likewise, that the optimal choice will be somewhere in the middle.

I wonder if the few extreme choices found in this paper could be due to EV + error.

error theory for risky choice: §IV.E notices that maximum likelihood gives implausible results, but least squares gives plausible results.

In a paper with a new methodology it is often difficult to get much novelty otherwise. The paper has no empirical findings of particular interest. The authors put forward as "striking fact" (p. 1921 end) that they find heterogeneity among subjects, but this is the common finding. Their term loss aversion is rank dependence (kink at safety).

In their references to measurements of CRRA they exclusively refer to experimental economics studies (p. 1922 2nd column), and in American Economic Review this narrow scope is, unfortunately, considered to be acceptable.

(**Prospect theory not cited**)

They take objective probabilities 1/3, 1/2, and 2/3. I wonder if subjects treated probabilities 1/3 and 2/3 just as 1/2, as this sometimes happens, but I could not find out. %}

Choi, Syngjoo, Raymond Fisman, Douglas Gale, & Shachar Kariv (2007) "Consistency and Heterogeneity of Individual Behavior under Uncertainty," *American Economic Review* 97, 1921–1938.

{% **revealed preference** %}

Choi, Syngjoo, Raymond Fisman, Douglas Gale & Shachar Kariv (2007) "Revealing Preferences Graphically: An Old Method Gets a New Tool Kit," *American Economic Review, Papers and Proceedings* 97, 153–158.

{% **revealed preference**: Measure violations of GARP from CenTER panel, the large representative sample from the Netherlands. Consider risky choices using the budget-framing that they used in preceding studies (Choi et al. 2007). Here two equally likely states of nature, with fifty-fifty probabilities, are specified, with (x_1,x_2) the usual act. Subjects are offered randomly determined budget sets. (I don't know why they are determined randomly.) So, on the Pareto line there is a fixed exchange rate between the two states, where it is natural to take the highest payoff under the cheapest state. Expected value maximizers will just take the highest payoff under the cheapest state. The more people invest in the most expensive state of nature, so, the more they move to the riskless diagonal, the more risk averse they are.

Use RIS. They pay in points, where one point is €0.25.

GARP is equivalent to transitivity. So, it does not test EU or other particular theories. They measure violations of GARP through Afriat's (1972) Critical Cost Efficiency Index (CCEI) which is roughly how much money a person must be overpaying in a situation involved in a GARP violation, and the maximum of that in the data of a person.

There are many methodological discussions. Because GARP is equivalent to transitivity and does not involve anything else, the authors call CCEI a practical, portable, quantifiable, and economically interpretable measure (p. 1519 3rd para). The 4th para continues and the 5th then comes with the authors offering a new approach to the methodological challenges they listed before, where the paper later explains that CCEI brings all that. P. 1527: "A key advantage of the CCEI is its tight connection to economic theory. This connection makes the CCEI economically quantifiable and interpretable. Moreover, the same economic theory that inspires the measure also tells us when we have enough data to make it statistically useful. Thus, this theoretically grounded measure of decision-making quality helps us design and interpret the experiments in several ways."

P. 1530 footnote 9: As so many studies they only have two-outcome prospects and, hence, most nonEU theories agree there, where the term biseparable utility is used to express this. Or, better Miyamoto's (1988) generic utility. Strangely enough, as seems to be a convention in this field, they only cite Gul's disappointment aversion theory as a case, and not for instance the more popular Nobel-awarded prospect theory.

Violations of GARP are negatively related to wealth, education, being male, and positive to age. The correlation of violations of GARP with the trembling parameter is 0.178 (p. 1542). Find a correlation of about 0.2 between Frederic's cognitive ability index and violations of GARP (p. 1543). Derive many conclusions about "important real-world outcomes." For instance, p. 1521 end of 2nd para is none too pessimistic on relation with wealth: "We interpret the economically large, statistically significant, and quantitatively robust relationship between decision-making quality in the experiment—the consistency of the experimental data with the utility maximization model—and household wealth as evidence of decision-making ability that applies across choice domains and affects important real-world outcomes." %}

Choi, Syngjoo, Shachar Kariv, Wieland Müller, & Dan Silverman (2014) "Who Is (More) Rational?, *American Economic Review* 104, 1518–1550. http://dx.doi.org/10.1257/aer.104.6.1518

{% The paper measures certainty equivalents for five lotteries and fits 1992 prospect theory with power utility and the Goldstein-Einhorn two-parameter probability weighting. They relate these estimates to cognitive ability. They find that likelihood insensitivity is strongly negatively correlated with cognitive ability, but that pessimism is unrelated. (**cognitive ability related to likelihood insensitivity (= inverse S)**). This wonderfully supports the cognitive interpretation of likelihood insensitivity. They correct for many variables including choice error. They have two samples of about 300 subjects, where the first sample has an exceptionally wide variation in cognitive ability, and for the second they did within-subject manipulation of time pressure. %}

{% Wakker (2022, AEJ, Microeconomics) comments on this paper and argues that the authors take ordinal utilit for choices between commodity bundles as cardinal. If one takes it as ordinal then all inconsistencies disappear and one can have one consistent utility for both risky and riskless choice.

A widespread misunderstanding about Tversky & Kahneman (1992) is that their paper would only concern risk. This is not so. Their paper writes again and again that it handles both risk and uncertainty. The present Chung et al. paper cites T&K on p. 34: " … we presented a model of choice, called prospect theory, which explained the major violations of expected utility theory in choices between risky prospects with a small number of outcomes." which might suggest otherwise. However, the words on the dots are "Some time ago" and T&K were only referring to their 1979 paper for it.

risky utility u = transform of strength of preference v:

I refer to this paper as CGT. CGT compares the utility function of prospect theory, denoted U here, with a riskless utility function capturing choices over commodity bundles (x_1,x_2) denoted V here. Assuming stochastic dominance, we then have U = φ∘V for a strictly increasing φ. Unfortunately, the authors throughout overlook the essential role of φ. Thus, they come to conclude that their empirical findings about V are inconsistent with those of U, but this is not so because φ can fix everything. Details are in Wakker (2019). I add further details here.

P. 34 ℓ. -5: The text cited by T&K92 is a bit misleading because, contrary to what is suggested, it does not refer to the situation of 1992. The words on the dots omitted are: "Some time ago". T&K refer there to the situation from the past. Big change in 1992 is that they also handle uncertainty, as emphasized throughout their paper. But this is irrelevant for CGT, so I understand that they avoid it.

P. 35 middle: the first paper usually praised for extending prospect theory to riskless choice is Thaler (1980), although I must say that I do not find this in itself a very big deal.

P. 37 ℓ. 3: one of the popular clichés in the modern literature is to call any experiment "novel," and so it happens here.

A problem throughout pp. 38-40, first part of Section I, is that the authors assign meanings to (diminishing) marginal utility, concave utility, (sign of) second derivative of utility, even though utility is only ordinal, and these concepts often are not meaningful. Proposition 1 seems to come from Arrow & Enthoven (1961), and uses the second derivative of utility U, but I trust that it is correct still. Probably, even though the second derivative itself is not meaningful, the sign of its combination with partial derivatives as written there still is. There are serious problems with Assumption 1 though, which does not pass the ordinality test. The assumption amounts to saying that it is reasonable to assume that the second partial derivatives of $U(x_1,x_2)$ pragmatically determine whether rates of substitution between the two goods satisfy quasi-convexity. But this is too "non-ordinal." Given that quasi-convexity of preference is the common and most plausible case, the critical part in Assumption 1 is part (ii), and this is violated by the risky U in Wakker (2019). But the authors do not discuss it, and only discuss the less critical Part (i) in the preceding text (using nonordinal concepts), probably to suggest that Part (ii) would be the same. But it is not. To show that Assumption 1 does not pass the ordinality test, note that it is satisfied by V in Wakker (2019), but not by its ordinal transform U. On p. 39 the authors qualify utility functions that do not satisfy Assumption 1.i as "monomaniacal." If they also qualify violations of Assumption 1.ii as such, then U of Wakker (2019) is monomaniacal, but its ordinal transform V is not, showing that the authors' monomaniacality is not an ordinal property.

Similarly as above, p. 40 Proposition 2 statement (ii) is just not meaningful for the ordinal indifference curves, and V, U of Wakker (2019) show it again. And, similarly as above, p. 54 3rd para last sentence discusses meaningless convexity/concavity of riskless utility, and so does p. 57 ℓ. -4/-3.

P. 41 penultimate para: contrary to what the authors write, loss aversion has much impact on risk aversion and is, I think, the main component of risk aversion.

P. 47 middle: The authors keep one good of (x_1,x_2) at level 1, and then measure the utility function of the other. Contrary to what they write, they thus do not take complementarities between the goods into account.

P. 58 ℓ. -7 refers to utils, which are meaningless for ordinal utility, but then the bottom of the page states this.

P. 60 1st para italicizes a sentence that refers to marginal utility for ordinal utility.

P. 60 2/3 writes: "The principle of decreasing marginal utility as well as the definitions of complementarity and substitution between the goods are not unique up to positive affine transformations and, hence, are meaningless under ordinal utility." It is not clear to me what it means that the mentioned concepts are "not unique up to positive affine transformations," or what that would have to do with ordinality. But the sentence suggests that the authors have some awareness of meaningfulness restrictions under ordinal utility. They don't seem to understand that complementarity and substitution do have meaning under ordinal utility. %}

{% **utility elicitation**; use data about households' decision to buy insurance against telephone line trouble. Probability is about .005 per month, expected cost per month $0.262, premium per month $0.45. Their parametric family for utility, Eq. (7) ($U(W) = a_1(W+a_2)^L$, seems to be only power and hyperbolic, not general HARA as they suggest. L depends on the monthly bill.

Eq. (3) uses as probability weighting function:

$G(p)/\big(1–G(p)\big) = (p/(1–p))^{a_1}\big(p_0/(1–p_0)\big)^{1–a_1}$ (or equivalently, $\ln\big(G(p)/(1–G(p))\big) = c_1 + c_2.\ln\big(p/(1–p)\big)$)

inverse S: They write that they do not find big overestimation of probability but footnote 15, using more restricted parametric family for probability transformation, writes "This suggests that consumers overestimate the mean probability to a degree that is small in absolute terms but large in percentage terms." Logit of weight is affine transform of logit of true probability

They find concave utility with decreasing absolute risk aversion. They find that a_2 in Eq. (7) is significantly different from zero, which rejects power utility. (P.s.: if a_2 could be interpreted as status quo ...)

Their estimations are quite complex, I understand it's a logit analysis. My main problem is that the argument of their utility does not seem to be money but !money per month!, and probability likewise. Then things are quite different. I did not understand the analysis regarding this point. It seems to me that only info about whether customers do or don't buy this insurance can never distinguish between utility curvature and probability weighting. %}

{% This paper on the sleeping beauty paradox argues for p = 1/2, whereas I think that it is p = 1/3. The paper surveys much literature the topic. Sleeping beauty is a strange creature, in a way can be two different creatures with split-mind, and traditional Savage-type-states-of-nature or traditional probability-space analyses, I do not see how they can be applied to her. For instance, the "event" of her being woken up is not an event in the sense of either happening or not, because it can happen twice. Conditioning on it, I do not know how it can be done in any traditional modeling way. This paper tries to do it, but I do not understand.

P. 328 middle: Time t is hard to understand for me. Does t = 2016 mean it is 2016 years after Jesus Christ was born (calendar time) or 2016 years after sleeping beauty was woken up (stopwatch time, and then Monday or Tuesday, or both?). I guess it is the latter in some sense. Then strange that on Tuesday it happens twice. The analysis on p. 328 ff. is from the Sunday perspective (p. 328 ℓ. −3), but then C_{xMt} (sleeping beauty perceives perceptions x on Monday on time t) and C_{xUt} (sleeping beauty perceives perceptions x on Tuesday on time t) are the same event (I assume only one possible perception x: Being woken up and being asked), one happening if and only if the other does and event C_{xt} (sleeping beauty perceives x at time t after having been woken up, without it being specified if it is Monday or Tuesday) is not an event in any formal sense that I can understand. Thus, I do not understand Eq. 1, specifying a probability from the Sunday perspective of event C_{xt}. And I do not understand the rest of the analysis. One can take events C_{xMt} (sleeping beauty perceives perceptions x on Monday on time t) and C_{xUt} as disjoint events from the perspective of sleeping beauty who has just been woken up, but this is a different creature than sleeping beauty on Sunday, or maybe I should say two different creatures. %}

{% **time preference**: Survey on intertemporal choice, paying much attention to the fungibility problem (**time preference, fungibility problem**). I enjoyed that this paper gives a balanced account of this issue, as well as other issues, and does not try to push dogmatic views. MEL abbreviates "money earlier or later" studies, so, studies that take money as outcome. One argument favoring money as outcome, despite the fungibility problem, is that discounting is of most interest for this outcome. (In another domain, health, life duration is also important.) Further, for any consumption taken as outcome, there will be much time-dependence of the utility of those outcomes, confounding (measurement of) discounting. See, e.g., p. 332 on thirsty subjects. P. 338 (in the Conclusion): "On the other hand, consumption-based analyses still require assumptions/inferences/controls regarding the curvature of the instantaneous utility function and the nature of intertemporal substitution"
For what follows, I take as the common terminology in the literature what

Halevy (2015) used. It is not entirely what I would have chosen if I could, but we should stick with it to have consensus and that is quite happening, fortunately. The term stationarity has always, also before 2015, been used in the same unambiguous manner. It is unfortunate and disappointing that the authors of this paper will still use this term differently; see below.

The usual ambiguity in time-preference conditions also applies to some statements in this paper (**time consistency stated ambiguously**). To prepare, if you want to maintain an equality $a + b = c$, but want to change one of the three inputs, then you have to specify which of the other two inputs changes. Further, one can distinguish between calendar time (this paper calls that absolute time) and stopwatch time (the paper calls that relative time). Now to time preference. I now let “current time” refer to calendar time t. Further, $t + \tau_1$ and $t + \tau_2$ are some future calendar times, and τ_1 and τ_2 are differences, which in some contexts can be called stopwatch time. Many authors define a preference condition by claiming that changes in t don’t matter, or in τ_1 and/or τ_2. A first ambiguity then is, does that change concern decision time or consumption time, or both? A second ambiguity relates to the above a+b=c. Thus, if for instance t is changed, then are stopwatch times τ_1 and τ_2 kept constant so that calendar times $t + \tau_1$ and $t + \tau_2$ change, or are those calendar times kept constant so that the stopwatch times τ_1 and τ_2 change? With this, see Footnote 1 (p. 300): “Preferences are dynamically consistent if and only if all the state-contingent preferences held at time t agree with the state-contingent preferences held at time $t + \tau$ for all values of t and τ.” Here “state-contingent” is a term that will be explained only later (p. 303) and only vaguely, but can be ignored. The footnote makes clear that decision-time changes, but not wheether calendar-time or stopwatch time of consumption is to be kept constant. In the former case, it is what the literature indeed calls dynamic consistency or time consistency. In the latter case it is what the literature calls time invariance. In this paper, it will be the former. The latter will just be made throughout this paper, as can be read on p. 303. The paper uses both the terms time consistency and dynamic consistency, apparently interchangeably, but never says so.

A drawback is that the paper is quite outdated. P. 302 Figure 1 writes that the literature search was done August 2014. Several references that have appeared by long, are still cited as working papers.

DC = stationarity: The authors do not really commit this confusion, but throughout assume time invariance which makes the two equivalent. Footnote 6 on p. 305 makes explicit that without time invariance (what they call stationarity) DC can be different. P. 303 §2.1 introduces notation but, unfortunately, deviates from standard terminology. It uses the term stationarity for what is usually called time invariance: Preferences remain the same if the calendar time of preference is changed from t into $t+\varepsilon$, and the calendar times of consumption are also increased by ε, so that all distances between consumption time and decision time remain the same. And this for all t and ε. This allows using stopwatch time. It also allows putting the decision time always at t=0. This paper will not always do so, for instance on p. 305 below Eq. 7 when discussing time consistency. Given the assumed time invariance, stationarity and time consistency become logically equivalent. And, thus, they can claim that constant discounting is equivalent to time consistency.

P. 310 nicely writes: "To date, heuristic-based models in the domain of intertemporal choice have primarily been descriptive and difficult to generalize. They would not typically be used for welfare or policy evaluation. In other words, these heuristic models are primarily positive and not normative in scope."

The authors in most of the paper discuss models with economic flesh, such as self-control or multiple selfs or temptation or all kinds of heuristics, monetary versus nonmonetary outcomes, field versus lab, binary choice versus matching versus choice lists. §4 discusses the more conventional studies that use monetary outcomes. They also discuss real versus hypothetical choice (§4.3), using balanced terms. P. 327 in §4.3 writes: "Because of such logistical challenges, the desirability of using real payments in a MEL task, as opposed to hypothetical rewards, is open to debate."

P. 321 considers measurements of discounting that need not assume linear utility and that need no utility curvature, but only cites a five-year old unpublished working paper co-authored by one of them, being Ericson & Noor (2015). It will be no surprise that I would have liked citation of Attema, Bleichrodt, Rohde, & Wakker (2010 *Management Science*), and/or Attema, Bleichrodt, Gao, Huang, & Wakker (2016 *American Economic Review*). %}

Experiments use hypothetical choice. Use choice lists to measure certainty equivalents of gambles on events.

P. 277 bottom argues for considering ambiguity attitude (they use different terminology: Optimism/pessimism) with risk attitude filtered out, which they oppose with Hurwicz's α-pessimism index that also comprises risk attitude. They don't do this by measuring matching probabilities but instead indirectly by measuring certainty equivalents and then comparing those.

They allow subjects to express indifference, in which case the exerimenter (who does not know more about the uncertainties than the subjects) chooses on their behalf.

For risk, they find risk aversion for gains and strong risk seeking for losses. They cannot infer **reflection at individual level for risk** because almost all subjects are risk seeking for losses.

For ambiguity, which they call complete ignorance, they do not control for suspicion. Given that choices are hypothetical, this is not a big problem. (**suspicion under ambiguity**)

For gains, they find ambiguity aversion (they call it pessimism) and for losses ambiguity neutrality (so, not entirely **ambiguity seeking for losses**). %}

{% This paper influenced me much. Several times, if I thought to have a recent new insight or opinion, I would discover that it was already in this paper. It comes from the times when Jaffray influenced me much and was in his hey days for decision theory.

They use the term uncertainty for what the literature today mostly calls ambiguity. Their term pessimism/moderate/optimism designates ambiguity aversion/neutrality/seeking.

- P. 1 ℓ. 5 ("Its two-step") nicely describes probabilistic sophistication (= the "first step "), called probability-oriented.

- P. 1 bottom, and the paper throughout, points out that unknown probability is the anchor and that people may treat known probabilities as if unknown, rather than the tendency throughout the ambiguity literature these days (2011) which does nothing but try to relate unknown probability to known probability where the latter is treated as heaven that we all long for. In partucular, it writes that unknown probability, and not known probability, is the common case.

- Insensitivity (towards known/unknown probability; underlies inverse S) is a central concept throughout, rather than focusing on the aversion/seeking dimension as most people do even today.

- The paper understands well that gain-loss reflection should not only be considered for group averages but, more or less independently, also at the individual level.

- The paper applies the random incentive system as it should.

- The paper pays one subject high instead of paying all subjects small (p. 3).

- The paper has nice measurements of indifferent and incomplete preferences (although subjects did not understand the incompleteness well).

- P. 13 middle defines the concept of ambiguity (though using different term: Uncertainty) as the difference between unknown and known probabilities, which I like, but then only when probabilities are completely unknown.

- Appendix nicely gives a formal account of isolation.

On all these points, often debated, I agree 100% with this paper.

N = 134 students. P. 3: Use **random incentive system between-subjects (paying only some subjects, only one in fact)**. Plead for this being better than paying all a small amount. P. 3: for losses: **losses from prior endowment mechanism**. Nicely explained using isolation effect.

This paper concerns the same experiment and data as the authors' paper published in Theory and Decision in 1985, but it does not give a cross-reference!?!? It may also be the same as a paper by these three authors published in French in 1983 in Bulletin de Mathématiues Economiques 18.

Introduction splits SEU up into two stages: (1) probabilistic sophistication; (2) Given probability soph., EU maximization à la vNM. It also points out that unknown probability is more familiar than known probability.

Subjects did questions repeatedly so that errors could be assessed. Unfortunately, errors for losses are not compared to those for gains.

P. 2 penultimate para: They use the choice list method, with a clarifying figure on p. 4. Thus, they belong to the numerous papers that preceded Holt & Laury (2002) in this.

They allow for "I do not know" and "equivalent," finding at each question about 10% of subjects using it (Cettolin & Riedl 2019 JET also found much use of it). Then they take the middle of the indecision interval as switching value.

P. 10 emphasizes that their definitions of risk aversion do not assume any model.

P. 10-11: they point out that risk aversion or seeking depends much on the probabilities considered (in perfect agreement with inverse S probability weighting both for gains and for losses, i.e., fourfold pattern!), and then write nicely (pp. 10-11):

"The reason why subjects' risk attitudes are not correctly conveyed by the conventional definitions may simply be that these definitions, despite their intrinsic character, take their origins in the EU [expected utility] model, and therefore share in its deficiencies."

P. 13 3rd para:

"The notion of attitude with respect to uncertainty, first introduced by Ellsberg (1961), does not claim to reflect subjects' absolute behavior under uncertainty but the differences between their behavior with respect to risk and with respect to uncertainty—more precisely, to the extreme situation of uncertainty known as complete ignorance."

One nice point here is that they do not take uncertainty [ambiguity] attitude in any absolute sense, but in a relative sense. Another remarkable point is that they do not take ambiguity attitude source dependent, as I would prefer, but as only the difference between complete ignorance and risk. Thus, ambiguity attitude becomes a property of the agent independent of the source considered. Then a very ambiguity averse person may exhibit moderate ambiguity aversion for some source because the person apparently considers the source not to be very ambiguous. This terminology is logically sound, but I think it will not work because ambiguity aversion will be too diverse. People can be ambiguity averse for one source and ambiguity seeking for another. So, I prefer to take ambiguity attitude as source dependent.

P. 13: they derive ambiguity attitude indirectly from elicited CEs (certainty equivalents).

P. 14, Table 5: for gains, 58% is ambiguity averse, and 5% is ambiguity seeking. For losses, 28.5% is ambiguity averse and 29.5% is ambiguity seeking (**ambiguity seeking for losses**: They find neutrality on average). Pity they do not separate likely and unlikely events.

Pp. 15-18 give an extensive and wonderful test of probabilistic sensitivity of subjects, showing they are less sensitive for losses.

Table 3 on p. 12: more risk seeking for losses than risk aversion for gains.

inverse S, stated on p. 10 ℓ. –10/–8 and visible in Table 2, p. 11. For probabilities 1/2, 1/3, 1/4, 1/6 at gaining FF1000, they find less risk aversion as the probability gets lower. They actually find quite a lot of risk seeking for gains and risk aversion for losses. For gains, risk aversion occurs only for probability 1/2 and strong risk seeking occurs for all other probabilities. For losses it is the opposite, for the same probabilities they find risk seeking for probabilities 1/2 and 1/3 and risk aversion for probabilities 1/4 and 1/6. This may be because they only consider probabilities ≤ 1/2.

Nicely, argue against regression to the mean because the variance in the CEs are not smaller for small probabilities.

CE bias towards EV: Appears from the large risk seeking for gains (see above). They determined CEs (certainty equivalents) through tables with sequential binary choices in such a way that the subjects could see that the CE was searched for so that, as Bostic, Herrnstein, & Luce (1990) suggested, subjects may have taken these as CE matchings.

reflection at individual level for risk & **reflection at individual level for ambiguity**: evidence against reflection: They find that both risk attitudes for gains and losses are unrelated; and ambiguity attitudes are unrelated too, at the individual level. Average weight of total ignorance (unknown 2-color urn) is .4; p. 2 ℓ. 1 interprets inverse S as insensitivity towards probability.

correlation risk & ambiguity attitude: They have the data at the individual level so could inspect, but they do not report it. Cohen (personal communication, 14Nov2011), let me know that the correlation between risk aversion and ambiguity aversion is 0.31 for gains and 0.30 for losses. %}

{% %}

Cohen, Paul J. (2008) "*Set Theory and the Continuum Hypothesis*." Dover Publications, New York.

{% Did an experiment in 355 cities in 40 countries, with 17000 "lost" wallets. Each time, a research assistant entered an institution such as bank/hotel, said to have found a lost wallet, gave it to the person serving at the counter (that I will call server), said to be in a hurry, asked the server to handle the case, and then left without leaving name or address. Wallets contained a key, a grocery list, an address, and either some money (mostly $13.45), or not. Surprisingly, wallets with money were returned more often than those without. In some countries they put 7 times more money in some wallets, and this only further increased the rate of return. The paper suggests altruism and self-image explanations.

Psychologists often have to work with vague ill-defined concepts, where there are many confounds beyond control. They then do 20 DIFFERENT experiments, each time showing their claimed effect. Each single experiment can be questioned, but the 20 together still make the claimed effect credible. This paper also collects much data, but everything always the same way. Thus, any deviating detail of their setup can lead to strange things, and explain the findings. In this study, I can think of such details and alternative explanation: (1) Because wallets had been found by someone else than the server, for wallets without money the server could conjecture that the finder might have taken out any money, and that the server could then be accused of having taken that money; hence they preferred not to return such money-less wallets. (2) keeping a wallet with money may be risky here because the finder may know about it and return to enquire about it. (3) People working at counters of institutions are a nonrepresentative sample, and may be subject to all kinds of special rules.

Another explanation may be that wallets without money have no value (the owner got a copy-key by now and already did shopping), so no use for the effort of returning it. This is like altruism. Only, there have been other studies (e.g. by

Jan Stoop) finding that that is not the case.

I regret that such a big study, costing $170,000 in total, has been done for just one such thin finding. (Or, hopefully, the authors will write several papers on this beautiful data set?) More remarkable/interesting than the whole rest of the paper could have been Figure 1, showing percentages for different countries. China is the worst here. I would expect Japan to be 1st, but Japan was not included. My country, the Netherlands, is nicely ranked 3rd, after Switzerland and Norway. Big problem with this figure, under a loaded heading such as civic honesty (see title of paper), is that there are (too) many confounds to make comparisons between countries meaningful, which may be why the authors do not discuss it much. For example, several people have argued, about China, that the finding may be because the experimenters work with email, but email is rarely used in China. This table, unqualified in this prominent journal, will do more harm than good. %}

real incentives/hypothetical choice; in pilot study, Appendix IV, for 53 subjects variations of the Allais paradox were tested, both for real payments and for hypothetical choice. No differences were found between the two. Shows that **RCLA** is violated more than compound independence, which gives evidence in favor of backward induction (**backward induction/normal form, descriptive**). On the reason that this ended up in an appendix under the name "pilot study," an insider whose name I will not reveal wrote to me:

"As it happens, Conlisk did this under protest from the editor and a brilliant, then-young referee, so it is perhaps no surprise that it was written up in the manner it was.…"

Probability weighting linear in interior: seems that few violations of independence in interior of probability triangle, and mostly at extremes. %}

https://doi.org/10.1007/s11166-022-09401-z

{% Subjects choose between two-stage lotteries, with only two prizes involved: €0 and €40. The second-stage probabilities are always 1/n for some n. The choices are done in an unusual manner: one two-stage lottery is called changing, and one unchanging (p. 115 top; p. 119 top). When the subjects made a choice, the changing lottery was modified by randomly removing one of its 1st stage lotteries, so that the remaining ones have probability 1/(n−1), until one 1-stage lottery was left. It seems that subjects did not know that this was the procedure. I do not understand this procedure, because it will give subjects all kinds of strange ideas that they are influencing next choices (even if in reality they aren't).

The authors do individual fit-predict, and a mixture model with fit-predict, for the following deterministic models: EU (which has no free parameters here and just maximizes the probability of getting the prize), the smooth model (SUM $\varphi(p_j)/n$ with p_j the 1st stage probability of winning and n 1st stage lotteries, each with 2nd stage probability 1/n), RDU (done with backward induction = CE substitution), and α maxmin. For the latter, 2nd stage probabilities are ignored. Results: for 53% of subjects the smooth model works best, for 22% EU works best, for 22% RDU works best, for 3% α maxmin works best. The poor performance of α maxmin is no surprise because, as implemented by the authors, it ignores the 2nd stage probabilities. The weak performance of RDU may be due to it being combined with backward induction (Eq. 5 p. 117), which is controversial under nonEU. The weak performance of EU may be due to it having no free parameters here. The good performance of smooth may be that the stimuli were designed for it, and not for RDU/α-maxmin.

DETAILS:

In the past the term multiple prior models referred only to theories where the set of priors is treated as a set. That is, a prior is in or out, and that's it. All in are in a way treated alike, and so are all out. Some in are not weighted more than others in. Models with different weighting of priors are for instance two-stage models. They were considered to be very different. Unfortunately, this terminology is being lost more and more. More and more, authors, when having a theory in which they think to discern a set of priors, already use the term multiple priors, to pay lip service to this model. Among the first to take this bad habit were Klibanoff, Marinacci, & Mukerji (2005) in their smooth model. They just have a two-stage model. However, the support of the second-stage distribution was designated by the authors as a set of priors and, hence, they used the term multiple priors for their model. The present paper by Conte & Hey follows the bad habit. Things get even worse on p. 131 beginning of 2nd para, where they suggest that the α maxmin model is not a genuine multiple prior model because it does not consider second-stage probabilities! The only thing non-genuine is the way C&H apply the α maxmin model to a situation where it is not meant to be applied.

P. 116 footnote 3 properly points out that the C&H assume the second-stage probabilities in the smooth model exogenously given, which is against the spirit of the smooth model where they are assumed to be endogenous. C&H rightfully point out that endogenous 2nd stage probabilities are hard to observe.

Pp. 116-117: C&H write the exponential utility function but do not know that with parameter $\alpha = 0$ this becomes linear utility and thus, erroneously, claim that EU is not part of it.

P. 117 beginning of §1.4: C&H claim that Ghirardato et al. (2004) “proposed”α maxmin and, thus, do not know that the model is over half a century old, being discussed in Luce & Raiffa (1957 Ch. 13).

P. 121 ℓ. –3 miscites Abdellaoui et al. (2011) on suspicion. In Abdellaoui et al., subjects were betting on all colors. Exhangeability was tested and found verified, meaning subjects did not find some colors more likely than others. This is one of the ways to control for suspicion.

§6.1: I do not understand why for nested theories they do not use BIC, but instead a likelihood-ratio test (which ignores number of parameters). %}

Cooper, William S. (1987) "Decision Theory as a Branch of Evolutionary Theory: A Biological Derivation of the Savage Axioms," *Psychological Review* 94, 395–411.

{% On ordinal revolution, concentrating on interpersonal comparability of utility. Many nice citations and references. The authors use Pareto's distinction between utility bringing usefulness and fulfilling needs (in principle objective and observable), and utility fulfilling desires (ophelimity, subjective). They argue that the ordinalists did not bring unambiguous progress in economics but instead changed the meaning of utility from usefulness (ordinal) to desires-fulfilment and changed the domain from welfare evaluation to consumer/price theory.

Pre-ordinalists (called "material welfare school" by Cooter & Rappoport) took utility not as revealed through choices, but still observable, by seeing how well a person is doing, usually taken at group level of number of sick people etc. This was taken as in principle objective and observable. Utility means usefulness, probably same as fulfilling needs ("wants"), and is normative/rational. Bad-tasting medicine for child gives usefulness but no ophelimity. (I don't see the difference, child misjudges desires by overlooking long-term desires. P. 516 footnote 23: Pareto (1896) seems to say that the two concepts should coincide for a rational person. So, then ophelimity is descriptive and usefulness is normative?)

P. 510: paradox of value (water is more useful than diamonds but we pay less for it) prevented utility to be useful in economics up to around 1870. Jevons (1871) resolved it by considering marginal utility.

Describes also the marginalist revolution of utility around 1870, initiated by Jevons.

marginal utility is diminishing: many refs and historical citations in diminishing marginal utility.

P. 516: "the power of commodities to satisfy material needs was called utility."

P. 520 etc.: big role for Robbins (1932/7) in ordinal revolution.

P. 527: "The belief that a utility structure was common to people made introspection an appropriate empirical tool."

I like the many details, but not the main message, of this paper. The ordinalists' idea to firmly base utility on observed choice was definitely a step forward. Only if ordinalists go too extreme by saying that all other things are useless ("meaningless," as ordinalists often argue, unfortunately) then they go too far I think. The authors make many distinctions on subtleties in utility, e.g. is it descriptive/normative, is it pleasure- or goal- fulfilling, is it on basic needs (food) or also on more abstract things (theatre, social life), etc. These aspects of interpretation of utility shift between different authors and in general over time, and some aspects are more prominent for ordinalist- than for other utility. I disagree that making distinctions on these details justifies the claim that ordinalists were dealing with completely different questions and concepts.

Lyons (1986) may be another reference for history of ordinal revolution. %}

{% **probability elicitation**: applied to experimental economics.

P. 731: "We merely view our results as suggesting that economists should start to ask whether it

is reasonable to assume that decision makers act on their beliefs without much difficulty in all decision problems." This can be taken as a plea to use ambiguity models.

The paper uses the quadratic scoring rule to elicit subjective probabilities in repeated games. The beliefs do not perform well. Calibration and discrimination are not good relative to real play (p. 742, top), and they are inconsistent with players' own choices. The source method provides an explanation through a-insensitivity, i.e., inverse S weighting of subjective beliefs, enhanced by the involved ambiguity. Then it seems as if the players take their opponents strategy choices as random. The authors describe the latter finding on p. 731: "The subjects' play of the games appears to be naïve, as if they expected their opponents to choose actions randomly. But in the belief statement task they calibrate better, predicting roughly that their opponents respond to uniform beliefs." (p. 731) %}

http://dx.doi.org/10.1371/journal.pone.0090742

{% **random incentive system**: Test this as well as several other payment schemes, such as PAS (pay all sequentially, immediately after each choice, without knowing which choice comes next), and in an experiment with N choices pay all choices, at the end, but multiplied by 1/N to get average, and not very large total payment (PAC/N). The C here refers to correlated: The lotteries were not independent, but maximally correlated (with events specified), so that Yaari's (1987) dual independence holds. Take as gold standard OT (one task), something that for instance Birnbaum (1992) took issue with. Find that repeated payments (which suffer from income effects) do best in the sense of staying closest to OT. Although they do not explicitly choose a winner, I gather from the results that PAC/N did best overall, with PAS second-best, from choice percentages in Table 4 being closest to OT.

Sections 3.2 & 9.1 & 10.1 suggest that the RIS (they write POR) is not incentive compatible if expected utility is violated, such as under RDU and PT. But the counterexamples make particular assumptions about dynamic decisions and RCLA. It is possible to have incentive compatibility for RIS and nonEU under particular other dynamic decision principles, e.g. backward induction. Cohen, Jaffray, & Said (1987), and many others, use the term isolation for such cases. Bardsley et al. (2010 p. 269) points this out too. Section 11 cites the working paper Harrison & Swarthout (2013), later appeared in 2014, affirmatively on this point, but the Harrison & Swarthout paper is a weak one to side with.

§6 1st sentence strangely writes: "It has been argued in the literature (e.g., Kahneman and Tversky 1979) that subjects evaluate each choice independently of the other choice opportunities in an experiment." I cannot imagine that Kahneman and Tversky would ever write such a weird universal claim, with violations shown for instance in Redelmeier, Donald A. & Amos Tversky (1992) "On the Framing of Multiple Prospects," *Psychological Science* 3, 191–193.

Section 9.1 incorrectly claims that using the RIS (they write POR) is

incompatible with nonEU theories such as PT (they write CPT). I discussed this point above. It also incorrectly writes that PT would assume independence of wealth level.

§11 writes: "there is no known "ideal mechanism" that will solve all the problems we describe."

The authors claim that the PAS treatment (pay all sequentially immediately) is incentive compatible under Yaari's (1987) dual independence, but I do not see this. I assume that the repeated payments are done probabilistically independently, and then a complex joint distribution results. %}

{% This paper discusses the role of preference foundations, i.e., preference axiomatizations, i.e., representation theorems. In particular, it considers the role of theoretical terms there. And then, the semantic role of giving meaning to those terms. P. 293: “Finally, the few explanations that have been offered as to why these results are so important sometimes reflect doctrines that have been largely abandoned in philosophy of science and in philosophy of language (notably operationalism and behaviorism).”

My opinion is a what the paper calls “anti-holist attitude towards meaning.” Preference foundations only show what the assumed existence (specifying also the decision theory, e.g., EU) means, not entirely the terms themselves. It is only part of the meaning. Showing how to measure them, which is something that particular proofs do (I always try to write my proofs this way), operationalizes them, which adds to their meaning.

P. 297 nicely relates to theoretical terms in natural sciences, such as electrons or genes. For this typical *existence* of subjective parameters in preference foundations I cannot think of an analog in natural sciences.

P. 297 3rd para: “The problem of the meaning of theoretical concepts is usually presented as follows: one assumes that theory T is formulated in a certain language, as a set of propositions, and that one can distinguish, in one’s conceptual repertoire, between two categories of terms. In the neo-positivist tradition, theoretical terms are contrasted with observational terms, where a term is considered observational when you can determine through observation whether or not it applies to an entity in its domain of application. Lewis (1970, 1972) liberalizes the distinction: the ‘theoretical’ terms are terms that are *introduced* by a theory T, and they are contrasted with terms whose meaning was determined *prior* to the theory T. For the discussion here, there is no need to decide between these distinctions. As standard, we will use the word *t*-terms to designate theoretical terms, and o-terms to designate observational terms *or* those introduced prior to the theory T.”

P. 297 last para: "Theoretical terms can be explicitly defined through observables, although usually this is complex, but mostly this is not done and the meaning is left implicit." The authors cite Ramsey (1929) and Carnap (1959), taking the RCL (Ramsey-Carnap-Lewis) approach. It takes theoretical terms as implicitly simultaneously defined in a theory.

Lewis defines every single theoretical term through the *existence* of all the other theoretical terms such that the theory considered holds. This is close to the existence sentences in behavioral foundations. P. 300 bottom seems to suggest that Lewis' definition may solve some philosophical problems but is trivial as regards its clarification of representation theorems. The main alternative is the causal-historical theory (p. 298 middle). It is something like through causal relations, but I did not understand. CRL fits best with decision theory.

P. 299 middle: "given the affinities between decision-theoretic and folk-psychological concepts (for example, between subjective probability and belief or between utility and desire), it may be asked to what extent the concepts used by decision theorists are truly theoretical terms, rather than (pre-existing) ordinary language terms. However, there are reasons to suspect that an objection along these lines is flawed. As Enç (1976) has pointed out in his discussion of similar examples from the natural sciences, there is a difference between terms such as 'heat' and 'magnet' on the one hand and 'caloric' or 'magnetic field' on the other."

P. 299-300 (**conservation of influence**): "First, this way of defining subjective utility and probability is very similar to the way in which, in the philosophy of mind, functionalists (such as Lewis himself) characterize ordinary beliefs and desires. More exactly the definitions are similar to forward-looking features in the characterization of mental states, i.e., features that refer to their effects, in contrast with backward-looking features, which refer to their causes." Unfortunately, the paper does not elaborate on this point.

§7 propagates constructive proofs of preference foundations, which show how the subjective concepts can be measured. If self-references can be allowed, I always week for such constructive proofs, as explained for instance in Step 4 of the five steps in Wakker (2010 p. 8), in Abdellaoui & Wakker (2018) "Savage for Dummies," and so on.

p. 304: "If one assumes that the axioms are satisfied, then the definitions in terms of preferences (Def-pref) seem to satisfy the strictest empiricist and operationalist criteria. Indeed, they correspond to what Carnap (1936/1937) refers to as 'explicit definitions. These theorems, and more specifically the [constructive] proofs discussed above, contain explicit definitions of decision-theoretic concepts that, in the eyes of an anti-holist … , are preferable to the Lewis definitions."

The authors suggest repeatedly, e.g. p. 306 ℓ. 15, that behavioral economics attaches less importance to behavioral foundations than was done before. I don't see this. Of course, behavioral models can be explicitly nonnormative, and then there is of course less interest in normative preference foundations. But there then is more interest in descriptive preference foundations. %}

{% Ellsberg's three-color paradox has an ambiguous ("unknown") urn with one-third of balls red, and 2/3 black and yellow in unknown proportion. This paper considers a variation with only two colors: Between 0/3 and 2/3 are blue, and the rest is orange. It is as if joining the colors red and black in Ellsberg's urn. They also have a known urn, and they also have the regular three-color Ellsberg urns. They consider gambles on Yellow in the regular Ellsberg urn, and on blue in the variation. In the former they find ambiguity neutrality, so, not the regular ambiguity aversion, in agreement with many current (2019) findings. In the variation, remarkably, they find pronounced ambiguity seeking (73% of subjects!; **ambiguity seeking**). One explanation can be a general drift towards uniform distributions. In the variation there are two colors, which in the case of ambiguity moves subjects in the direction of 50-50, and it does so more than with risk. Such a drift is analyzed by Fox & Clemen (2005) for ambiguity. A similar (but I expect weaker) drift for risk is in Viscusi's (1989) prospective reference theory. It may also play a role that, whereas in the Ellsberg urn, the winning color yellow plays a role symmetric to its counterpart black, in the variation the winning color blue is a sort of a focal event, which may bring overweighting. In the treatment where some voluntary subjects, otherwise uninvolved and not knowing even that there would be bets with winning colors, could determine the composition of the ambiguous urn, on average they indeed put more than 1/3 of blue balls. That is, an ambiguity-neutral Bayesian who can predict this would prefer the ambiguous urn!

The above case always had an a(mbiguity)-neutral probability 1/3 of winning. They do similar things with an a-neutral probability of 2/3 of winning. So, in the variation there are between 1/3 and 3/3 blue balls as winning color. Here they find ambiguity aversion for Ellsberg (66%), but even stronger for the variation (73%)! Here the voluntary subjects who could determine the composition of the ambiguous urn, on average put less than 1/3 of blue balls. That is, an ambiguity-neutral Bayesian who can predict this would disprefer the ambiguous urn.

Putting together, there is more insensitivity for the variation. %}

Crosby, Fave (1976) “A Model of Egoistical Relative Deprivation,” *Psychological Review* 83, 85–113.

{% **questionnaire for measuring risk aversion**: the authors introduce the BRET (bomb risk elicitation task) method: Subjects can choose a number of boxes from 100 boxes. One of those contains a bomb. Payment is linear in number of boxes if no bomb (10 €-cents times), and 0 if bomb. Risk neutrality implies choosing 50 boxes. The authors consider both a dynamic version, choosing boxes one by one until stop-decision, and all-in-once version. They analyze the data assuming EU with power (CRRA) utility.

A good move: Whether or not the boxes selected contain the bomb is determined only at the end of the experiment, thus avoiding truncation. Hence, the bomb is called time bomb.

The authors favor the dynamic version, but my hunch is to prefer the all-in-once version because the dynamic version does not inform subjects that their choices will influence future options offered.

Nice, and similar to balloon task of Lejuez et al. (2002) which the authors cite. These are all variations of the Binswanger (1981) method. Even closer, and maybe nicer (for not referring to the emotional bomb) is the Columbia card task by Figner et al. (2009, *Journal of Experimental Psychology* 35, 709–730), which the authors are unaware of, maybe because it is in a psychological journal.

decreasing ARA/increasing RRA: In one task, they double the stakes. It leads to higher relative risk aversion, confirming the common increasing RRA. In another treatment, they let subjects first make some money from another task, and then carry out the bomb task. Then they find no clear result, with risk aversion increasing for prior gains between 0 and €2.7, but decreasing after, so, no clear results on increasing/decreasing ARA. I think that whatever effects the prior gains have, these are psychological effects other than wealth effects, because the prior gains are too small to generate real wealth effects.

gender differences in risk attitudes: analyzed in §3.2, where a reference point of €2.5 is framed in. Here, and in several places, the authors claim to find that women are more loss averse then men, but their results in fact are not significant. Women are not more risk averse otherwise. This agrees with Booij &

van de Kuilen (2009).

The authors’ BRET method has some less risk aversion than other methods, which surprises me because I would expect the term bomb to generate risk aversion. %}

Crosetto, Paolo & Antonio Filippin (2013) “The “Bomb” Risk Elicitation Task,” *Journal of Risk and Uncertainty* 47, 31–65. https://doi.org/10.1007/s11166-013-9170-z

{% P. 615 Footnote 2: BDM (Becker-DeGroot-Marschak) is difficult. Analyze four ways to elicit risk attitudes: Multiple price lists (I prefer the efficient term price list; bw., to me this is not a specific risk elicitation, but in general a way to obtain indifferences), ordered lottery selection à la Binswanger (1981), investment game, and bomb elicitation. They also do general introspection. They first analyze the different methods using simulations, to see what differences are due to the methods. Then they investigate in an experiment. There they find differences more than what the methods themselves induce, showing that the underlying risk theory is violated. Unfortunately, the authors implicitly assume EU throughout (stated only on p. 631), with constant relative risk aversion (CRRA), so, logpower utility. Much is known about violations of EU which gives insights into what happens here, but, as often in experimental economics (Holt & Laury 2002), the authors ignore this literature. (**Prospect theory not cited**) They find that the presence or not of a riskless, sure, option matters a lot. This is no surprise given that the certainty effect is about the main cause of EU violations. The authors do mention this point on p. 637 2nd para in the discussion. They don’t find clear superiority of any method. %}

Alias: Wakker (1999) http://personal.eur.nl/Wakker//pdf/alias.pdf

This paper is very very similar to my Alias paper and my Alias lecture (Madrid 92 and many times after), bringing out clearly the way independence follows from dynamic principles. It was called to my attention by David Kelsey when I did my Alias presentation in Birmingham (26 April 1996). The paper was thus important to me that I spent about 5 days full time studying it.

The paper is not always accurate in its graph-definitions, although it greatly improves on Hammond (1988) in this respect. Thus, on page 3, lotteries are not defined. They apparently can be compound. The formal def. does not say that n0 is the only node without predecessor. There might be other such nodes and then trees would consist of separate components that have nothing in common (they can then never meet, as can be proved). Only p. 3 l. -2 excludes this case; it should have been in the definition. It would save some symbolism (e.g., the capital O) if end nodes were identified with the prizes/gambles there. I would prefer it if only prizes, not compound gambles, could be end nodes; in this paper, the identity of T1 and T2 on p. 4 has to be imposed as another formal condition. Also, definitions are not highlighted by italicizing or so.

A major omission is that the analysis assumes that all “isomorphic” trees are treated the same way, but does not make that explicit. In other words, the name of a node does not matter. Many papers have that assumption only implicit. This paper does so for instance when defining “the” simple choice tree, and runs into trouble in Footnote 9 because of it.

Identifying a plan with the terminal node(s) that it is heading for is nice, avoiding some discussions about what to do in counterfactual decision nodes. The definition with connectedness to specify when nodes are not separated by decision nodes but only by chance nodes serves to make that possible. The nonemptiness requirement may be too weak. It only requires nonempty choice at !some! decision node, whereas one would expect that at all noncounterfactual decision nodes.

Footnote 7 says that DC is automatically built in in the approach of Hammond (1988). That of course (?) refers to DC as defined in this paper which is in the very weak sense, see hereafter.

The paper uses the term consequentialism in an overall sense to comprise all conditions, so different than I will do hereafter (I use the term for Cubit’s axiom A2).

Plan: shouldn’t there be some completeness in the sense that for every noncounterfactual decision node there is at least one possible terminal node? For the purposes of this paper, only deriving implications for static preferences, it need not be. It is supposed to choose everything that is best, not just be a partial restriction.

A major complication for my understanding of the paper was the concept of “plan.” Many papers use that concept in an informal sense, which I do not like. This paper formalizes it in a mathematical sense, indeed, as a subset of available strategies (through end-nodes). Its decision-status is, however, not very clear. I can think of two different interpretations that considerably affect the meaning of the axioms, mainly A1 and A3. Only the discussion Section 5 and the conclusion section 7 make clear that what I hereafter call the deviation-interpretation is what is meant to be.

Committed plan: Plan means what you would do if at a given node you could lay down all your decisions in following nodes with commitment, so without being able to deviate later; that is, if you can choose between strategies from there on.

Deviation-plan: Plan means what you do if at each subsequent node you can deviate if you like.

Deviation-plan can still be in backward sense as in sophisticated choice or in forward sense as in resolute choice à la Machina (1989), who favors resolute choice but does not need a commitment device for it. Later on in the paper it becomes clear that the deviation-interpretation is meant to be. I will discuss also what the conditions would be under the commitment interpretation.

Plan can be given more decision-theory meaning by letting a tree be a choice option in another decision node (say one where a sure amount is an alternative, to do evaluation in terms of certainty equivalents). That then, however, would require a consideration of more complex decision trees and more assumptions about sequential decisions versus one-shot decisions which, for the mere derivation of independence, would be just too much.

Note that the ambiguity in the meaning of plans does not play a role when the only decision node is the initial node, so there the decision-theoretic meaning of decision is clear.

A1, DC: This is a quite weak condition and only excludes myopia, something that plays no role in Alias because I work with committed plans there.

For committed plans, the condition would be strong, being (b) => (c) in Alias.

A2 is forgone-event independence (Cubit's term separability is unfortunate because this only compares pref. over alternative with pref. over "subalternative" = conditional act). It is (a) => (b) in Alias. The difference between committed and deviation plans is not important here.

Later A2 will be split up into A2a, independence from past chance nodes, and A2b, independence from past decision nodes.

A3 is irrelevance of the timing of the resolution of uncertainty. It speaks to the interchange of a chance and decision node when that is strategically equivalent. In the case when the decision node comes last, it does not involve a "nondecision tree" as in my Alias Figure (c), but puts a decision node (which might be trivial) before it all and considers “plans” at that decision node.

For deviation plans as is Cubit’s interpretation, A3 is, as usually, hard to interpret in a decision theory sense, but it looks really strong because under deviation plans there is really little reason to take the prior perspective. It then captures about all of Machina’s dynamic consistency where one considers risks borne in the past to be relevant (not really all because it also needs A1 but A1 is really weak, only excluding myopia).

For committed plans, A3 is step (c) => (d) in Alias which is not very strong. (Cubit’s terminology that a plan “offers a lottery” on p. 9 suggests a bit the latter interpretation.)

A4 is reduction of compound lotteries, not in full force, but all that is needed to derive independence.

A5 is reduction of consecutive choice nodes, i.e., Plott’s path independence. It says that prior plan in sequential tree is prior plan (= choice) in reduced tree. It then needs A1 to relate the prior plan in the sequential tree to what is really done in the final decision node and A2 to relate that to what is done in the “sniped-off tree.” A5 is not very strong.

Under committed plans, it is very weak and is similar in spirit to A3.

Section 5 contains the discussion. The forward/backward discussion on top of p. 13 shows that the author has the deviation-plan interpretation in mind. Principles relating normal representations to extensive representations, such as A3-A5, are in general forward because they entail that all ways to write a backward representation for the same forward representation should give the same. For A3 and A5 the point is clear, for A4 less so because A4 is not very easily reformulated as a decision principle.

Under committed planning, A1 would be forward and A3/A5 would be weak.

In Table 1, I don’t find it very convincing that A1 and A3 are in the column of chance. Well, if that means that it does not only refer to chance-less trees then OK, but then it’s not very interesting.

The text following Proposition 3, on A1, once more suggests that this paper uses the deviation-interpretation for plan.

On the discussion of splitting Hammond’s consequentialism up or not, I think there is interest in both views, but I like Hammond’s much. I like seeing this all as one idea.

P. 15 has a useful discussion of McClennen. %}

Cubitt, Robin P. (1996) "Rational Dynamic Choice and Expected Utility Theory," *Oxford Economic Papers* 48, 1–19.

{% "We cannot observe plans, only actions." %}

Cubitt, Robin P. (1997) discussion at FUR conference in Mons 1997.

{% The authors investigate the DE (decision from description versus experience) gap. (**DFE-DFD gap but no reversal**?) I think that the early literature on decision from experience (DFE) oversold their case for marketing purposes. One can expect a gap with less overweighting of extreme events in decision from experience, which is unsurprising. But not a reversal leading to underweighting of extreme events, as the early literature claimed. Many recent studies have confirmed this (no reversal), and the present study also does so. This paper is close to Aydogan (2021, Management Science), which also corrects for many things and also finds no reversal.

This paper considers the role of sampling bias (rare events are mostly undersampled), ambiguity attitude, likelihood representation, and memory. Only for the sampling bias they find an effect.

In the unambiguous treatment, subjects sample without replacement a whole urn with 40 balls and are told so. In the ambiguous treatment the same info is given except that subjects are not told that they have sampled the whole urn, and they may think that there were more balls. Although this in principle, in theory, is correct as implementation, I think subjects are so overwhelmed with info at that stage, and inability to handle it all, that this difference (complete sampling or ot) will not matter much. The study indeed finds that ambiguity plays no role. So, I still think that ambiguity attitude plays a role here, also in the unambiguous treatment. %}

{% Discuss the BDM (Becker-DeGroot-Marschak) mechanism and random incentive mechanism, referring to the independence-violation criticism of this mechanism leveled at the end of the 1980s. They do not refer to the counterarguments based on isolation published in later papers such as Cubitt, Starmer, & Sugden (1998), which are referred to only for other reasons. Instead, they use an alternative design, claimed not to be subject to the same criticism. At first it was not clear to me why the alternative design would not be subject to the same independence-violation criticism. The logic seems to be as follows: Even if there is no isolation, no systematic differences of directions of preference reversals can be expected. So, although they have a random lottery, they have a stronger test for preference reversals because they need not rely on the isolation demonstrated in Cubitt, Starmer, & Sugden (1998). %}

Cubitt, Robin P., Alistair Munro, & Chris Starmer (2004) "Testing Explanations of Preference Reversals," *Economic Journal* 114, 709–726.

{% Preference elicitation where subjects indicate CEs and are rewarded by some BDM (Becker-DeGroot-Marschak) procedure. In addition, subjects are asked to indicate an interval for the CE value, where they doubt. This is not incentivized (would be hard to find incentivization). The authors investigate factors influencing the intervals. %}

Cubitt, Robin P., Daniel Navarro-Martinez, & Chris Starmer (2015) "On Preference Imprecision," *Journal of Risk and Uncertainty* 50, 1–34. https://doi.org/10.1111/j.1468-0297.2004.00238.x

{% **time preference, fungibility problem**; The paper analyzes experimental intertemporal choice from a purely theoretical perspective, assuming that there are market opportunities outside the laboratory of borrowing or lending at the market interest rate, and assuming a perfectly rational optimizing agent. It argues that there then is no easy way to experimentally elicit the subjective interest rate, for instance. The paper in particular discusses Coller & Williams (1999), which also addressed this question. This C&R paper is the best to cite on this problem.

I think that an argument against perfect-market driven is the individual variation in measured discount rates. %}

Cubitt, Robin P. & Daniel Read (2007) "Can Intertemporal Choice Experiments Elicit Time Preferences for Consumption?," *Experimental Economics* 10, 369–389.

{% **dynamic consistency**: Use the term separability for what is often called consequentialism in dynamic decision making under risk, and which here entails both indendence of forgone acts and of forgone events. Test the condition and do not find it violated, even though the subjects do violate independence/EU. %}

Cubitt, Robin, Maria Ruiz-Martos, & Chris Starmer (2012) "Are Bygones Bygones?," *Theory and Decision* 73, 185–202.

{% Compare, for choices between simple lotteries, **the random incentive system** to single-choices (with real payment), and find they are not different, confirming their 91- American Economic Review finding. This paper adds to it a check of cross-task contamination, which is something between complete isolation and complete no-isolation I understand. Seems that they also test (paying only some subjects) (**random incentive system between-subjects**).

P. 116 takes single choices as gold standard: "We define true preferences with respect to a given task as those that would be elicited by *single choice* experimental design in which each subject faces onlym that task, and knows it to be for real." [italics from original] Birnbaum (1992 *Contemporary Psychology*) gives counterarguments.

They conclude that isolation may hold for simple stimuli as studied in their paper, but can still be violated for complex stimuli, citing Beattie & Loomes (1997) for it. %}

Cubitt, Robin P., Chris Starmer, & Robert Sugden (1998) "On the Validity of the Random Lottery Incentive System," *Experimental Economics* 1, 115–131.

{% **dynamic consistency**. Nicely split the static vNM independence condition for risk (that axiomatizes EU) into four dynamic decision principles: Separability (I'd prefer the term forgone-event independence), timing independence (I'd prefer the term time consistency), frame independence (I'd prefer the term decision-tree independence), and RCLA. I disagree with them suggesting that frame independence would be the one that Kahneman & Tversky in their prospect theory would want to give up so as to explain violations of independence. K&T consider its violations of frame independence, but never commit to other conditions not being violated.

They find that timing independence is mostly violated (e.g. p. 1378). %}

https://doi.org/10.1111/1468-0297.00346

{% Discuss Plott's discovered preference hypothesis versus the constructive view of preference. Then discuss their experimental methods where each subject will only make one choice in one situation, which should not mean that the subject is not well-instructed or -trained.

Para on pp. 401/ 402 says that people commonly find power utility with power 0.3 (so, RRA = 1 – 0.3 = 0.7). Says that utility in terms of final wealth can, in fact, not explain this, and outcomes must be reference dependent.

P. 401 second half suggests that if subjects by learning and repetition get closer to EU, it may be not because their true preferences are EU and are better revealed, but because subjects better learn to use heuristics independently of true preference and these heuristics, rather than true preference, may get closer to EU.

P. 402 writes:

"…are entirely explained by the relative sizes and relative probabilities of the payoffs in each task. This striking regularity …. we cannot eliminate the possibility that the regularity is induced by context-dependent heuristics which are learned in the course of these experiments."

This is very reminiscent of Stalmeier's proportional heuristic for time-tradeoff questions in the health domain.

It is like their shaping hypothesis as they call it in later papers (e.g. Loomes, Starmer, & Sugden 2003 EJ), but the term is not yet used here. %}

{% **Nash bargaining solution**: P. 761 extensively discusses the (weakness of) assuming vNM utility in game theory. P. 762 links vNM utility with evolutionary replicator dynamics.

P. 770 4th para explains that transitivity is a kind of separability requiring separate preferability of each individual prospect. So, that it is kind of unitary evaluation, in Burks' (1977) terminology. %}

Cubitt, Robin P. & Robert Sugden (1998) "The Selection of Preferences through Imitation," *Review of Economic Studies* 65, 761–771.

{% **dynamic consistency**; **Dutch book**, etc.; gives formal definition of money pump, relating it to the sure-thing principle; argues, citing Fishburn (1988 pp. 43-44), that an agent would not take all trades knowing several trades are to come. They formalize "surprise choices," being choices not announced beforehand. %}

Cubitt, Robin P. & Robert Sugden (2001) "On Money Pumps," *Games and Economic Behavior* 37, 121–160.

{% **dynamic consistency**; Assume some independent boxes, each with probability p a win box and with probability 1−p a loss box (p may depend on box). A subject is endowed with an initial endowment b > 0, and m > 0 is a constant. At each round, if the subject draws a win box, then his endowment of that moment is multiplied by m, if a loss box then by 0 (so, the game is over with no gain). Subjects can choose to take 0, 1, or 2 (extra) rounds. Some do only this (de novo). Others, prior to this choice, had to take 4 compulsory rounds, and only if they win all these they get the choice. Of these others, some do prior commitment, others do posterior choice. This framework is the usual test of consequentialism and dynamic consistency. Given the dynamic framing, no common ratio effect is to be predicted a priori, as shown by Kahneman & Tversky (1979). What emotions the prior-commitment rounds arouse, I could not predict. It turned out that they make the subjects less risk seeking, so, lead to a reversed common ratio.

In the beginning of the paper, the authors present a formal model way more complex than used in the experiment, and they discuss several general issues of decision theory before turning to their particular experiment. %}

Cubitt, Robin P. & Robert Sugden (2001) "Dynamic Decision-Making under Uncertainty: An Experimental Investigation of Choices between Accumulator Gambles," *Journal of Risk and Uncertainty* 22, 103–128.

{% N = 88 subjects, with RIS.

The authors organize two-stage uncertainty as follows: A black bag contains 12 balls each with no. 1 or no. 2 on them, in unknown proportion. There is another bag, a white bag (called ambiguous urn in the paper but not to the subjects), containing 10 balls, either (composition 1) 7 colored orange and 3 colored blue, or (composition 2) 3 colored orange and 7 colored blue. First a ball is drawn from the black bag. If its number is 1, then the white bag gets composition 1, and if its number is 2, then the white bag gets composition 2. Then a ball is drawn from the white ball, its color inspected, determining a payoff. Here the Savage state space S can be taken to have two elements, being the color of the ball drawn from the white bag, which is orange or blue. Subjects get partial info, subject-dependent, about result of number of draws and they can little bit peek into a bag.

In this very simple case the set of possible 1st order probaility distributions over S contains only two elements. The space of second-order probability distributions over the 1st order distributions can be equated with [0,1], specifying the subjective degree of belief that the white urn has composition 1. **Important to note** is that the novelty of the smooth model, of assuming no exogenous two-stage setup with a conditioning event determining an objective probability over S, is NOT the case here. Instead, the two-stage composition is exogenously determined by the experimenters, with the conditioning event the composition of the white ("ambiguous") urn, just as in the Ellsberg urn and in numerous experiments on recursive utility. And, in all experiments of the smooth model that I am aware of … That the absence of this exogenous two-stage setup in the smooth model is "too" general has often been discussed, and the authors address it when writing:

"However, the fact that a second-order belief is involved is widely regarded as making the estimation of the parameters of the smooth ambiguity model a particular challenge (see, e.g., Wakker 2010, p. 337; Carbone et al. 2017, p. 89). We are motivated, in part, by the goal of showing that a subject's second-order belief can be estimated solely through revealed preference, that is by observing his choices over first-order acts." (p. 278)

As will be clear from my preceding comments, I think that the authors did not succeed in achieving their goal. I find it telling that in an apparent attempt to demonstrate the observability of the smooth model, the authors still did not succeed in avoiding an exogenous two-stage decomposition.

The authors assume log-power (CRRA) utility for the EU in the first stage with the vNM utility function, and linear-exponential (CARA) transformation φ capturing ambiguity in the second stage, giving three parameters in total (μ the third). They measure CEs and then fit data. After fitting they can calculate monetary risk- and ambiguity premia, which they find about equally big. %}

Cubitt, Robin, Gijs van de Kuilen, & Sujoy Mukerji (2018) "The Strength of Sensitivity towards Ambiguity: A Qualitative Test and a Measurement," *Theory and Decision* 85, 275–302.

{% P. 709: "The pioneering models in the decision theory literature on ambiguity, and arguably still the most popular, are the Choquet expected utility model of uncertainty aversion introduced in Schmeidler (1989) and the maxmin expected utility (MEU) model of Gilboa and Schmeidler (1989). These models have preference representations that show the DM behaving as if she has a set of probability distributions that she considers possible or relevant." The authors may be right on CEU, but I am more interested in this model with likelihood insensitivity instead of uncertainty aversion. Then it is not a subset of multiple priors.

P. 710: "The literature is therefore at a point where clearer guidance on the relative empirical performance of these models in particular—and the broader classes that they exemplify—is needed." This is, indeed, the case. There are many models now and it must be found out which work best.

This paper provides an experiment distinguishing between the smooth model and the α maxmin model. However, it tests hedging-against-ambiguity predictions in multistage settings that depend much on the dynamic assumptions that for instance α maxmin is coupled with. α maxmin is coupled with the usual backward induction that precludes the hedging found. Then the smooth model does better. I take it more as a test of dynamic principles than of ambiguity models. %}

{% Always real incentives with RIS.

Find that "other-evaluation" hypothesis, (choice should be justifiable to others) explains ambiguity aversion.

Do usual two-color Ellsberg in five ways.

1 (hostile nature). Ask subjects if they think that the unknown urn will be biased to their disfavor.

2 (other-evaluation). Subjects must stand in front of the whole group when their choice is revealed and the content of the unknown urn is also revealed.

3 (self-evaluation). Content of unknown urn is revealed to subject but in private, others don't know.

4 (forced choice). People are actually indifferent and ambiguity avoidance is second-order lexicographic.

5 (general uncertainty avoidance). Ambiguity avoidance is related to risk aversion, general aversion to lacking info. (If true, would imply **correlation risk & ambiguity attitude.**)

Only 3 (self-evaluation) is found to have an effect.

P. 235 2/3: subjects could choose winning color (**suspicion under ambiguity**)

P. 253 contains a strange argument suggesting that accepting the null hypothesis does give strong evidence.

They gave subjects normative arguments for and against ambiguity aversion, as did Slovic & Tversky (1974). 80% preferred to be ambiguity averse.

correlation risk & ambiguity attitude: find none. P. 239: Experiment 1 finds no correlation between risk- and ambiguity aversion, but N = 26 is small. Experiment 2 (N = 39) confirms this (p. 241), also if the data of the two experiments are pooled. P. 252 suggests that, according to the hypothesis of general uncertainty aversion, risk aversion should be positively related to ambiguity aversion. (**correlation risk & ambiguity attitude**). The text doesn't show awareness that risk and ambiguity aversion are in a way complementary.

I think that the explanation on p. 255 about contradiction about composition resulting from ambiguity aversion is incorrect. %}

{% Multiattribute preferences can be approximated well by additive representations. %}

Currim, Imran S. & Rakesh K. Sarin (1984) "A Comparative Evaluation of Multiattribute Consumer Preference Models," *Management Science* 30, 543–561.

{% The analysis of for example value function etc. essentially uses OPT which I consider to be less interesting. Unlike the authors, I here use the OPT abbreviation of the 1979 version of prospect theory

End of abstract: - for the paradoxical choices, OPT outperforms EU - on other choices it does not do better

utility elicitation;

§2: nice simple summary of original prospect theory of 1979;

P. 24 point (ii) points out that shifting reference point (à la Shalev) has problems with PT's assumption that U is concave above the reference point and convex below: "Note that the utility function for gains and losses cannot be s-shaped with respect to a moving reference point. To see this consider an interval $[x_1, x_2]$, $x_2 > x_1$. Now if w is the initial wealth and $w + x_2$ is the reference point then $u(w + x)$, $x_1 \le x \le x_2$ is convex; whereas within the same range it is concave if $w + x_1$ is the reference point. The inconsistency between the utility function for final wealth and the induced utility function for gains and losses does not occur if a person's utility function is exponential or linear."

P. 28 contains a nice method of eliciting utility for OPT nonparametrically

Parametric utility elicitation is by taking exponential utility (p. 26: “as is traditionally done”)

P. 26: “By choosing simple scenarios, we have conveniently avoided the complications of the editing phase”

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): On p. 28 they suggest that the value function of prospect theory is a riskless utility function (where “certainty method” is a kind of direct rating): “The value function in the prospect model can either be assessed by a *certainty method* or by a *gamble method*. We employed both methods even though we believe the certainty method is more desirable for capturing the psychological effects assumed by the prospect model, and is easier to implement.” They suggest this point also in their conclusion on p. 39.

Data analysis is hard to interpret because of the many assumptions made. Conclusions on p. 39 are nice

- properties of value function and probability transf. in OPT hold

- Parametric fitting of utility (“that smooth out errors”) provide predictions superior to those of directly assessed values.

- **PE doesn’t do well**: certainty method (direct assessment of values without risk present) is easier to implement, and more accurate, than gamble method (where risky choices are used). (This suggests strongly that they are willing to interpret the value function in prospect theory as riskless.)

- probability transf. seems to be different for gains than for losses

- **concave utility for gains, convex utility for losses**: P. 30, where two-piece u is concave for gains, convex for losses (They use term value function here. The term utility function refers to what utility would be if expected utility were to hold, so, is less interesting I think.)

P. 39: “It is not uncommon in consumer research that tradeoffs are made between generality of a model estimated and burden on respondents.”

real incentives: use hypothetical choices.

P. 39: Argue for parametric fitting as opposed to parameter-free methods: “analytical forms for the utility and value functions that smooth out errors provide superior predictions than directly assessed values.” %}

{% **proper scoring rules**

Proper scoring rules, quadratic being most popular, are incentive compatible under subjective expected value maximization. This requires linear utility of money. —As an aside, I think that linearity of utility is reasonable for small stakes, and empirical violations of expected value are more driven by other "nonEU" factors such as nonlinear probability weighting.— An old idea to get linear utility, at least under expected utility (EU), is to take as unit of payment probability of winning a prize (Roth & Malouf 1979). This can be done for proper scoring rules as well. One then has incentive compatibility under EU, more general than expected value. Selten, Sadrieh, & Abbink (1999) observed that one does not need all of EU for this. Reduction of compound lotteries (RCL) is enough. Then maximizing EU amounts to maximizing the probability of winning the prize. It leads to what is called the binarized scoring rule (BSR), for which Hossain & Okui (2013) are usually cited, although they did some more complex things.

Whereas a generation ago, 1990-2010, researchers were well aware that RCLA, and some other principles for dynamic decision making, are less innocuous than first meets the eye (e.g., see Machina 1989, JEL), this is less well-known at this moment of writing, in 2022. There are already many violations if all the probabilities are known, objective, and available to decision makers so that they can readily do multiplication (e.g., Bernasconi 1994; see keyword RCLA). The violations will be way and way more serious if some of the probabilities involved are subjective, making RCLA way more problematic even in an as-if sense. I think that it is way more likely that subjects in the BSR do backward-induction with violation of RCLA and nonlinear probability weighting hitting in in full force. (And also ambiguity attitudes ...) That these deviations from linearity are bigger than with monetary payment. Comes to it that the two-stage payment in BSR is more complex. The authors seem to overlook the critical role of RCLA when they write that BSR is incentive compatible for "any decision-maker who maximizes the overall chance of winning a prize." (p. 2852 middle) However, their paper goes in the right direction by showing empirically that the BSR works poorly.

The aforementioned incentive compatibility works theoretically if one assumes RCLA, but not empirically because of the violations. The authors go in this direction when writing "We argue that to secure truthful revelation, elicitation mechanisms need to not only be incentive compatible in a purely theoretical sense, but also in a behavioral one." This is the main motivation of the paper. Note that many people are aware of this, as in criticisms of the BDM mechanism and Bardsley et al. (2010 §6.5, p. 265 & p. 285), which also distinguishes between theoretical incentive compatibility and behavioral incentive compatibility. But yet more people are not aware of this and typically only discuss theoretical incentive compatibility.

In one treatment, subjects receive a calculator that does the RCLA calculations and gives the overall probability of winning the prize. I did not read the paper enough to know what first-order subjective probabilities were used for these calculations, and how they were related to scores that subjects provide.

To test the method, they use it for risky events for which objective probabilities are given and then the subjective probabilities should agree with those ("truthfulness"). They show that this is *worse* with BSR than with no incentives at all, both in the sense that fewer subjects do it (their first weak incentive compatibility criterion), and in the sense that fewer subjects choose the proper optimal r with BSR then without (their second weak criterion). I must admit that I see no difference between these two criteria, but never mind.

I think that future work should focus on best clarifying instructions to give to subjects. %}

https://doi.org/10.1257/aer.20201248

{% An accessible, but not specialized, discussion, of behavioral versus theoretical incentive compatibility. These nice terms I first saw in Bardsley et al. (2010).

The paper focuses on belief measurements. More narrowly, iIt focuses on belief measurements in situations where true objective probabilities are clearly existing (e.g. relative frequencies) and even known to the experimenter and, sometimes, also to the subjects. Belief measurements are more interesting in cases of probabilities unknown to everyone or even objective probabilities not conceivable, as with unique events.

A very negative conclusion, based mostly on another paper by this team:

explaining incentive compatibility seems to worsen the case, with more/bigger errors. The authors are negative on the binarized scoring rule.

It will not surprise the readers that I think that the Prince method of Johnson, Baillon, Bleichrodt, Li, van Dolder, & Wakker (2021) will fare better. I regret that the authors never mention the important role of ambiguity nonneutrality. %}

{% **decreasing/increasing impatience**: provides theoretical arguments for the possibility of increasing impatience.

Consider intertemporal choice when there is probability of earlier or later payment than thought. Show that all kinds of plausible probability distributions of the latter can imply decreasing (as in hyperbolic) discounting at $t = 0$. There are also plausible probability distributions that imply increasing discounting at $t = 0$, such as the example of Sozou on p. 1292, and the example at the beginning of §III, pp. 1294-1295. In these examples of nonconstant discounting, a reversal of preference at a different timepoint is not dynamic inconsistency, but can simply follow from Bayesian updating: arriving at the later timepoint without consumption received yet gives the extra information that the "risk" of receiving the consumption before that later timepoint did not happen.

P. 1290, footnote 2, nicely explains how the term hyperbolic discounting originally meant something specific (discount rate depending inversely on time) but nowadays (2005) is used for anything with decreasing discounting.

P. 1291, first para of §I, mentions that discounting can be due to uncertainty about the future, referring to Yaari (1965) for it.

DC = stationarity: **dynamic consistency**; End of §I carefully distinguishes between variation in the time of consumption ("comparisons across decision problems") versus variation in the time of decision making ("comparison within the same decision problem") and properly says that the former is not a violation of **dynamic consistency**. §IV gives example of preference change when decision timepoint changes, so, dynamic inconsistency, which however rationally follows because the model is more complex than just single intertemporal choice and more is going on. The more going on is that it is in fact a repeated decision with learning, where learning is taken in an evolutionary sense. Refer for it to experimental evidence with pigeons. %}

{% **foundations of probability**

1837-1842 six authors discussed objective-subjective probabilities. Originally, probabilities were primarily taken as subjective/epistemic, although (observed) relative frequencies were also considered from the beginning. Around 1840 the objective concept became more established. Cournot, well known for his equilibrium, was important here. The first part of the paper, pp. 332 ff., discussed the terms objective versus subjective, which also developed and changed over time. Quite some authors argued that only certainty can be objective (p. 332 middle). It surely can achieve a high degree of objectivity, not available to uncertainty.

P. 336 middle discusses separation of inside and outside of human mind (Descartes)

P. 335 ℓ. –5/–4 cites Poisson on arguing that the law of large numbers is the "base of all applications of the calculus of probabilities," which is close to the frequentist interpretation. The next text cites Poisson on using the term probability for subjective probabilities (which he, thus, still did consider) and the term chance for objective probabilities. The chance of heads-tails is not precisely 0.5, but the probability is. During my collaborations with Amos Tversky, early 1990s, I noticed that Amos liked to use the term chance for objective probabilities.

P. 336 middle cites Cournot (1843):

> The "subjective probabilities" based on equal ignorance of outcomes were fit only for the "*frivolous use of regulating the conditions of a bet*" [9, 111, 288], and were moreover the "*cause of a crowd of equivocations [which] have falsified the idea one ought to have of the theory of chances and of mathematical probabilities*" [9, 59]. [italics added here]

Then it cites Cournot on calling upon statisticians to avoid subjective inputs.

P. 337 cites later editions of Mill (1843) on admitting the (subjective) more probable than concept and relating it to betting on!:

> Mill grudgingly conceded that "as a question of prudence" we might rationally assume that "one supposition is more probable to us than another supposition," and even bet on that assumption "if we have any interest at stake" and if we were in the desperate (and rare)

situation of having no relevant experience whatsoever
[31, 7:535-536].

P. 337 middle:

Mill curiously remained the most traditional of the revisionists in his interpretation of all probabilities as epistemic.

My opinion may fit with Mill: basically, all probabilities are subjective, but in communications and virtually all applications except the final decision almost exclusively the objective probabilities are relevant.

P. 339 starts with an interesting topic: "The objectivity of chance in a deterministic world." It discusses stable vs. variable causes, but most I could not understand. %}

{% Despite the broad title of the paper, it focuses on what I might call one-dimensional utility, and, basically, violations of transitivity or, roughly equivalently, of revealed-preference axioms such as IIA or SARP. This paper considers deviations from transitivity/IIA due to attraction effects, overlooking choice options, threshold preferences, probabilistic choice, and many other reasons. Rationality requirements beyond transitivity, that concern tradeoffs, such as the sure-thing principle, are not considered. The authors here side with a tradition in revealed preference theory, e.g. the textbook Mas-Colell, Whinston, & Green (1995) that I often criticized: to use the term rational for weak ordering (≈ transitivity). First, the natural-language term rational is so important for our field, that we should not lose it to some mathematical concept. Second, weak ordering is way to permissive to capture all of rationality.

Reference dependence and loss aversion are discussed to the extent that they violate transitivity. But the authors cite much literature on the focus of the paper, including much psychological literature from long ago. The discussion of the use of axiomatizations in §4 does not enter the issues of operationalization and making observable, or of the unobservability of technical axioms. §4.3, with title limited data, points out that many axiomatizations need full rich domain. They give a central place to Bernheim & Rangel (2009) and Salant & Rubinstein (2008), but I have found those papers straightforward. %}

{% The following poem, translated from Dutch, nicely illustrates loss aversion. By reframing the status quo, a loss is turned into a gain in the last four lines. The fool in the beginning of the poem is also trying to get mileage from playing with the reference point.

Translation (joint with Thom Bezembinder; the Dutch word “geluk” means both happiness and lucky thing. This identity is lost in the translation.)

“Lucky thing, it could have been worse

As for the fool from the joke,/
who, continuously hammering on his head,/
when asked for the reason, said/
“Because of the joy when stopping it/
so things are for me. I have stopped/
losing you. I have lost you./

Maybe this is happiness: lucky thing, it could have been worse/
maybe happiness is: lucky thing/
That I can remember you, for instance,/
instead of someone else./”

Original text:

“Nog een geluk dat”

Zoals met de gek uit het grapje/
die zich voortdurend met een hamer/
op het hoofd sloeg, en naar de reden gevraagd, zei/
“Omdat het zo prettig is als ik ermee ophou” -/
zo is het een beetje met mij. Ik ben ermee opgehouden/
je te verliezen. Ik ben je kwijt./

Misschien is dat geluk: een geluk bij een ongeluk./
Misschien is geluk: nog een geluk dat./
Dat ik aan jou kan terugdenken, bv.,/
in plaats van aan een ander./ %}

de Finetti, Bruno (1930) "Problemi Determini e Indetermini nel Calcolo delle Probabilità," *Rendiconti della Academia Nazionale dei Lincei* XII, 367–373.

{% §13, Postulate 4 introduces additivity axiom for qualitative probability. **Dutch book**.

§3 (p. 296 in English translation) refers to Bertrand (1889) for idea that equally probable judgment can be inferred from equal willingness to bet either way. %}

de Finetti, Bruno (1931) "Sul Significato Soggettivo della Probabilità," *Fundamenta Mathematicae* 17, 298–329. Translated into English by Mara Khale as "On the Subjective Meaning of Probability." *In* Paola Monari & Daniela Cocchi (1993, eds.) "*Probabilità e Induzione*," 291–321, Clueb, Bologna.

{% The necessary and sufficient conditions for EU with a continuous strictly increasing utility U are:

[1] CE(x) = x;

[2] Strict stochastic dominance;

[3] CE(F) = CE(F*) $\Rightarrow$ CE(tF+(1-t)G) = CE(tF*+(1-t)G) for all 0 < t < 1. (pp. 379-380).

P. 380 explains that this condition is close to associativity as in Nagumo (1930) and Kolmogorov (1930).

Condition [3] above is nothing other than the celebrated independence condition. Should we then credit de Finetti as the first to have had the vNM EU characterization? I asked my Italian colleague Enrico Diecidue to read the whole paper to check if anywhere de Finetti points out that the weights are probabilities and that this can concern decision under risk. But he nowhere does. Maybe deliberately because he wanted to push subjective probabilities with his famous statement "Probability does not exist." Anyway, for this reason I do not credit de Finetti for preceding vNM. Muliere & Parmigiani (1993, p. 423) cite de Finetti (1952, 1964) for discussing the decision interpretation.

Nagumo (1930) and Kolmogorov (1930), cited by de Finetti, had such results before, but only for equally likely prospects, which comprises all prospects with rational probabilities, and where their independence condition was the associativity condition for taking means.

P. 386 bottom shows the Pratt-Arrow result that CEs (certainty equivalents) are smaller the more concave utility is. %}

de Finetti, Bruno (1931) "Sul Concetto di Media," *Giornale dell'Istituto Italiano degli Atturia* 2, 369–396.

{% **coherentism**: this paper expresses, unfortunately, the viewpoint that the only criterion for rationality is preference coherence.

P. 174 of English translation (1989): "… however an individual evaluates the probability of a particular event, no experience can prove him right, or wrong; nor in general, could any conceivable criterion give any objective sense to the distinction one would like to draw, here, between right and wrong." de Finetti has many such narrow views, showing that he is not of the same intellectual league as the kindred spirits Savage or Ramsey. Dennis Lindley, at age 90, in an interview by Tony O'Hagan in 2013, cited de Finetti on this narrow view and sided with de Finetti, stating "coherence is all." He also, rightfully, pointed out that de Finetti's writings are obscure. %}

{% **foundations of probability** %}

de Finetti, Bruno (1951) “Recent Suggestions for the Reconciliation of Theories of Probability.” *In* Jerzy Neyman (ed.) *Second Berkeley Symposium on Mathematical Statistics and Probability,* University of California Press, Berkeley.

{% P. 77 following Theorem 3.4.1 on the Pratt-Arrow measure:

On p. 700/701, this following paper introduced, before Pratt/Arrow, the

Pratt/Arrow measure –u´´/u´ and its elementary properties such as:

- it being a measure of concavity;

- the 50/50 gamble for gaining or losing h being equivalent to losing h^2 divided by the measure (P.s.: that's the special case of risk premium when expected value is zero);

- the measure also being related to an excess probability for gaining;

- it entirely comprising all of u that's relevant.

P. 700 points out that expected utility in a mathematical sense is the associative mean and refers back to his and Kolmogorov's work on associative means of 1931. Had de Finetti written that one interpretation taking only one sentence also in 1931, he would also have been the predecessor of von Neumann & Morgenstern. %}

{% **proper scoring rules**: Seems to propose using proper scoring rules for grading exams. This does not work because for proper scoring rules it is important that there is no other consequence than the payment received from the proper scoring rule. Grades of exams have many more consequences. All the rest of the student's life society will reward/punish him in unpredictable manners for the grades obtained for the exam. %}

de Finetti, Bruno (1965) "Methods for Discriminating Levels of Partial Knowledge Concerning a Test Item," *British Journal of Mathematical and Statistical Psychology* 18, 87–123.

{% **Dutch book**;

This is a collection of texts, often informal but nice brief expressions, published by de Finetti. Its Ch. 1 is what brought me in the field of decision theory! When I, as a mathematics student in 1978, was amazed about my statistics teacher's claim, frequentist as I know now, that the probability of life on Mars could not be defined, and was at all treated very differently than the probability of a coin toss, he told me that an, in his words, crazy, Italian had argued for the same, and wrote the name de Finetti on a piece of paper. With this piece of paper I went to the library, found this book, and read its first chapter. It opened to me the technique of preference foundations, and the possibility to tangibly define something as seemingly intangible as one's subjective degree of belief. I felt electrified by the idea, and decided that I wanted to work on these ideas. Thanks to the freedom provided by the Dutch academic system and the generous Dutch unemployment benefits of those days, I could work on these ideas even though for some years I could not find other researchers with similar interests, many related references or even journals, and for a while could not find a paid job to do this work. I hope that these ideas can be as magic to the readers as they have always been to me.

Preface, pp. xviii – xxiv explain why it is useful notation to equate events with their indicator functions, and probabilities of events with expectations of their indicator functions. %}

de Finetti, Bruno (1972) "*Probability, Induction and Statistics.*" Wiley, New York.

{% Book, preface p. x, opens with the famous: "Probability does not exist."
coherentism: P. 8 seems to write: "From the theoretical, mathematical point of view, even the fact that the evaluation of probability expresses somebody's opinion is then irrelevant. It is purely a question of studying it and saying whether it is coherent or not; i.e., whether it is free of, or affected by, intrinsic contradictions. In the same way, in the logic of certainty one ascertains the correctness of the deductions but not the accuracy of the factual data assumed as premisses."

Pp. 22-23 explain that this is meant to be a text book and that, therefore, references are minimized.

Dutch book; Ch. 3 is, probably, the best account available in the literature about the book argument. §3.4 ff. discuss the domain on which preference is defined because of book argument, and that it can be a subset of the set of all acts. §5.4 discusses **proper scoring rules**. §5.5 gives many applications of proper scoring rules, to expert-opinion elicitation such as geologists for oil drilling, forecasting sports events, replies to multiple choice,

P. 196, §5.5.7, footnote there, recognizes game-theoretic complications of book argument when opponent is better informed.

{% Seem to measure prospect theory parameters from revealed preferences regarding risky transportation decisions. %}

De Lapparent, Matthieu (2010) "Attitude toward Risk of Time Loss in Travel Activity and Air Route Choices," *Journal of Intelligent Transportation Systems* 14, 166–178.

{% N = 107; **losses from prior endowment mechanism**: Was not done, but hypothetical choice was used, because for losses real incentives are hard to implement. The authors argue against **losses from prior endowment mechanism** because of house money effects (p. 119 last para), and I agree with this viewpoint (would add the more general term income effect as objection against losses from **prior endowment mechanism**). I also think that for losses hypothetical is better.

natural sources of ambiguity;

ambiguity seeking for losses: They investigate the competence effects not only for gains, but also for losses (the latter is the novelty.) Use temperatures on more and less known places. They control for the belief component in several ways: (1) They take pairs of places that actually have very similar climates, and the same temperature event for both places.

(2) **source preference directly tested**: They test EXACTLY the source preference condition with source preference if a bet on an event and its complement is preferred.

(3) They also asked for direct subjective probability judgments.

Find the usual competence effect confirmed for gains, but mostly H_0 for losses, with a reflection (source preference AGAINST source with most competence) significantly for one of six cases considered. One explanation that they put forward is that loss choices are noisier (p. 129; confirmed by logit parameter λ).

Each subject made only one choice for each case (and not many as in choice lists when going for indifferences for instance) and then a representative agent was assumed.

reflection at individual level for ambiguity: they have the data for it, but do not report.

They also test the two-stage model, assuming representative agent, and taking direct judgments of probability as inputs. So, much of the deviation from additivity and EU can then be comprised in the probability judgment. P. 113 1/3 writes that the two-stage model cannot capture source preference, which is true by the basic spirit of that model, although one (not me) could argue that source preference can be captured in the belief component.

There is much collinearity between the elevation and curvature parameter (p. 127). The authors take the curvature parameter at its best level, keep it there, and then let only the elevation parameter vary to test source preference (p. 127). It confirms the other claims, being more elevation for known sources under gains (with parameter values similar to Kilka & Weber (2001), and significantly so for all six cases considered, and no significant effects for losses.

P. 126 2nd para: assume that weighting function, and not utility, depends on the source.

losses give more/less noise: p. 129: choices for losses are noisier, and take more response time, than for gains. %}

{% This paper investigates experimenter demand effects in some standard experiments (dictator game, risky investment, time budget, trust game as first or second mover, ultimatum game as first or second mover, lying game, real effort with/without payment, and some of these both hypothetical and with real incentives. To do so, or at least provide bounds for the effect, the authors do the following, for, say, the dictator game. In one "positive weak demand" treatment, they tell subjects: "we expect that subjects who are shown these instructions will give more that they would normally do." In a "negative weak demand" treatment, they tell the same but with "more" replaced by "less." They also have strong treatments, where they write "You will do us a favor if you give more/less than you normally would." They expect, and find, that most subjects will be compliant, and offer more in the positive treatment, and less in the negative.

(They call this monotonicity.) Some subjects will defy and act the opposite way. At any rate, they expect experimenter demand effects to be stronger under these explicit treatments than in regular treatments. They call this bounding. It seems that they add monotonicity to what they call bounding, and that they need it for their tests of group averages, and that too many defiers would invalidate their tests (p. 3276 last para). Probably tests at the individual level could have avoided this (seems to be possible in their seventh experiment). They find little difference between positive and negative effects, like 0.13 standard deviation, usually not significant, and take this as evidence that there is not much experimenter demand effect. They can also see which factors impact the effects. There is more for the trust game than for effort tasks, for instance.

The basic idea is nice and useful.

It may seem that the paper uses deception. If for half the subjects they say they expect a positive result, and for the other half they say they expect a negative result, it may seem that at least one is untrue and must be a lie. But this is, fortunately, not so because the instructions are self-fulfilling profecies.

A bit of a difficulty, especially for the strong treatment, where experimentes' hope is expressed, is that it would be lousy research because researchers are not supposed to try to influence data that way. This may give a general bad impression of research, which is especially damaging if done in an often-used lab. Also, this can arouse emotions in subjects that can distort the experiment.

This paper is only of interest to specialists doing experiments and has no other implication of interest to general economists. It think it would have been better in a specialized journal, not in this broadly read journal.

The authors develop a theoretical model for experimenter demand effect but I must say that it did not seem to be helpful to me.

P. 3276 footnote 11 is incomprehensible to me. The authors "thank" an anonymous referee for it. Often, when authors have to add something weird because of a silly referee (and possibly weak editor) and are annoyed by it, they add a thanks to the referee so that the readers know so.

P. 3292: as the authors explain, it is very natural to find more experimenter demand in hypothetical choice than with real incentives, but they do not find this at all.

P. 3294: women are more prone to experimenter demand than men. %}

{% **biseparable utility**: satisfied.

event/outcome driven ambiguity model: event driven

Assume Anscombe-Aumann framework with the restrictive backward induction assumption of CE substitution, but do not assume EU for the second-stage lotteries, but Quiggin's RDU. This is desirable for empirical purposes but loses the main pro of two-stage models: tractability. P. 380 footnote 7 follows up

on this and mentions that omitting the two-stage could be desirable. More precisely, they consider a set of probability measures and a SET OF probability weighting functions (and only one utility function), over which they do maxmin RDU. Wang (2022, Management Science) will do maxmin RDU with a set of probability measures but only one weighting function.

The authors use an endogenous utility midpoint operation (p. 381), the one used by Ghirardato, Maccheroni, Marinacci, & Siniscalchi (ECMA 2003), which involves several certainty equivalents (so, many measurements!), and use it to mix acts statewise. On p. 383 they adapt it to decision under risk and mix lotteries by taking as joint distribution of two lotteries the comonotonic distribution (maximizing correlation). Then under RDU and also under biseparable utility the utility midpoints come as under EU. As a memory from youth, Wakker (1990 JET) showed that such comonotonic mixtures are preferred less than noncomonotonic ones if and only if pessimism holds under RDU. Fortunately, the authors use only this midpoint operation and not the extended subjective mixture operation as Ghirardato et al. (2003) did. The latter has the problem that it is too far from direct observability, requiring infinitely many observations for its very definition, e.g. for 1/3-2/3 mixtures. An alternative concept of endogenous utility midpoints was used by Baillon, Driesen, & Wakker (2012): if $x_p\alpha \sim y_p\beta$ and $x_p\beta \sim y_p\gamma$, comonotonic, then β is the endogenous utility midpoint between α and γ. This requires fewer indifferences by not using certainty equivalents, and no multistage. Baillon et. al. in their footnote 2 cite several preceding alternative definitions of endogenous utility midpoints.

Using the endogenous midpoint operation, the authors define quasi-convexity of preference (Axiom 5 p. 384) and the analog of certainty independence (Axiom 6 p. 386). They thus get a multiple prior representation for uncertainty. It is reminiscent of Alon & Schmeidler (2014) (improved by Alon 2022). Importantly, they do not need the EU assumption of the Anscombe-Aumann framework in this, using the endogenous operation instead. It gives them the freedom to use alternative models for risk, where they characterize a risky analog of Maxmin EU taking a minimum over RDU functionals. Their characterizing Axiom 4 is bisymmetry-type to get biseparable. They can thus define ambiguity attitudes in more realistic manners, using conditions that, in my terminology, are of the source-preference type. A restriction is in Definition 7 that they only do it for agents with the same risk attitudes, as common with the Yaari CE type conditions as used here.

P. 386: "The RDU model is arguably the most well known non-expected utility model for objective lotteries. The cumulative prospect theory model of Tversky and Kahneman (1992), for example, is based on this framework." (**Prospect theory/Rank-Dependent Utility most popular for risk**)

P. 393: The authors very properly point out that ambiguity neutrality means probabilistic sophistication but with added that this involves (agreement with) objective probabilities. They state this more or less implicitly in Definition 6, and make it more or less explicit in Footnote 31. Probabilistic sophistication in itself does not mean much if we do not specify the domain on which it is valid. The footnote is about comparing with general probabilistic sophistication à la Machina & Schmeidler (1992). The latter was, erroneously, taken as ambiguity neutrality by Epstein (1999). His confusion came from his desire to avoid using objective probabilities, something impossible when defining ambiguity neutrality, as every experimenter will know. The last sentence of footnote 31 is:

"At the same time, both notions differ from probabilistic sophistication as defined by Machina and Schmeidler (1992) in a Savage setup, as here we require that not only the agent reduces subjective uncertainty to objective risk using a prior π, but also that the non-expected utility functional used to evaluate such reduction is the same one used to evaluate objective lotteries."

P. 396 points out that they have nontrivial overlap with the cautious model.

Their whole analysis is focused on pessimism and aversion, and does not consider insensitivity for instance, which is another direction of generalization that I hope for.

Their model is called multiple priors-multiple weighting. %}

{% With N=190 subjects in a lab they do standard measurements of many decision attitudes: Present discounting, risk aversion, common consequence, common ratio, ambiguity aversion, aversion to compound risk, altruism. They consider relations. Ambiguity aversion is strongly related to compound-risk aversion (80 percentage points) supporting Halevy (2007), mixed (gains and losses) risk aversion, common ratio (40 pp.), common consequence (20 pp.). Ambiguity aversion is also strongly positively related to risk aversion. (**correlation risk & ambiguity attitude**)

The presence effect is strongly positively related to risk aversion, and discounting in general is weakly positively related to risk aversion. Strangely, presence effect it not related to common ratio or common consequence. Loss aversion is positively related to the endowment effect, also after correction for risk aversion. These results survive correction for all kinds of demographic variables.

Cognitive ability is measured using Raven's matrices. It is not related to the other variables. (**cognitive ability related to discounting**; **cognitive ability related to risk/ambiguity aversion**; **cognitive ability related to likelihood insensitivity (= inverse S)**). %}

{% On the year of publication (1959 or 1960): The conference was 1959 but the book 1960. Hence, 1960 is the right year. But many people see the year of the conference upfront and then go by 1959.

Since the 1970s, this paper is given all the credit for deriving additively decomposable representations from separability preference conditions, and I agree with this for simplicity reasons. But it is good to know that these results had essentially been known before, by Leontief (1947), Nataf (1948), and Fleming (1952) for instance, who in fact used weaker separability assumptions. However, those papers used differentiability assumptions, which are especially problematic for preference foundations. Debreu's contribution is to do with only continuity and not use any differentiability assumption.

Theorem 2 gives utility-difference representation, using Shapley's (1975, 1982) crossover property, assuming existence of quantitative ordinal representation already, and using solvability; formulates it for choice probabilities.

I never understood the last lines of Debreu's proof regarding the function g, and conjecture that he assumes that local additivity implies global additivity on subsets of Cartesian products, which need not be true in general. I visited Debreu end 1990s and asked him but he did not remember. I also corresponded with Fishburn who in his 1970 book has similar problems. (See my annotations to his book.) He did not remember either. These things made me work on Chateauneuf & Wakker (1993 JME), where the missing steps are provided. %}

{% Study risky choices where the outcome received is certain but the time of receipt is risky, citing Chesson & Viscusi (2003) and Onay & Öncüler (2007) as predecessors. Unlike their predecessors, they use real incentives.

The main new condition is called stochastic impatience. Assume that you own (0.5: (t=0, x); 0.5: (t=01, x)): With probability 0.5 you receive $x today (t=0), and with probability 0.5 you receive $x tomorrow (t=1). You can choose which of the two small amounts $x > 0$ is improved into $X > x$. So, you can choose between

(0.5: (t=0, X); 0.5: (t=01, x))

and

(0.5: (t=0, x); 0.5: (t=01, X))

Stochastic impatience says that you should prefer the former. In general, the sooner you can get an improvement, the more you should like it, given that it occurs with the same probability. The condition is a special case of multivariate risk seeking. It is a convincing special case and can be given a normative status. (Another normatively convincing case is for chronic health states, where an improvement of health quality should be preferred more as it is associate with a longer time duration.)

The authors show that, within a large class of models, stochastic impatience implies risk seeking over time lotteries. This is not so if one relaxes independence between different periods.

§4 discusses several generalizations of discounted expected utility, and whether to first integrate over time or over risk.

The experiments consider 50-50 lotteries over various timepoints. Thus, there

is a richer domain of timepoints than of risk levels, and more to do for time attitude than for risk attitude. %}

{% Abstract: "We also argue … that nonchoice data, interpreted properly, can be valuable in predicting choice and therefore should not be ignored."

P. 258 argues for what I would call the desirability of homeomorphism:

"Confidence in the story of the model may lead us to trust the model's predictions more. Perhaps more importantly, the story affects our intuitions about the model and hence whether and how we use and extend it."

Friedman argued against the desirability of homeomorphic modeling, arging that all that matters is good predictions, but his argument weak because we usually cannot know what exactly will be predictions needed in the future. I argued this way in Wakker (2010 p. 3). I take it that these authors have the same opinion because they write on pp. 260-261: "Finally, even if a model does not immediately change or enlarge our set of predictions, it may yield a clearer understanding of why A might cause X. Why would such an understanding be useful? The primary value of such understanding is that it may lead in the long run to more or better predictions. Lest this comment be misinterpreted, we emphasize that understanding may involve concepts for which the translation into observables is not direct."

Several authors have argued that direct introspective questions on risk attitude are more useful than decision-under-risk experimental measurements because they better predict real-life decisions. I disagree. First, introspective questions often amount to just asking the same as the real-life decisions. But, second, risk attitudes are connected to rich theories with, for instance, meaning in normative models. I take it that these authors have the same opinion because they write on pp. 261: "For example, if A is the description of an agent's choice problem and X is his purchase of insurance, we could trivially explain the choice by saying that he just likes to buy insurance policies. However, a fuller and therefore more appealing explanation is that insurance reduces risk and the agent values it for this reason. One reason this explanation would be more appealing is that it would lead us to make other predictions about his behavior—e.g., investment decisions. Hence a decision-theoretic model that provides a formal notion of risk and risk aversion provides a broader range of other predictions."

P. 261: Besides fit, also intuitive interpretation of a model is important. I take it that these authors have the same opinion because they write on pp. 261: "As Kreps (1990) argues, this consistency with intuition is just another kind of consistency with data. Thus, in making out-of-sample predictions, we may be more inclined to trust an intuitive model with slightly worse predictions in sample than a less intuitive model that is more consistent with sample data. Conversely, if we find the story implausible, this may make us less willing to accept the predictions." Then follows a footnote diplomatically criticizing Gul & Pesendorfer (2008): "Gul & Pesendorfer (2008) argue forcefully that the implausibility of the story of a model cannot refute the model. We entirely agree. However, the implausibility may make us less confident in the predictions of the model."

P. 262 has the nice metaphor that a model can never be perfect similarly as a map cannot have scale 1 inch = 1 inch. The rest of §2, up to p. 264, gives many illustrations of this point, and that a falsification need not imply that we abandon the model.

P. 266 points out that axioms can be used to criticize and falsify a model.

§3.1, pp. 265-269, discusses preference foundations, with axioms necessary and/or sufficient. It does not discuss the problematic nature of completeness and (not-purely-technical) axioms such as continuity. It takes behavioral economics as different than decision theory and then discusses differences.

§4.2, pp. 274-275: unlike Gul & Pesendorfer (2008), they are not entirely against using nonchoice data in economics.

§4.3 discusses good and bad axiomatizations. P. 276 claims that Kreps & Porteus (1978) and Segal (1990) were first to abandon RCLA, but the keyword

second-order probabilities to model ambiguity

in this bibliography gives earlier references, including Kahneman & Tversky (1975) and Yates & Zukowski (1976).

P. 276: "Identifying the key behavior and the domain is the most essential step, but also the step that is closest to an art. Thus we find it difficult to tell the reader how to do it or how to distinguish good and bad modeling choices."

P. 276: "Axioms should be about variables of interest that are at least potentially observable." I would state it more strongly: DIRECTLY observable.

P. 276 last para argues that axioms should not be too close to the representing functional. Here I disagree somewhat. In general, and maths., it is true that one wants axioms to keep a gentlemanlike distance from what they axiomatize, because otherwise the result is trivial. But decision theory is a different ballgame. Here the name of the game is to get behavioral axioms, not to do deep logic. I often prefer that the axioms are close to the functional axiomatized, because they then clarify the empirical meaning of that functional.

P. 277: "First, it is generally better to state axioms in terms of the preferences, not a series of relations derived from the preference. For example, a key in Savage's representation theorem is the more-likely-than relation, which is constructed from the preference relation. Yet Savage states his axioms in terms of the preference, not in terms of the derived relation, as the preference is what we are making predictions about." (**derived concepts in pref. axioms**) I think that derived concepts can be used if they greatly simplify things. I disagree much with the claim on Savage. As my annotations of Savage (1954) explain, most of his axioms use derived concepts.

P. 277 2nd para argues against "there exist" quantifiers, but "for all"

quantifiers are just as problematic. One can more readily be verified, and the other falsified.

P. 277, 4th para points out that often there is a great deal of interaction between axioms, so that each in isolation does not give much. %}

{% This paper provides an expected utility axiomatization for decision under risk, extending the von Neumann-Morgenstern axiomatization to nonsimple prospects. Several preceding axiomatizations used conditions implying continuity of utility. This paper provides results that do not require continuity of utility. As pointed out by Spinu & Wakker (2012), more general results, neither using continuity of utility, had been obtained before by Fishburn (1975, Annals of Statistics, Theorem 3 = Fishburn's 1982 monograph, Theorem 3.4), Kopylov (2010 JME), and Wakker (1993, MOR, Theorem 3.6).

An appealing feature ofTheorem 1 in this paper, obtaining expected utility on the set of all probability distributions by no more than the usual weak ordering, independence, and Archimedeanity, and then stochastic dominance, is that it can be stated entirely in elementary terms, unlike the preceding references. It does imply boundedness of utility. %}

{% **PE higher than CE**; a nice paper. For two-dimensional options, say (X1,X2) versus (Y1,Y2), one of the four values is left out, say X1´, and the value of X1 is found to give indifference. But then (X1´,X2), (Y1,Y2) is presented, one of the other three value is left out, say Z, and then the value of Z is found, say Z´, to give indifference. Under rationality, Z=Z´ should be. But there are many biases, such as scale compatibility, going on, and we find Z´≠ Z. Very nice, irrespective of which of the other values are chosen, irrespective of which values are higher of

lower, and other things, always Z´ ends up too close to its opposing value. For instance, if Z was Y2, Z´ will end up too close to X2, so, between Y2 and X2.

The author takes the term framing narrow, it refers to only one thing: if one chooses between a riskless and risky option, the riskless option is taken as reference point. He avoids this.

P. 1385: "the tendency for preferences to appear more compensatory in quantitative than in qualitative evaluations"

P. 1385 describes the, advanced, method to measure indifferences, combining bisection and direct matching, although the choices were hypothetical: "All matching responses were obtained through a converging sequence of choices to help subjects determine their indifference values. This standard psychometric procedure was managed by a computer program which iteratively generates new choices based on subjects' own choices, so as to progressively narrow the range of possible matching values. To avoid directional biases, bounds are tightened on both sides. Once the algorithm has converged to a sufficiently narrow range, subjects are finally invited to enter their *numerical* matching responses. This whole process was presented to subjects as an aid to accurately determine their matching responses and they were encouraged to fully rely on it." [italics from original]

P.. 1395: "simple trade-off of two quantities, which is the central, irreducible and delicate part of subjective evaluation."

P. 1395, final sentence: "The premise of any prescriptive analysis of a decision problem is that there exist correct, unbiased answers to the problem. This very premise may be in jeopardy if we prove unable to elicit coherent, unbiased opinions from individual decision makers." %}

{% Assume a prospect $x = (p_1{:}x_1,\ldots,p_n{:}x_n)$. The authors assume that x is kind of compared to an independent replica. If the subject evaluates x_i, he thinks that it could have been x_j with probability p_j. Thus, he evaluates the prospect by (using my notation)

$$\sum_{i=1}^{n} p_i U(x_i) + \sum_{i=1}^{n} p_i\Big(\sum_{j=1}^{n} p_j D(U(x_j) - U(x_i))\Big)$$

where in the second summation $D(U(x_j) - U(x_i))$ is the disappointment of having gotten just x_i and not x_j. If x_i is better than x_j then it is negative disappointment, so, it is elation. The authors use a different symbol E for the disappointment function defined on its negative domain.

It is natural that in disappointment emotions all other possible outcomes float around in the mind of the agent.

biseparable utility: for the most common D, which is piecewise linear with a kink at 0. %}

Denoeux, Thierry (2008) "Conjunctive and Disjunctive Combination of Belief Functions Induced by Non Distinct Bodies of Evidence," *Artificial Intelligence* 172, 234–264.

{% A good and well-organized review. Section 2.2 is on complete ignorance. Section 2.2.1 presents some common decision models for total absence of info, being maximax, maximin, Hurwicz, Laplace, minimax regret. Section 2.2.2 presents ordered weighted average (OWA), which is in fact RDU taking uniform probabilities, nicely citing Yager (1988), for it, and with a pessimism index (Eq. 7) equivalent to the pessimism index of Abdellaoui et al. (2011 AER). Section 2.2.3 goes into axiomatizations. Section 2.3 gives vNM EU, briefly mentioning Savage. (A small detail: P. 93 erroneously writes that Ellsberg 1961 would have done experiments. This is not so.) Section 3 considers belief functions, with p. 94 mentioning imprecise probabilities, i.e., using sets of priors. Section 4 nicely presents decision models for belief functions as extensions of the models of §2. Belief functions can be taken as probability distributions over states of complete ignorance, providing the basic link. Section 4.2 gives the generalized Hurwicz criterion, §4.3 Smets' pignistic model (like Jaffray's but in its strictest version taking Laplace-type average utilities under complete ignorance; this was the first time I understood Smets' model, having known its existence since youth). §4.4 has the generalized OWA criterion, §4.5 generalized maxmin regret, §4.6 Jaffray's model exactly as I came to understand it. §4.7 considers dropping completeness. §5 considers imprecise probabilities, i.e., sets of priors. §6 presents Shafer's (2016) decision theory, and §7 concludes. %}
Denoeux, Thierry (2019) "Decision-Making with Belief Functions: A Review," *International Journal of Approximate Reasoning* 109, 87–110.

{% **substitution-derivation of EU**: in their §2.
A generalization of Jaffray's (1989) linear Utility Theory for Belief Functions (*Operations Research Letters*). Let us assume a best outcome M and a worst outcome m. If I understand right, they do not require that for every belief function

over outcomes an equivalent objective lottery over {m,M} exists, but only some sort of belief u in M and belief v in m (so, 1−v is plausibility of M). For focal sets, preference only if both u and v dominate. Is extended to general belief functions by taking probability-weighted averages over u and v. Gives incomplete preferences. Jaffray' theory is the special case where u=1−v always. Then we get completeness. Their Assumption 4.6, called monotonicity, is restrictive by more or less just assuming the representation in terms of u and v.

Assumption 4.7, called dominance, requires that preferences between focal sets are determined only by their best and worst outcomes, with an obvious dominance added. The authors rightfully point out that this is restrictive, implying the PCI (**principle of complete ignorance**), and violations of some sorts of monotonicity axioms, illustrated in their Example 8. With this assumption added, Theorem 4.3 results: a sort of two-tire representation, specifying two Jaffray-type functionals with local pessimism indexes $\alpha_{m,M}$ and $\beta_{m,M}$, respectively, and preference only if both functionals are higher.

Section 5 conveniently compares with other decision theories, such as Smet's. Jaffray used sets of priors (called credal sets in belief-function-theory) to justify his axioms, but this interpretation does not seem to sit well with Dempster-Shafer combination of belief functions. He uses regular probabilistic mixing whereas this paper uses the Dempster-shafer combination rule for multistage mixing.

The authors take the belief functions over outcomes as observable (p. 200 ℓ. -4), which fits with Dempster (1967) who took them as objective but I think not with Shafer (1976) who took them as subjective.

P. 213 writes about Shafer's (2016) new decision theory: "Shafer's constructive decision theory needs to be fleshed out before it can be applied to practical decision-making situations." %}

{% This paper axiomatizes a subcase of the smooth ambiguity model. However, I think that this subcase is, essentially, recursive expected utility (REU). More precisely, it is isomorphic to REU. Explanation follows. For simplicity, I assume the state space finite and monetary outcomes with continuous utility.

REU (Kahneman & Tversky 1975 pp. 30-33; Kreps & Porteus 1978; Neilson 2010) assumes a two-stage event space with expected utility maximization at each stage (objective or subjective) and backward induction, but it deviates from EU by allowing for different utility functions in the two stages.

Notation is as follows. Events C_1, …, C_n partition the universal event. Each C_j is partitioned into $E_{j_1,\ldots,j_{m_j}}$, where it is conceptually useful (see later) to note that m_j can depend on j. Exactly one of the C_j is true and conditional on C_j, exactly one of $E_{j_1,\ldots,j_{m_j}}$ is true. Outcomes are real-valued (money), and acts map events E_{j_i} to outcomes. In principle, every assignment of outcomes to events is conceivable, and the act space, the domain of preference, is $\mathbb{R}^{m_1+\cdots+m_n}$. In the smooth model, analogs of the C_j are called *second-order*, and analogs of the $E_{j_1,\ldots,j_{m_j}}$ are called *first-order*, and I will follow this terminology here for REU. (In some other fields these terms are reversed, unfortunately.) Acts depending only on the C_j are called *second-order*. The C_j are also called *conditioning events*.

For a utility function U, conditional on each E_j, EU is maximized using U. (U could also depend on j but we assume not here. He, 2021, has a model with such dependence.) We do certainty equivalent (CE) substitution at each C_j through such an EU model. After this done, we aggregate over the C_js using EU with another utility function $V = \varphi \circ U$. The probability distributions conditional on C_j, so over the $E_{j_1,\ldots,j_{m_j}}$, are called *conditional* or *first-order distributions*. The probability distribution over the C_js is the *second-order distribution*.

Apart from $V \neq U$, REU may be just any Bayesian model with multistage resolution of uncertainty as occurring in every application, and having nothing to do with ambiguity. But REU can be interpreted to capture ambiguity. We then take the probabilities conditional on the true C_j as true/correct, but unknown in the sense that we do not know which C_j is true. Some observations: The C_j are exogenously determined. One can conceive/implement gambles on them, i.e., they can be outcome-relevant. For this reason, they have been called physical/identifiable. Further, the events $E_{j_1},\ldots, E_{j_{m_j}}$, for different j, may just be different events, just disjoint, with nothing in common otherwise. In particular, the m_js can be different. We don't say $E_{i_1}=E_{j_1}$ in any sense. We call each set $\{E_{j_1},\ldots, E_{j_{m_j}}\}$ a *conditional state space*.

REU is a particular ambiguity model that is not widely applicable. Its two-stage setup is rarely available. Usually, uncertainty about true probabilities cannot be specified in terms of physical/identifiable events. A gamble like "if the true probability of E exceeds 0.65 then you receive €40" is usually inconceivable because we cannot identify the winning event. Ellsberg urns do allow for such gambles if the content of the urns can be inspected, but this is not representative of natural ambiguity.

The smooth ambiguity model (SAM) seeks general applicability. It uses a functional form like REU, but with two differences. First, the events C_j to specify the true probabilities are not required to be identifiable. They are allowed to concern nothing other than specification of the true probabilities, and can be equated with them. The probability distribution over the C_js then is simply a "second-order" distribution over the first-order distributions. (That there are infinitely many such events does not affect any claim in this analysis.) Thus, the smooth model becomes applicable whenever one is willing to accept a concept of true probability, where that probability is allowed to be subjective. (Although most ambiguity theories popular today (2022), including multiple prior theories, use a concept of true but unknown probability, I think that it is not meaningful in many applications.) Second, $m_j = m$ is independent of j and for each i we identify all $E_{i_k}=E_{j_k}$ for all i≠j and k, writing $E_{i_k}=E_{j_k}=E_k$. Thus, the first-stage probability distributions all concern the same events. I call $\{E_1,\ldots,E_m\}$ the *unconditional space*. The crucial restriction for unconditional state space that we impose is that any act should assign the same outcomes to all $E_{i_k}=E_k$ for all i and k. Thus, the act space, the domain of preferfence, is not $\mathbb{R}^{m_1+\cdots+m_n}$ or $\mathbb{R}^{mn}$ but $\mathbb{R}^m$ (to be expanded later). Because there is no exogenous specification of second-order events it is sometimes said that it is endogenous. Strictly speaking, the set of all first-order distributions is given beforehand though and can be called exogenous. The second-order distribution is subjective and endogenous—as it can also be in REU. Because all second-order distributions are now considered, and not just those over the C_js, this free parameter of SAM is of very high cardinality with little parsimony.

That the second-order events are no more identifiable, brings serious observability problems for experimental and theoretical analyses of SAM. The analyses provided in the literature as yet invariably assumed identifiable second-order events. They concerned REU rather than SAM.

Klibanoff, Marinacci, & Mukerji (2005), KMM provided a preference foundation. However, in this they assumed second-order acts, maps from the set of all first-order probability distributions to outcomes, available. For those, the second-order events should be identifiable after all. The authors acknowledged and discussed this problem on p. 1856.

Denti & Pomatto (2022) provided a preference foundation for a subclass of SAM, but it is in fact REU, or isomorphic to REU. They do not explicitly assume a two-stage model, but require separability (the sure-thing principle) of the second-stage events C_j. It is well-known, though, that two-stage backward induction is equivalent to separability of the conditioning events. As for an unconditional state space, a conditional state space can always be formally turned into an unconditional state space as follows. The unconditional state space S is defined as the union $\{E_{j_1},\ldots, E_{1_{m_1}}\} \cup \cdots \cup \{E_{n_1},\ldots, E_{n_{m_n}}\}$, containing $m_1 + \cdots + m_n$ states. Let P_j denote the REU conditional probability measure on $\{E_{j_1},\ldots, E_{j_{m_j}}\}$. Then Q_j is the unconditional probability measure on S that agrees with P_j on $\{E_{j_1},\ldots, E_{j_{m_j}}\} \subset S$ and assigns probability 0 to the rest of S. This way REU with a conditional state space can formally be turned into SAM with an unconditional state space. However, it is a very special case, where the conditional probability distributions have empty support. I call this case a *quasi-unconditional state space*. It is isomorphic to REU. It is similar to Cerreia-Vioglio, Maccheroni, Marinacci, & Montrucchio's (2013 PNAS) orthogonality which also imposes disjoint supports and then shows that a second-order distribution then is identifiable.

Exogenous concepts can be turned endogenous using the "there exists" quantifier. Thus, in REU, instead of assuming the two-stage decomposition with separable events E_j given beforehand, one can start from a general state space and then assume that *there exists* a two-stage decomposition with separable E_j, and then impose all restrictions. A nice thing with separable events, noted by Gul & Pesendorfer (2014), is that usually there is a maximal partition/sigma-algebra of those events, a common refinement of all. It obviously is unique. The point is that if two events are separable then by Gorman's theorem usually so is the algebra generated by them.

I think that this paper axiomatized REU. It used separability as equivalent to two-stage folding back, a quasi-unconditional state space, and a "there exists" endogenization of something exogenous, but the result is isomorphic to REU. In particular, the main novelty of SAM over REU, nonidentifiability of the conditioning events, is not there. It is needed to move from REU to general ambiguity.

I next discuss terminologies and notation used by the authors. The abstract suggests a preference foundation for the general smooth model. But it is only if there are identifying conditioning events. The authors use the Anscombe-Aumann framework. The authors interpret the identifiable conditioning events to be statistical models. But they can be any kinds of events satisfying separability. Equating separability with being a statistical model is an interpretation. P. 552 middle writes: "Under this view, ambiguity is generated by uncertainty about the correct law of nature p, rather than by inability to express decisive first-order beliefs." Thus, they assign some objective physical meaning although it will be purely subjective and endogenous in this paper. The sentence "We ask P to satisfy what is perhaps the single most fundamental assumption in statistical modeling, that of being identifiable." (p. 552) shows how important the identifiability assumption of the authors is to themselves. Identifiability in the first displayed eq. on p. 552 means disjoint supports of the correct laws of nature, i.e., they are 100% incompatible, which of course is a very restrictive assumption. The later sentence "identifiable smooth preferences formalize the common view that ambiguity is due to lack of information" puts identifiability in a broad perspective.

The predictive assessment π is the overall probability measure over the state space that gives the probabilities of the conditioning events E_j and, conditioned on E_j, the candidates for being called correct law of nature. The sigma-algebra T is the one generated by the conditioning events. The last sentence on p. 552 was incomprehensible to me: "Both T and π are purely subjective and make no reference to any agreed-upon statistical notion of "true" law of nature." Because just before the authors endorsed the interpretation of true law of nature.

The main axiom in the axiomatization is Axiom 4 (p. 560). It combines the sure-thing principle for the conditioning events with the vNM independence condition (using the mixture in their Anscombe-Aumann framework) conditional on the conditioning events, the latter formulated indirectly via a $\succcurlyeq^*$ relation.

Proposition 4 has a condition of more perceived ambiguity which is roughly equivalent to having the same 1st order utility and a less refined set of separable (conditioning) events. Proposition 5 has the usual more-ambiguity-averse relation through Yaari-type certainty-equivalent comparisons, which capture the desired attitudinal component, ambiguity aversion in this case, by assuming all other components (the vNM utilities in the 1st order events) fixed. Then it corresponds with φ being more concave and same πs.

P. 566 2nd para nicely points out that identifiable events may not be available. %}

{% They show that salience theory can accommodate skewness preference. However, they do not take salience theory in its original form, but a continuous version that in fact is a special case of (generalized) regret theory. Fortunately, they state this explicitly, in §2 (I would have preferred in the intro though).

P. 2063 para below Def. 3 discusses a normalization. But it should be understood that the preference functional is invariant up to multiplication by any positive function g(C) where g can entirely depend on the choice situation C, so that this normalization has no empirical meaning.

In itself it is not surprising that salience theory can accommodate much because of its big generality, also its continuous version. In an experiment they find violations of transitivity. This is a violation of every transitive theory including prospect theory (**PT falsified**). It can be taken as support for salience theory

§2.2 defines certainty equivalents. In the absence of transitivity, these do not mean much.

§7.3 critically discusses regret theory. For one, the authors argue that regret must be anticipated, requiring info about the forgone outome. This info need not ocur in their experiment, for instance if subjects reeive a sure outcome. I see this differently. First, regret theory is only more convincing if info about foregone outcomes, and will still be working, but weaker, if not. But, seond, this holds the same for salience theory. Salience will be weaker if no info about foregone outcome. Further, this is only a difference of interpretation, not of preference functional. %}

{% Subjects trade state-contingent payments in an experimental market. They get a prize conditional on an event, either a chance event with known probability 0.5, or an event about temperature exceeding some value in some city. The temperature was always the median, although subjects did not know this. In one treatment, subjects indicated about which cities they were knowledgeable, in the other not. If subjects understood arbitrage, all market probabilities would satisfy the laws of probability.

Subjects may pay more for gambling on an ambiguous event than on a chance event, not because they are ambiguity seeking, but because they consider the ambiguous event more likely, especially if they are knowledgeable. Hence, just testing that is not good. The author, properly, always takes the price for a gamble on an event PLUS the price on its complement, thus avoiding likelihood effects as mentioned and truly testing ambiguity attitudes.

Subjects paid most for ambiguous events they were knowledgeable about (**ambiguity seeking**), more than for random events, and paid more for the latter than for ambiguous events they were not knowledgeable about. This confirms the competence effect of Heath & Tversky (1991). As explained by the author, it also implies arbitrage opportunities. %}

{% **losses from prior endowment mechanism**: Subjects receive £10 as prior endowment, and then are faced with a risk of losing these £10 again, and can "insure" against it. This term insure is NOT used in the instructions for the subjects. It is described to them as "reduce this potential loss to zero." In one treatment they receive probabilities of loss, in second it is said that an expert has guessed a probability, in a third an expert has expressed an interval of probabilities, and in a fourth ("SOP") the probability is mean of second-order probability distribution. Difficulty with second treatment may be that there is no full control of belief, and a regression to the mean (0.5) can be expected because of absence of control for beliefs, and not because of ambiguity attitude, in the same way as this occurs in studies by Einhorn & Hogarth.

They interpret the second-order probabilities treatment as more probabilistic information and less ambiguity than the expert-judgment treatment, but find no significant differences in the data (though they discuss nonsignificant trends).

ambiguity seeking for losses: find this for high probabilities

ambiguity seeking for unlikely: they find the reflected effect; i.e., ambiguity aversion for unlikely losses.

Find ambiguity neutrality for intermediate probabilities (0.20 to 0.50).

reflection at individual level for ambiguity: only losses so does not consider it. %}

Di Mauro, Camela & Anna Maffioletti (2001) "The Valuation of Insurance under Uncertainty: Does Information about Probability Matter?," *Geneva Papers on Risk and Insurance Theory* 26, 195–224.

{% **ambiguity seeking for losses**:

Study ambiguity attitudes for gains and losses (comparing gambles with known probabilities to those with unknown). Ambiguity means second-order distributions. Use WTP questions. For losses they have, in fact, regular CE (certainty equivalent) questions and there their findings agree with those in the literature; i.e., with ambiguity seeking for events of moderate and high likelihood.

For gains, the WTP questions mean that, after aggregation of the gamble obtained and the price paid, it is a gamble with a gain and loss, so, loss aversion comes in.

Real incentives: by means of auctions among 8 subjects each time.

reflection at individual level for ambiguity: only losses or mixed (that is what WTP for gains is) so does not consider it.

correlation risk & ambiguity attitude: Table 6: no relation. %}

Di Mauro, Camela & Anna Maffioletti (2004) "Attitudes to risk and Attitudes to Uncertainty: Experimental Evidence," *Applied Economics* 36, 357–372.

{% Compare bidding behavior and prices in market-like settings to valuations obtained from individual pricing tasks. Repetitions of the market experience tends to improve SEU. (**real incentives/hypothetical choice**) Presence or absence of financial incentives does not matter.

second-order probabilities to model ambiguity: ambiguity is generated through second-order probabilities.

It is not easy to derive aspects of individual risk and uncertainty attitudes from the findings of this paper. First, subjects get 8 (or 8 times 4?) repetitions of gambles and are paid the sum of the separate gambles, so, it is not single choice

but repeated and integrated choice. Second, the bidding and market environment can distort. Third, for the real incentives experiments, subjects receive a prior payment so that in total they never really lose and, therefore, the part of the subjects who integrate the payments and don't do isolation do not really perceive losses. (The third argument does not hold for the hypothetical payment subjects.)
The real incentives were 1% of the nominal amounts. %}

{% The authors give an appealing and very efficient preference foundation of RDU with: (a) Power weighting; (b) exponential weighting; (c) **inverse S** weighting with a power function cp^a up to some reflection-point probability t, and a different dual power function $(1 - dw(1-p)^b)$ thereafter.

The result is efficient because, first, it only uses the richness present in the probability scale anyhow, and no richness of outcomes. Second, besides the axiom to characterize the particular shape of w (such as $P \geq Q \Rightarrow \alpha P + (1-\alpha)0 \geq \alpha Q + (1-\alpha)0$ to have power-w) the authors only use a general rank-dependent additive separability condition, and nothing extra to separate probability weighting from utility. The latter comes free of charge, so, to say.

The result is appealing because all preference conditions used are direct weakenings of vNM independence, with the power weighting axiom directly related to the common ratio effect and the exponential weighting axiom directly related to the common consequence effect.

So, this paper is exemplary both regarding the technical richness conditions and regarding the intuitive conditions! %}

{% **tradeoff method**: Regret theory gives up transitivity. It is hard to imagine what optimization then means, and what a utility function could mean. This may explain why measuring or axiomatizing it is hard. Mainly Fishburn worked on axiomatizations with his skew-symmetric models. Bleichrodt, Cillo, & Diecidue (2010) showed that the tradeoff method can be used to still measure the theory.

This paper shows that it can give an axiomatization of the most popular special case with nonlinearly transformed utility differences. D-transitivity generalizes transitivity by imposing it only whenever one of the antecedent preferences is by dominance. The proof heavily uses a nontransitive state-dependent utility axiomatization by Fishburn (1990). The acknowledgement makes clear that Horst Zank contributed much. %}

{% Proposes and axiomatizes an original ambiguity model. Consider act $(E_1:x_1,\ldots,E_n:x_n)$,with $(E_1,\ldots,E_n)$ a partition of the universal event and the x_js outcomes. The act is evaluated by SL expected utility (the abbreviation SL I did not see explained)

$$\sum_{i=1}^{n}\sum_{j=1}^{n}u(x_i,x_j)P(E_i,E_j)$$

where $P(E_i,E_j)$ is something like: the subjective probability of what is probably event E_i but might also be event E_j, and $u(x_i,x_j)$ is something like: the subjective utility of what is probably outcome x_i but might also be outcome x_j.

There is a sigma-algebra of unambiguous events E, which I guess have $P(E,F) = 0$ for all $F \subset E^c$ and $P(E,E) = P(E)$ is a regular probability measure, with $u(x,x) = u(x)$ regular utility. These events are, I guess, characterized by satisfying the sure-thing principle, i.e., being separeable, and are, I guess, called S events. There is also a sigma-algebra of completely ambiguous events, sort of complete ignorance, probably similar to Gul & Pesendorfer's diffuse events E, for which $P(E_i,E_j) = P(E_i) \times P(E_j)$. They are defined as L events through Definition 2, entailing in a way that they are orthogonal to the ambiguous events, so that acts measurable with respect to one can serve as outcomes for the other, in quasi two-stage. The author interprets interactions $P(E_i,E_j)$ as ambiguity (perception), and $u(x_i,x_j)$ as ambiguity perception. The total sigma-algebra is the one generated by the other two.

I have the impression that the disappointment model by Delquié & Cillo (2006) is a special case of the model of this paper. %}

{% The paper analyzes the common ratio effect. Unfortunately, what the authors call common ration is not so, but the authors add uncommon things. It is in Definition 2, p. 4. The new condition of his paper, called indistinguishability of small probabilities ($\lim_{p \to 0} w(\Delta p)/w(p) = 1$ for all $0 < \Delta < 1$), only comes about because of the authors' uncommon things. Next follow details.

First, the authors' definition restricts attention to two lotteries of the same expected value (Δp: z) (receive outcome z with probability Δp, and outcome 0 otherwise) versus (p: Δz) (where $0 < p < 1$, $0 < \Delta < 1$), where p varies. Hence, a preference reversal must always combine risk aversion with risk seeking. Second, they require that there is only one preference reversal. A difficulty is that the definition is not clear on its quantifiers. Is it for every such pair of lotteries? Is it supposed to happen for EVERY possible utility function? Proposition 1 gives a formal result. As it turns out there, for each fixed lottery pair they want the preference reversal FOR EVERY UTILITY FUNCTION. It is only this restrictive and unusual assumption that implies the new condition of his paper, indistinguishability of small probabilities.

P. 1 2nd column: The preference condition of Prelec & Loewenstein (1991) is

equivalent to the other definitions as soon as utility is regular (strictly increasing and continuous). Contrary to what the authors claim here and repeat later, it does NOT depend on utility beyond it being regular.

The discussion on p.2 2nd column last paras, and several other places, not only has the problem that the authors are restricting attention to lotteries of the same expected value, but also that on the domain considered (one nonzero outcome), a joint power of probability weighting and utility is in general unidentifiable. It becomes identifiable only if one adds further assumptions such as specifying utility. In this paper a restriction on the transformations that can be considered comes from the assumption that utility is concave (for gains). Yet this leaves too much flexibility to speculate meaningfully on convexity/concavity or overweighting/underweighting of the probability weighting function. %}

{% Unfortunately, what the authors call Allais paradox is not so, but is the common ratio effect. The Allais paradox concerns only the case where one probability is 1, so that the certainty effect is involved. The common ratio paradox can also apply to small probabilities near 0, making them be overweighted much, which increases rather than decreases the value of the St. Petersburg paradox. The authors here use a part of the common ratio effect that is NOT the Allais paradox.

Btw, whether empirically there is risk seeking or risk aversion for truncated versions of the St. Petersburg paradox is not so clear. Tversky & Bar-Hillel (1983) predicted risk seeking. %}

{% By, unlike this paper, using mother sets (basic starting sets from which everything comes), I present a simplified version of this paper's model: Assume a Savagean "mother structure" of a mother state space S and mother outcome set X. T is a set of contexts. For every context t, a structure called a Savage Structure S_t, X_t is given where S_t, X_t partition $\mathbb{S}_t \subset S$ and $\mathbb{X}_t \subset X$, respectively. An act maps S_t to X_t. An element $x \in X_t$, so $x \subset X$, is a set of outcomes that the subject cannot distinguish, so, blurs, and $s \in S_t$ is similar. It reflects limited awareness. For each Savage structure an SEU model is given.

Consistency conditions between Savage structures are imposed. If U denotes a "mother utility" on X, then $x \subset X$ may have as utility the minimum of U, or maximum, or something else, but if different contexts have overlaps of outcomes then there their utility functions are affinely related. Probabilities over different contexts are assumed to be consistent in having the same event-probability-ratios where-ever there is overlap, as resulting from Bayesian conditioning and so on. St and $\mathbb{X}_t$ are called objective states and outcomes encompassed in context t, respectively, and S_t and X_t are subjective.

The paper does not start from an underlying mother structure, but starts from the various Savage structures. Then ensuring consistencies such as handling states of nature appearing in different contexts, (partially) overlapping, and giving no violations of set-monotonicity of probability for instance, is more complex to handle.

Although the paper assumes that every S_t and X_t are finite, it also assumes that each such structure can be extended to an infinite structure that maintains all axioms and satisfies Savage's P6 to the required degree, and in this sense still assumes infinitely many Savage structures, in Axiom 6** on p. 19. Axiom 6 on p. 20 is similar. The paper descibes this on pp. 18-19:

"Just as Savage's 6th postulate, Axiom 6* is very demanding. It forces the agent to conceive plenty of small events, ultimately forcing all state spaces St to be infinite (assuming Axiom5 for non-triviality). I shall thus use a cognitively less demanding Archimedean axiom, which permits all state spaces S_t to be finite. To avoid 'state-space explosion', it allows the events A_1, ..., A_n to be *not yet* conceived in context t: they are conceived in *some* possibly different context t´. So the agent can presently have limited state awareness, as long as states are refinable by moving to a new context/awareness. The slogan is: '*refinable* rather than (already) *refined* states'. To refine states, it suffices to incorporate new contingencies into states until a sufficiently fine partition exists;"

The paper also considers structures with partially objective states, and then assumes those infinitely many. See Remark 20, p. 26. The agent is stable in preferences and beliefs for objective levels of description, but instable for subjective levels.

The paper cites Ahn & Ergin (2010) for a related partition-dependent model. Such models were also used by Luce, unknown to Ahn & Ergin and this author; see my comments to the Ahn & Argin paper. %}

{% **risky utility u = transform of strength of preference v**: this paper revisits the old idea of decision analysis of the 1980s and 1990s, giving a new turn to it. The old idea was that risk attitude should be more than intrinsic ("riskless") utility, and therefore the risky vNM utility function should transform the nonrisky one, often called value function, nonlinearly. In my paper Wakker (1994), I argued that probability weighting of prospect theory (and also loss aversion) can be used to let risk attitudes have properties beyond riskless marginal utility, so that it was

no more needed to transform riskless utility. This paper argues, and I agree, that Wakker's proposal means deviating from expected utility which means (I agree) that it cannot be done normatively. My position has always been to let cardinal riskless utility be equal to cardinal risky utility, as a normative position. But one can see that differently of course, and this paper does so. It then develops theory for it. Truly reviving the old idea in the bold keyword above. %}

{% P. 144: "Given that Savage is one of the all-time greats of decision theory". I think that the first half of Savage (1954) is the greatest contribution in all of decision theory.

The authors revisit Savage's violation of the sure-thing principle when first confronted with the Allais paradox, and how Savage then corrected his error, as he put it.

The authors seem to want to criticize what they call behavioral economics. P. 145: "Savage's concept of error correction is coherent, but it is not the concept that behavioural welfare economics invokes." They seem to think that behavioral economics should make people better off *in their own perception*, with which I disagree. They cite Gilboa (2010) on it, on p. 145: "a mode of behaviour is rational for a given decision maker if, when confronted with the analysis of her behaviour, the decision maker does not wish to change it", and Thaler & Sunstein (2008): "make choosers better off, as judged by themselves". I did not check T&S08 on this, but speculate that they take this as a definition of nudge or libertarian paternalis but not of behavioral economics. One can argue that Dietrich et al. take this as definition of behavioral economics. Then Savage's resolution of his sure-thing principle violation may not always work because there exist decision makers silly enough not to understand the relevant reasonings. But, again, these definitions deviate from mine.

The authors discuss the case also from the perspective of a theory by Broome with a variation by Dietrich. An individual has a set of mental states, being pairs (p,a) where p is content and a an attitude type. P. 148: Broome defines rationality as requirement that the set of mental states satisfies some conditions (which is dangerously close to the, I think silly, coherence view of rationality) and seems to think that it has nothing to say about how the mental states change. Such theories are, of course, too simplistic to capture reasoning, but the authors only use them to shed new light on rationality and behavioral economics.

P. 160: "We conclude that Savage's concepts of error and correction are very different from those that behavioural welfare economists use to identify individuals' latent preferences." This holds for the authors' definition of behavioral economics, but not for my definition.

P. 161 points out that Slovic & Tversky (1974) had too few subjects to reach significance. Humphrey & Kruse (2024) redo Slovic & Tversky (1974) and reach significance, confirming the findings. %}

Dietrich, Franz, Antonios Staras, & Robert Sugden- (2021) "Savage's Response to Allais as Broomean Reasoning," *Journal of Economic Methodology* 28, 143–164. https://doi.org/10.1080/1350178X.2020.1857424

{% I discovered this in Sep. 2011 because Nicolas Gravel sent it to me. Many theorems on EU with finitely many equally likely states. P. 358 explains how the theory of general means is related to decision making. It discusses consistency in aggregation, as used by Nagumo and the like, and as generalized associativity or substitution independence from DUR. Section 3 shows that you essentially only need it for binary decompositions of the attributes and for the overall attributes, and not for all decompositions of the attributes. This is similar to Köbberling &

Wakker (2003, p. 407 bottom), who wrote, on multisymmetry: "The preference conditions need to be imposed only on one mixing event. With the exception of Quiggin (1982), all the works mentioned imposed the preference conditions on all mixing events." K&W are somewhat more general because they have no symmetry. They did not know about Diewert's chapter.

Diewert also discusses constant absolute and relative risk aversion for these functionals, and aversion to mean-preserving spread type conditions.

End of §4 mentions that log-power and linear-exponential is "all of the nontrigonometric elementary functions of one variable."

§7 considers variable dimension, with all finite-dimensional subspaces. It points out the omission in Blackorby, Primont, & Russel (1977) of not imposing consistency across different dimensions so as to ensure the same utility function there (following Proposition 20). It points out that one gets all rational-probability prospects this way. It also tries to extend to nonrational-probability prospects by taking limits, but then from Eqs. 150-152 implicitly uses that the functional is continuous in probability (the continuity it refers to is of the EU functional, and not of the functional considered and yet to be proved to be EU).

The paper throughout gives generalizations to implicit (betweenness) functionals as studied primarily by Chew. It heavily leans on Chew & Epstein (1989), a paper that unfortunately has several mathematical problems. %}

Diewert, Walter E. (1993) "Symmetric Means and Choice under Uncertainty." *In* Walter E. Diewert & Alice O. Nakamura, Elsevier, (eds.) *Essays in Index Number Theory*, 355–441, Elsevier, Amsterdam.

{% Discovering new particle in physics requires p-value of $1/(3.5 \times 10^6)$. Reason is that apparently H_0 and H_1 were not specified well a priori. This is called the problem of multiple comparisons, or, in popular press, the look-elsewhere effect. %}

Dijkgraaf, Robert (2015) Column in NRC, December 19, 2015.

{% **intuitive versus analytical decisions**; In simple situations, conscious deliberation gives best decisions. In complex situations, unconscious thought does better.

Abstract ℓ. 2 writes that the authors use recent insights into …, so as to suggest novelty. The novelty viz-a-viz many preceding studies into analytic versus intuitive decision making seems to be that these authors put forward some explanation about unconscious, but this is speculation and other explanations as in Wilson & Schooler (1991) work as well.

P. 1005 middle column writes: "the idea that conscious deliberation is the ideal (if not always attainable) way to approach a decision forms the backbone of classic (4, 5) as well as contemporary perspectives on decision making (6,7) …" I disagree. Also decision theorists including me and many others know that in most decision situations decision theory has absolutely no help to offer. Only if very particular conditions are met (such as completeness of preferences over a rather rich set of prospects), it can be of some use. During my work in health this happened for 1 out of 1000 diseases. (Many decision theorists, unfortunately, oversell their theories by making the mistake, common in any science, to pretend that they cover everything in life.)

One of the many problems for the studies is that the evaluation of what is the best option is weak in each study. In the car studies (studies 1 and 2) the criterion taken is that the car is to be best that is best on MOST attributes (described as "normative" on p. 1006 middle column). But very obviously, different individuals weigh the attributes differently. (P. 1006 2nd column end of 1st para qualifies this as normative.) Maybe the subjects subconsciously just went by majority-attribute rule as a heuristic. In study 2 they may just have reported bigger evaluation differences because of lack of nuance. In studies 3 and 4, the outcomes of deliberate choice need not be worse, but instead there may be an error in the evaluation of the outcomes of nondeliberate choice being that people here haven't thought enough about the drawbacks of their choice so that their evaluation as given is too optimistic, and there then is more space for instance for cognitive dissonance. Also, people may think more, or less (which may depend on complexity) BECAUSE they like it less. There are too many interactions between selection criterion and dependent variable of how much they like it. Wilson & Schooler (1991) in a thorough study on the same topic, write (p. 182 2nd column penultimate para): "evaluating a stimulus on several different dimensions causes people to moderate their evaluations."

They claim, p. 1005 top of 3rd column, that scientists have investigated the pros of unconscious decisions "infrequently" and that they are going to show the opposite, suggesting novelty on this point. But there have been dozens of solid studies doing and showing it before, as the keyword **intuitive versus analytical**

decisions in this bibliography shows. To not only claim this novelty for the superficial readers, but also defend against closer readers that they do not claim this novelty and that they do credit predecessors, the next para lists a number of predecessors.

P. 1005 3rd column middle writes "Two reasons why conscious deliberation sometimes leads to poor decisions have been identified" but there are many similar biases.

P. 1006 claims: "Unconscious thought does not suffer from low capacity," citing a paper by one of the authors for this unqualified claim.

P. 1007 2nd column 3rd para is typical of psychology: for each study alone one can raise doubts, but the studies together are so many that they support the general hypothesis.

The last para suggests, optimistically and based on a "there is no reason that not" argument, that the findings of this study, studied only for consumers, will not hold for politicians, managers, and, may I add, why not for all of mankind?

Nieuwenstein et al. (2015) does a meta-analysis on the Deliberation-without-Attention Effect with a negative conclusion.

The sample sizes are small, as indicated in the corresponding figures: 18 to 22 for each of the four conditions in Study, same in Study 2, 49 for Study 3, and 27 for both conditions in Study 4. %}

Dillenberger, David, Juan Sebastián Lleras, Philipp Sadowski, & Norio Takeoka (2014) "A Theory of Subjective Learning," *Journal of Economic Theory* 153, 287–312.

{% Imagine that an agent maximizes SEU. As pointed out primarily by Karni, may be the subjective probabilities are not the tue beliefs, and U is not the true utility. There may be state-dependent utility with all utilities for states in event E multiplied by 2, and all probabilities within E divided by 2 (followed by renormalization). Default is that we choose the simplest model, being state-independent. But there can be alternative info, such as introspective, pointing at another model.

This paper does something related, but of course different. (It discusses Karni and other similar approaches in §4.3.) Assume risk aversion with concave utility U. Utility may in reality be linear. But the decision-maker has act-dependent pessimistic transformations of probability that always "happen" to give the same certainty equivalent as would result with the concave utility function. Again, introspective info could make one go for such a model.

P. 1165 considers a perfectly fitting SEU model with supposed utility U, but real utility V ≠ U. Then there can be many SEU models with V and act-dependent probabilities (optimistic or pessimistic or otherwise) that assign the same certainty equivalent to the act, and the act-dependent probability model is too general in this sense. The authors suggest on p. 1165 that one then takes the model whose probabilities minimize the Euclidean distance to the SEU probabilities.

P. 1165-1166: If one can additionally observe choices with objective probabilities and it is plausible that those give the real utility function, then one can observe that the Savage SEU utility is not the real one and that something like the model of this paper must be going on. Note here that this analysis assumes that the objective-probability events are not part of the Savage state space, and for instance are not like the ones in Machina (2004 ET).

P. 1166 footnote 9 very properly points out that source-dependent SEU can do things like Anscombe-Aumann, but totally avoid the complications of multi-stage.

Pp. 1166-1167 consider a known and unknown Ellsberg urn. For both urns SEU may hold, with ambiguity aversion captured by a more concave U for the unknown urn, as happening for Chew et al. (2008)'s source-dependent SEU, with similar things in the smooth model. As p. 1167 argues and I fully agree, the utility explanation is not plausible. The outcomes are the same in both cases, so why would utility be different? They write: "After all, the prizes are the same across both domains; it is only the probabilities that differ." (**event/outcome driven ambiguity model: event driven)** Researchers who want representations to not just represent choices, but also be psychologically plausible (homeomorph), will be open to such arguments. This paper argues that pessimistic probability weighting may be more plausible. I fully agree, and this is the basis of the source method of ambiguity that I work on. The source method leads to preferences deviating from SEU or source-dependent SEU, whereas this paper focuses on preferences that stay within SEU, or source-dependent SEU.

In my words, this paper says: "Even if a utility-driven model perfectly fits the data, then still we don't believe it." It makes this paper one of the strongest going against **coherentism**. %}

{% After their paper in the Journal of Financial Economics, this is the second paper following up on Dimmock, Kouwenberg, & Wakker (2016 MS; DKW). This paper has considerably more content than the JFE paper. It uses the same data set as the JFE paper, with same arguments of why not controlled for suspicion and so on. But now it also uses the likely (p = 0.9) and unlikely (p = 0.1) urns. Further, for the fifty-fifty urns it also does hypothetical loss. The ambiguity aversion in these four questions will all be positively correlated. The authors explain (p. 222 footnote 3), and I agree, that hypothetical is better than paying from prior endowment. (**losses from prior endowment mechanism**)

ambiguity seeking for losses: they find it (p. 228 last sentence).

ambiguity seeking for unlikely: they find it.

reflection at individual level for ambiguity: ambiguity aversion for gains and losses is positively related (p. 229 penultimate sentence of first para)

The authors use the α-maxmin model to analyze things. They take an ε-contaminated set of priors. For the stimuli considered, with only two-outcome prospects, and with EU for risk, it is equivalent to the source method of

Dimmock, Kouwenberg, & Wakker (2016 MS; DKW) with a neo-additive source function, as shown by Chateauneuf, Eichberger, & Grant (2007), and as pointed out by the authors. But a restriction is that their model assumes EU for risk whereas DKW do not need that restriction. The authors propose an index δ that they interpret as perceived ambiguity, and then the α index of ambiguity aversion. As they point out in their footnote 20 (p. 231), their indexes δ, α are transformations of the a-insensitivity index a and the ambiguity aversion index b of DKW. More precisely, their perception index δ is identical to the insensitivity index a and for their aversion index α we have $\alpha = (b/\delta + 1)/2$. The linear rescaling $b/\delta \rightarrow (b/\delta + 1)/2$ is immaterial. But the division of b by δ means that their index gives ambiguity aversion per unit of perceived ambiguity δ, whereas b of DKW is an index of absolute ambiguity aversion. Which is more convenient depends on context. The important thing is that the two pairs of indexes are equivalent. This relation between the two index pairs was first pointed out at the end of §2 of the 2013 working paper version of

Baillon, Aurélien, Han Bleichrodt, Umut Keskin, Olivier L'Haridon, & Chen Li (2018) "The Effect of Learning on Ambiguity Attitudes," *Management Science* 64, 2181–2198.

As regards their findings, in the neo-additive terminology of Chateauneuf et al., their α (ambiguity aversion) is 0.56 and their δ (confidence in probability, = 1–a-insensitivity) = 0.60 (p. 221 ℓ. –5). They test a number of less interesting sets of priors but those all perform poorly.

P. 241 2nd para: ambiguity aversion is positively related to being male, old, and, strangely enough, college-educated.

P. 241 3rd para: confirms the Fox-Tversky finding that ambiguity aversion is higher if the ambiguous option is presented after the risky one, than when before.

Ambiguity aversion is positively related to being male, old, and, p. 241 4th para: a-insensitivity (or level of perceived ambiguity) is positively related to being male, white, and, again strangely enough, college-educated (vs. high school), going against some cognitive hypotheses. (**cognitive ability related to risk/ambiguity aversion**)

correlation risk & ambiguity attitude: positive but weak (p. 222 2nd para), both for gains and losses. Correlation risk aversion and a-insensitivity: not significant (p. 222 2nd para). P. 241 last para of §4 repeats it, saying that it is plausible if perceived ambiguity is formed independently from risk preferences.

Pp. 239-240: the authors make the assumption that perceived ambiguity is the same for gains and losses, which is plausible if this is cognitive.

They assume that a-insensitivity is the same for gains and losses, citing Baillon & Bleichrodt (2015) for it. It is plausible because a-insensitivity is cognitive.

Ambiguity aversion is stronger for subjects who first get the risk aversion question, confirming the contrast effect of Fox & Tversky (1995).

P. 242 argues against universal ambiguity aversion.

reflection at individual level for ambiguity: seems that $AA_{0.5}$ and $AA_{-0.5}$ are positively correlated (0.25), going against reflection at the individual level. %}

{% Data set: publicly available from the RAND American Life Panel (ALP) website, as survey number 243:

https://alpdata.rand.org/

The authors were so kind to provide me with their questionnaire.

Abstract: "In this paper we test the relation between ambiguity aversion and five household portfolio choice puzzles: nonparticipation in equities, low allocations to equity, home-bias, own-company stock ownership, and portfolio under-diversification. In a representative US household survey, we measure ambiguity preferences using custom-designed questions based on Ellsberg urns. As theory predicts, ambiguity aversion is negatively associated with stock market participation, the fraction of financial assets in stocks, and foreign stock ownership, but it is positively related to own-company stock ownership. Conditional on stock ownership, ambiguity aversion is related to portfolio under-diversification, and during the financial crisis, ambiguity-averse respondents were more likely to sell stocks."

correlation risk & ambiguity attitude: find positive relation.

suspicion under ambiguity: in the end of §2, p. 563, the authors carefully explain, with good arguments, that they deliberately do not control for suspicion.

This paper is a follow-up on Dimmock, Kouwenberg, & Wakker (2016 MS; DKW hereafter). DKW used some 1935 subjects from the Dutch population of which only half were incentivized (paying €7650 in total). This study has 3258 subjects from the US that are all incentivized, paying $23,850 real incentives (!; p. 560 3rd para), and measuring way more of their financial decisions. DWK measured both ambiguity aversion and insensitivity, but this paper considers only aversion. It, thus uses only the fifty-fifty likelihoods, with the standard known and unknown Ellsberg urns. DKW used richer stimuli, also including 0.05 and 0.95 a-neutral probabilities. DKW found: Relation financial decisions with insensitivity is significant but with aversion it is not. (As possible explanation of the latter DKW suggest that their standard measurement had only considered gains, whereas for financial decisions also (ambiguity attitude for) losses is relevant.) This paper finds the opposite: Relation financial decisions with aversion is significant but with insensitivity it is not. These findings are not inconsistent! Erroneously claiming inconsistency is qualified as misinterpretation 16 in Greenland et al. (2016). The significance of aversion may be because of more subjects. Because it has rich financial data, it finds many relations, a.o. with home bias, showing that ambiguity aversion is important for finance. Ambiguity aversion is negatively related with stock market participation, fraction of financial assets in stocks, foreign stock ownership. It is positively related with homebias, own-company stock ownership, portfolio-underdiversification, and selling stocks during financial crisis. Also with being male (**gender differences in ambiguiuty attitude**), college educated (vs. high school), and young (**relation age-ambiguity attitude**).

They confirm many common things, with 52% ambiguity averse, 10% neutral, and 38% seeking.

The intro, p. 561 2nd column 3rd para, misleadingly writes that DKW would use a theory, the source method, which would differ from models used in the finance literature. However, the theory used in the present paper is identical to that in DKW, and is just an equivalent rewriting (details below). The authors further write that, hence, DKW’s predictions do not align with the theoretical predictions in the literature. This is again misleaeding as explained above, e.g. through misinterpretation 16 in Greenland et al. (2016).

Details on identity of models used: The model used by DKW (biseparable utility) is, for the stimuli considered (gambles with no more than two outcomes), equivalent to the α maxmin model that this paper uses. Because this paper satisfies the axioms of Chew & Sagi (2006, 2008) as can be seen, it is in fact a special case of the source method used by DKW (having within-source probabilistic sophistication), and therefore is not different after all. The ambiguity aversion index used in this paper is equivalent to the one used by DKW. Further, the ambiguity perception index used in the JRU follow-up paper by these authors is equivalent to the a-insensitivity index used by DKW, as the authors point out there in their footnote 20 there. This relation between the two index pairs was first pointed out at the end of §2 of the 2013 working paper version of

Baillon, Aurélien, Han Bleichrodt, Umut Keskin, Olivier L'Haridon, & Chen Li (2018) "The Effect of Learning on Ambiguity Attitudes," *Management Science* 64, 2181–2198,

not cited by the authors although they had been informed about it way beforehand. Anyway, hence the decision theory and index in this paper are not different than DKW, but are identical.

cognitive ability related to risk/ambiguity aversion: This paper relates cognitive ability with ambiguity aversion but finds no relation. It does, surprisingly, find higher ambiguity aversion among higher educated than lower educated. §2 nicely explains in words that matching probabilities are so nice to measure ambiguity attitudes because everything of risk attitude drops. %}

Dimmock, Stephen G., Roy Kouwenberg, Olivia S. Mitchell, & Kim Peijnenburg (2016) "Ambiguity Aversion and Household Portfolio Choice Puzzles: Empirical Evidence," *Journal of Financial Economics* 119, 559–577. https://doi.org/10.1016/j.jfineco.2016.01.003

{% **tradeoff method;** Comments on version of August 2018, NBES Working paper 24928, http://www.nber.org/papers/w24928.

Use representative sample from US of N = 2,072 subjects, paying them $16,020. Use tradeoff-method based choice questions to assess utility, but do not do chaining and derive theory-free risk premium index to capture concavity. Their main focus is on certainty equivalents for risky choices that are used to derive an index of inverse S, taking, in their Eq. 4,

PW88% + PW75% + PW50% − PW25% − PW12% − PW5%

as index of inverse S, where PWp% is a proportional risk premium for the certainty equivalent of a lottery giving a prize with probability p. I would have liked it if they had in some way added PW95%, possibly dropping PW50%, and I would also have liked it if they had taken the some of the six to capture optimism/pessimism.

Find extensive Inverse S (**inverse S**). It is positively related with nonparticipation, underdiversification, preference for positively-skewed equity portfolios and, strangely enough, weakly but significantly with education numerical reasoning and financial literacy (**cognitive ability related to likelihood insensitivity (= inverse S)**). They interpret the positive relation with cognitive ability and so on as evidence that it is not probability misperception but deliberate preference.

P. 3: "We find that high Inverse S is associated with large Sharpe ratio losses due to idiosyncratic risk. In particular, our results imply that a one-standard deviation higher Inverse S implies a cost to the average (median) stockholder of $2,504 ($351) per year, as for the same amount of risk the person could have had a higher expected return." This nicely makes the irrationality of inverse S very tangible!

P. 10: they properly do NOT equate risk aversion with utility curvature.

They find that utility curvature and inverse S are empirically unrelated.

The authors are enthusiastic and claim, last sentence in abstract: "We are the first to empirically link individuals' elicited probability weighting and real-world decisions under risk." %}

event/outcome driven ambiguity model: outcome driven

§III describes an experiment for the three-color Ellsberg urn. For gains the great majority of subjects is ambiguity averse, for losses about as many are ambiguity seeking as averse. So, mixed evidence on **ambiguity seeking for losses**.

second-order probabilities to model ambiguity: Models ambiguity through subjective second-order probabilities with recursive expected utility. This is very similar to the recursive (smooth) ambiguity model of KMM. But it is different. It is as follows: Imagine an act a that can give n outcomes $x_1,\ldots,x_n$. There is a random variable $\theta = (\theta_1,\ldots,\theta_n)$ reflecting a subjective first-order probability distribution over the n outcomes generated by act a. θ itself is a random variable, reflecting subjective uncertainty about the first-order probabilities. $(p_1,\ldots,p_n)$ is the first-order distribution that results by averaging out the θs. The author denotes by ψ the expected utility of a w.r.t. $(p_1,\ldots,p_n)$ but I think that it plays no particular role here. Anyway, after an outcome x_j results, the agent can update the second-order distribution of the θs using Bayes formula. He can recalculate the updated $(p_1,\ldots,p_n)_j$ here. He can then calculate the updated EU of act a under the updated $(p_1,\ldots,p_n)_j$, which we write as $EU_j(a)$. Now he uses a utility-transformation α, much like φ of KMM, and evaluates a by

$\sum_{j=1}^{n} p_j \alpha(EU_j(a))$. If α is the identity then we just get ψ, α concave gives something smaller (ambiguity aversion), and α convex gives something bigger.

One may wonder why an agent, after receiving x_j, would bother to re-evaluate the whole act a. The author argues for an ex-ante regret-like psychology. He also argues that this is just a way to capture ambiguity using tools similar to usual EU studies of risk, and that it does not need to resort to nonadditive or transformed probabilities (p. 435 2nd para and before). This he also shares with the smooth model.

The author puts reflection central, with ambiguity seeking for losses, which he can model by α being convex for losses. This is indeed where he beats non-reference dependent nonadditive models. The smooth model can also handle sign-dependence this way.

P. 424 penultimate para: his functional generates overweighting of unlikely events/outcomes (for the RDU workers: unlikely is not the same as extreme).

P. 420 2nd para writes that getting 2nd-order probabilities will be harder than getting 1st order ones, an argument also advanced by Lindley (1996). Dobbs counters that much knowledge of the 2nd order distribution is not needed for his analysis, only some general characteristics. (p. 421 top: all we need are mean values and a covariance matrix of 2nd order probabilities).

Nicely, the model is tested with an experiment on Ellsberg 3-color, both with gains and losses within subjects. Subjects can choose neutral if they like. Hence, there are $3^4 = 81$ choice patterns. 5 of those fit with the author's theory (neutral, and the four combinations of amb. av. or seeking for gains and losses; the author only allows neutral for both gains and losses, apparently).

reflection at individual level for ambiguity: The data in Table 2, p. 428, give numbers of observations for the five most interesting choice patterns. Unfortunately, there is almost no ambiguity seeking for gains in these five patters and, hence, we cannot asses reflection at the individual level. Would have been possible if more data on deviating patterns had been provided, but it isn't.

Roughly, of the ambiguity averse people for gains as many are ambiguity averse for losses as ambiguity seeking.

P. 430 2nd para points out (admits I would say when it is beyond sign dependence) that in this model ambiguity attitudes depend not only on the probabilities but also on the outcomes. The author's writing here and in general is mature. %}

{% Use a 2004 representative sample in Germany. Risk and trust attitudes are measured using purely introspective questions of the type:

"How much do you like to take risks."

Find that risk attitudes of children are associated with those of their parents. %}

Dohmen, Thomas, Armin Falk, David Huffman, & Uwe Sunde (2012) "The Intergenerational Transmission of Risk and Trust Attitudes," *Review of Economic Studies* 79, 645–677.

{% Impressive sample of 22,019 (from 11,803 families) in the 2004 wave of the Socio-economic panel (SOEP), representative of the German population (later the paper restricts this to adult Germans). In addition, 450 people, representative for the 22,019, are visited at their home and interviewed. Asked to the 22,000 people and also the 450 people, on 11-point scale (0-10), to indicate how much they were willing to take risk, (0) in general (1); car driving; (2) financial matters; (3) sports and leisure; (4) career; (5) health. Then they ask other questions about risky behavior from such domains, such as about smoking etc.

From the 450 people they also revealed an indifference of the prospect $300_{0.5}0$ by measuring the switching value for increasing sequence of sure amounts, with random incentive system paying one of every seven subjects (p. 532: Doing a 1/7 chance for every subject, rather than select one from every seven; as often, subjects could not verify this randomization. This is why I prefer selecting in class rooms one of every 7 subjects, visible for all.) (**random incentive system between-subjects**). That's an average payment of about €25 per subject. Subjects were not paid cash on the spot, but by check sent by mail. Their CEs (certainty equivalents) ranged from 0 to 190, so, did not allow for much risk seeking as the authors explain on p. 532). 87% (= 78%+9%) was risk averse (pp. 533-534) and 13% (4% + 9%) was risk seeking. The correlation between introspective general risk attitude and CE of $300_{0.5}0$ is about 0.5 (Table 2), correcting for some variables, and is significant ($p \leq 0.01$).

Relate it to demographic variables, where risk aversion is enhanced by being female (**gender differences in risk attitudes**), being old (**relation age-risk attitude**), having low education and, remarkably, being small.

They obtain natural and intuitively plausible results: The willingness-to-take risk question are all positively related to the real-incentive choice (see above, regarding the 450 subjects). The general question best correlates with the whole of the others. Domain-specific question better correlate with questions specific to their domain, e.g. health-risk willingness better correlating with smoking.

As the authors point out, the general attitude questions, in contrast to the prospect-choice questions, comprise not only risk attitude, but also risk perception and risk exposure. A person with a good job does not take career risks, not because he is risk averse, but because he has little to gain and much to lose.

P. 538, end of 2nd para, when discussing a correlation, precedes it with:

"The answer to these questions is of obvious importance from both a methodological and a practical point of view."

Positive relations found are described as "economically significant."

real incentives/hypothetical choice: p. 543 is positive about asking hypothetical questions:

"In light of these findings, the usual practice of only eliciting risk attitudes in the context of hypothetical financial lotteries would be expected to have benefits for predicting financial decisions, but be a less effective approach for providing a summary statistic of risk attitudes across other nonfinancial contexts."

P. 523 advanced another argument against real incentives: They are very expensive, and also cumbersome, to implement in large samples such as 22,000 subjects. To those subjects a hypothetical risky choice was asked, not reported but briefly discussed on p. 543, which correlates well with things. %}

{% An interesting study, nicely investigating central topics of prospect theory about source preference and source sensitivity.

Both the ambiguity that is objective in the terminology of this paper, and that is subjective, combines objective (lack of) info about choice stimuli with preference conditions. What they call objective is comparing probability intervals with their midpoints (the latter as known, objective), what they call subjective is a kind of source preference (each part of a partition dominates its counterpart).

Fig 1, p. 285, is w^{inv}(W), so, it is matching probability, i.e. the belief index of my ’04 Psych. Rev. paper. P. 286 mentions that the “subjective” approach of this paper cannot elicit source sensitivity (“venture-theory relationship” in the terminology of this paper). In my Psych. Rev. paper it is shown how it can be done.

P. 287: unfortunately, in the ambiguous choice subjects cannot choose the color for which they win, so that they have extra reason to be suspicious (**suspicion under ambiguity**) and the data will have extra ambiguity aversion. P. 288, subjects get vague info about experimenter choosing proportions "arbitrarily."

P. 290, adding complementary values (for 5% and 95%, etc.) leads to a test of source preference and not of source sensitivity.

ambiguity seeking for unlikely: p. 293: ambiguity aversion for moderate and high likelihood, ambiguity neutrality for low likelihood (5% and 10%).

For the comparative ignorance hypothesis, they do not find it, with not more prudence in comparative situation than in noncomparative.

All ambiguous high likelihoods had the explicit possibility that the unknown probability was 1, increasing attractiveness, and going against ambiguity aversion and subadditivity. All ambiguous low likelihoods had the explicit possibility that the unknown probability was zero, decreasing attractiveness, and reinforcing ambiguity aversion but going against subadditivity. %}

{% Plead for experienced against decision utility for health measurements in an unqualified manner;

P. 215 ℓ. –1 writes that economists use *hypothetical* choice to elicit utility!

Gold et al. (1996) argued that QALYs should be measured from the general public and not from patients, and I disagree with their arguments. The approach of this paper goes in the opposite direction, as the authors point out (p. 230 3rd para).

Paper does not very consciously distinguish between intertemporal tradeoffs, risky tradeoffs, and so on. The hedonimeter of Edgworth (p. 215 1st para) and the adaptation (§1 opening para) concern merely intertemporal aggregation. When discussing rationality on p. 215 2nd para the authors suddenly switch to risky tradeoffs, consider the assumption of expected utility to be rational (without committing to it), which merely concerns risky tradeoffs. As an aside, Tversky considered expected utility to be rational and so did the early papers by Kahneman & Tversky, but in several later papers Kahneman argued that deviations are rational. P. 217 3rd para, in the context of general utility, suddenly turns to only intertemporal aggregation through the reference to streams in "the fundamental problem with such utilities, which is that they do not accurately represent the utility streams associated with different health states."

P. 227 last line again connects to EU and risky tradeoffs, probably because they connect to rationality.

QALY overestimated when ill: P. 218 cites studies for and against it through adaptation. P. 223 top gives further references, arguing that most find that ill overestimate.

intertemporal separability criticized: p. 228 ℓ. 2-3.

P. 230: "Although many economists, as well as a consensus panel convened by the US Public Health Service (Gold et al., 1996), recommended the use of utilities from the general public, eliciting decision utilities from those currently experiencing the health state in question will avoid some of the problems associated with eliciting decision utilities from the public." %}

{% Uncertainty aversion in Anscombe-Aumann setting suggests preference for randomization. I called this equation a historical accident in Wakker (2010,

§11.6). The authors test both usual Ellsberg ambiguity aversion and preference for randomization (as per Schmeidler's uncertainty aversion) in an Anscombe-Aumann setting. Most subjects are neutral towards randomization, even slightly more are averse to it, and preference for randomization is unrelated to Ellsberg ambiguity aversion. So, this is bad news for the Anscombe-Aumann approach, supporting the claim in my book. (**criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**) %}

{% **updating: testing Bayes' formula**: Whereas most updating studies consider single events, this paper measures entire distributions. Something that confused me is that I think that base rate neglect (paying too little attention to the prior) and conservatism (paying too little attention to new observation) are complementary, and one is minus the other, this paper seems to treat them as different concepts that can both happen at the same time. Probably they have in mind a model with prior probabilities and some probabilities over signals, but the weight for the prior probabilities still indeterminate, i.e., the joint distribution still undetermined. This indeed turns out to be the case, in their Ellsberg urn stimuli; see below. They also seem to assume 2nd order distributions, on p. 965 suggesting this as universal. The experiment will consider an unknown Ellsberg two-color urn and have subjects specify their subjective probability distribution regarding the composition of the urn. Then one can indeed speak of a 2nd order distribution because the compositions of the urn are identifiable events, and letting prior refer to the composition and observations to drawings, the joint distribution of the composition and the observations is not yet determined but depends on the weight of the prior, as in Carnap's induction models. They use Goldstein & Rothschild's (2014) method. %}

Drèze, Jacques H. (1958) "Individual Decision Making under Partially Controllable Uncertainty." Ph.D. dissertation, Columbia University.

{% This paper is remarkable, being from the author's Ph.D. thesis. It axiomatizes maxmax EU, which can easily be transferred to maxmin EU, famously axiomatized by Gilboa & Schmeidler (1989), using the same basic axioms. The author has a different interpretation. It is not about ambiguity. It is about moral hazard, with the agent having control over the priors. The agent can choose, after the act chosen, which prior will be the true one. He, of course, will take the best one, leading to maxmax. It makes the interpretation of quasiconcavity of preference very plausible. In a mixture of acts the agent must choose one and the same prior for the two acts, whereas for the nonmixed acts he can choose different priors for the different acts and can choose the best prior for each individual act.

I do not assign priority to this paper because it does not provide proofs of its theorems. I asked the author in personal communication if he had proofs available, and if only handwritten. But he could not provide such. Hence, not much credit to this paper. In general, no credit for theorems that are stated without proofs given. I add in 2024: proofs only provided in Online Appendixes are undesirable also. Good-quality proofs are essential for verifiability, essential for mathematics.

The author does provide an improved version in Ch. 2 of his 1987 book, with a proof, and that does deserve the priority. The postscript in Ch. 3 of his 1987 book, which is just the English translation of this 1961 paper, explains the case. %}

{% Ch. 2 is highly remarkable. It axiomatizes maxmax EU, which can easily be transferred to maxmin EU, famously axiomatized by Gilboa & Schmeidler (1989), using the same basic axioms. The author has a different interpretation. It is not about ambiguity. It is about moral hazard, with the agent having control over the priors. The agent can choose, after the act chosen, which prior will be the true one. He, of course, will take the best one, leading to maxmax. It makes the interpretation of quasiconcavity of preference very plausible. In a mixture of acts

the agent must choose one and the same prior for the two acts, whereas for the nonmixed acts he can choose different priors for the different acts and can choose the best prior for each individual act.

Pp. 11-12 strongly suggest that continuity is innocuous. P. 12 affirmatively cites Arrow's (1971) text: "The assumption of Monotone Continuity seems, I believe correctly, to be the harmless simplification almost inevitable in the formalization of any real-life problem." I, and many with me, disagree. See the keyword **criticizing the dangerous role of technical axioms such as continuity**.

state-dependent utility; P. 15 has example where consequences are act-dependent. The letters of Savage and Aumann on it are in Appendix 2.A.

Mononen (2023) showed that the claimed uniqueness in Theorem 8.2 can be violated in degenerate cases where the utility ranges over different states have no (nondegenerate) overlap. Then only the minimal set of priors is unique, but the set of priors can be a strict superset thereof. If the utility ranges for different states have sufficient nondegenerate overlap (sort of connecting all states) then the set of priors is unique and, hence, minimal and the uniquess holds. %}

{% This paper studies risk sensitivity in bargaining. That is, how the solution is affected by changes in risk attitudes. More precisely, it assumes the Anscombe-Aumann framework and considers both risk attitudes, through the vNM utility function where, here, EU is assumed, and ambiguity attitudes, through a nonadditive weighting function. In this, it assumes exactly Schmeidler's (1989) RDU model. The Nash bargaining solution has no clear results and mostly things can go any way. This paper follows up on Köbberling & Peters (2003). For ambiguity, they use the Ghirardato & Marinacci (2002) comparative results giving pointwise dominance of capacities. %}

Driesen, Bram, Michele Lombardi, & Hans J.M. Peters (2016) "Feasible Sets, Comparative Risk Aversion, and Comparative Uncertainty Aversion in Bargaining," *Journal of Mathematical Economics* 67, 162–170.

{% This paper reconsiders the Holt & Laury (2002) measurement of risk attitudes. On **Prospect theory not cited**, the present paper puts everything right, with many nice sentences. The authors make clear that choice lists were used long before Holt & Laury, and cite the important Cohen, Jaffray, & Said (1987).

P. 89: "This observation about MPLs is well known to experts in the field of risk preference elicitation, and yet in our experience, it is not well known to newcomers or those outside the field."

P. 90 footnote 1: "The word "multiple" in multiple price list is redundant since the word "list" already implies repetitive choices. Nevertheless, we adopt the phrasing MPL in this paper as it is more commonly used in the literature than other variants such as "choice list." "

P. 91: "In what follows, we show that H&L's original MPL is, perhaps ironically, not particularly well suited to measuring the traditional notion of risk preferences — the curvature of the utility function. Rather, it is likely to provide a better approximation of the curvature of the probability weighting function. P. 93 2nd para gives a reason: the amount involved are too moderate to capture much utility curvature." %}

Drichoutis, Andreas C. & Jayson L. Lusk (2016) "What Can Multiple Price Lists Really Tell Us about Risk Preferences?," *Journal of Risk and Uncertainty* 53, 89–106.

{% The authors measure risk and time attitudes. For risk they use the Holt-Laury method and a certainty-equivalent measurement. Unfortunately, they only use expected utility to analyze their data. They do cite Drichoutis & Lusk (2016) on the claim that the Holt-Laury rather measures probability weighting, which I agree with, but also on the claim that the certainty equivalent, by varying

outcomes, would measure utility curvature, which I never understood. Whereas Drichoutis & Lusk (2016) put many things in good perspective, for instance in citing much literature that used choice lists prior to Holt & Laury, the present paper follows again the tradition of the field and journal Experimental Economics by ignoring all the literature from behavioral economics and psychology. (**Prospect theory not cited**) Characteristic is also that for every detail they cite papers by Glenn Harrison.

The authors test stability over time of risk and time preferences, and find that well satisfied. %}

{% They transform the probability distribution using probability weighting. Then, however, they do not take expectation, which would lead to RDU and CPT, but they do mean-variance with that new distribution. That one can do other things with transformed cumulative probabilities than taking expectation was pointed out and axiomatized by Sarin & Wakker (1994, Econometrica). The authors

derive all kinds of implications for finance. They assume neo-additive probability weighting, meaning that only the two extreme outcomes are overweighted, and they only consider the symmetric case, giving insensitivity but no source preference. They assume that all traders can only take long positions, i.e., buy positive quantities, of assets. Traders cannot take short positions. They assume that there exists an event where all assets at the same time have their best outcome, and also one where they all at the same time have their worst outcome. In view of neo-additive weighting, this implies that all traders use the same weighting of events, irrespective of their financial position. %}

{% Real incentives: use hypothetical choice;

Measure ambiguity attitudes for gains versus losses (manipulated by putting the benchmark for supposed managerial decision above or below all outcomes considered), when ambiguity is modeled the usual way through events and "vague probabilities" versus when ambiguity is modeled deviating from conventions through ambiguous outcomes (**ambiguous outcomes vs. ambiguous probabilities**), and when ambiguity is modeled through separate evaluation of

prospects through certainty equivalents (pseudo-pairwise choice, PPC, modeled as the choice for the option with the higher certainty equivalent) or when it is modeled through joint evaluation in direct pairwise choice (PC). Ambiguity is generated by giving probability intervals, and they also measure the effect of interval range.

P. 1797 1st para of 2nd column: strangely enough, subjects are risk seeking.

ambiguity seeking for losses: This they find. Subjects are ambiguity averse for gains but ambiguity seeking for losses (p. 1797 2nd column), although the latter is not significantly different from ambiguity neutrality (p. 1798 Table 3).

Pp. 1798-1799: People get more ambiguity averse for gains if ambiguity increases (so, larger probability intervals), and more ambiguity seeking for losses if ambiguity increases, although the effect for losses is smaller than the effect for gains.

Table 5 displays choices from straight choice. Interesting is the middle left matrix, which considers a classical preference reversal for ambiguity. Unfortunately, the data are not clear and may be mostly noise. In the upper row of people preferring ambiguity in pairwise choice (PC) exactly half prefers ambiguity in pseudo-pairwise choice. In the lower row of people preferring unambiguous in PC, some more, 60%, prefers unambiguous in PCC, but this difference apparently is not significant.

reflection at individual level for ambiguity: no data because gains-losses was between subjects.

loss aversion without mixed prospects and/or **loss aversion: erroneously thinking it is reflection**: P. 1800 2nd column 2nd para erroneously suggests that loss aversion can play a role in their data on losses. This paper has no mixed prospects and, hence, loss aversion can play no role at all. %}

{% Imagine a Savage-style decision model, where we focus on countable additivity and ℝ is the outcome set. If there is an atom in the state space, then not all probability distributions over outcomes can be generated—none of them is atomless of course. If the state space is atomless, then all probability distributions over ℝ can be generated. The latter is called open-mindedness in this paper. The paper mainly examines this open-mindedness for multiple priors, giving theorems when a state space endowed with a set of priors is rich enough to generate all sets of priors over outcomes. This is of course useful to know, but the papers argues more that this is important than I can agree with. For instance, p. 664 has the following overstatement on the multiple prior approach to ambiguity: “In order for this approach to be effective, it is *necessary* that the set of priors be open-minded, that is, that the set can induce, via consequence-valued measurable functions, any closed, convex set of distributions on any compact metric space of consequences.” [Italics added.]

The authors, as do so many, equate ambiguity with sets of priors. For example, on p. 664: “Ambiguity is a separate kind of epistemic uncertainty. It can be captured by modeling decision makers as believing that actions lead to sets of possible distributions over outcomes.” %}

{% **DC = stationarity**; no real incentives, but flat payments.

Paper considers two factors in discounting: insensitivity and elevation. Insensitivity for this one-side-bounded scale means relatively low discounting (so, high weighting) of the near future and relatively high discounting (so, low weighting) of the far future. (For the two-side-bounded probability scale it means inverse S.) Manipulations such as giving subjects limited time leads to bigger insensitivity in discounting. It has sometimes been suggested that people in such situations resort to lexicographic manipulation of the most important dimension, but here apparently subjects designate time as the most important dimension but pay less and not more attention to it when having less time. Adding visual scales leads to bigger insensitivity. Such manipulations do not have a similar effect for the outcome scale, suggesting more insensivity for time than for outcomes. Experiment 1 does data fitting only for aggregate data. For this purpose, Experiments 3 and 4 do utility measurement through direct introspective rating, not by deriving from decisions, so, not revealed preference.

The paper proposes the constant sensitivity family, which is exponential discounting but t taken to some power. This family was generalized by Bleichrodt, Rohde, & Wakker (2009) who called it CRDI. Now I think unit invariance is a better name. On March 5, 2014, I discovered that Read (2001 JRU Eq. 16) proposed this basic family before.

Introduction seems to consider constant discounting to be complete insensitivity. I do not understand. The other kind of insensitivity, where only two categories of time are considered, being present versus all future timepoints, so that all future timepoints are weighted the same, be it less than the present, I agree with more.

End of paper mentions well-known problem that the rational (!?) constant discounting implies overly strong discounting of the far future, so that only zero discounting remains as possibility. %}

Ebert, Jane E.J. & Drazen Prelec (2007) "The Fragility of Time: Time-Insensitivity and Valuation of the Near and Far Future," *Management Science* 53, 1423–1438. https://doi.org/10.1287/mnsc.1060.0671

{% **dynamic consistency**; This paper derives a funny paradox for PT in dynamic decisions under naivite, as follows. Overweighting of small probabilities generates risk seeking for long shots. It does so for mixed prospects, as typically faced in financial markets, if the risk seeking induced by small probabilities overweights loss aversion. The latter happens for common parametric families of weighting functions because they have infinite derivatives at the extreme probabilities $p = 0$ and $p = 1$. It does so irrespective of utility curvature if utility is differentiable (outside status quo) because the latter means, for small amounts, that utility is approximately linear. Thus, people will never stay stable but always prefer to take long-shot risks if those are available. This also holds for dynamic decisions under naivity. A nice point is that long-shot lotteries of the kind preferred by PT are always available in complete financial markets, so that PT predicts that naive people always invest in those and never stay put.

The abstract of the paper writes that the above prediction of PT is unrealistic and the authors suggest abandoning probability weighting. I disagree here for two reasons: (i) in reality there do exist people that naive that they always keep on investing and keep on playing in casino as long as they can (until ruin). (ii) the result requires extreme steepness of w at extremes, which is not empirically realistic even if the parametric families common today have it (they have it because it allows for tractable formulas, not because it is empirically realistic).

Proposition 1, p. 1624, shows that a similar result cannot occur for EU even if risk seeking. This holds because EU is locally almost linear. This is similar to Arrow's result that under actuarially unfair coinsurance (loading factor in insurance premium) and EU with concave utility, no complete insurance is taken. The first-order nature of risk seeking of PT is essential for the results of this paper.

The negative effects of the referee system with referees having too much power is felt in the last para of the discussion (p. 1627), where an unsubstantiated negatively formulated criticism of PT comes out of the blue. The authors make clear in the usual way that a silly referee is to blame by "thanking" him/her in footnote 8. %}

{% %}

Ebert, Udo (1995) "Income Inequality and Differences in Household Size," *Mathematical Social Sciences* 30, 37–55.

{% **tradeoff method**: Uses comonotonic tradeoff consistency to get RDU. Does it for the context of welfare. (s_1: x_1,…,s_n:x_n) refers to a society with n persons, where each person sj receives \$$x_j$. It is equivalent to a (1/n:x_1,…, 1/n:x_n) lottery in decision under risk. The paper has variable population size, i.e., all simple equally likely lotteries are present and, hence, all simple rational-probability lotteries. Theorem 2 on p. 429, the principle of progressive transfer (Def: p.428) is pretty and powerful. It means that transferring a small amount from a rich to a poor person (so small that the ranking is not changed) is always an improvement. Under compact continuity, it is necessary and sufficient for U being concave and w being convex. The principle is both weaker than aversion to mean-preserving spreads, and outcome-convexity, so, it shows that each of these is necessary and sufficient for convex w and concave U, having Chew, Karni, & Safra (1987) as corollary. Importantly, as pointed out on p. 430, the author, unlike CKS, does not need differentiability. So, it is a valuable result!

The aforementioned result is less new that the author is aware of. Chew & Mao (1995), for the context of decision under risk but also considering only simple equal-probability lotteries, define elementary risk aversion which is the same as the principle of progressive transfer. They also show that it is equivalent to the stronger aversion to mean-preserving risk, under continuity. Their Table II displays that under RDU this holds if and only if U concave and w convex. But they assume some smoothness differentiability there (although they do not say this very clearly); see my annotations there. %}

Echenique, Federico, Masaki Miyashita, Yuta Nakamura, Luciano Pomatto, & Jamie Vinson (2022) "Twofold Multiprior Preferences and Failures of Contingent Reasoning," *Journal of Economic Theory* 202, 105448.

{% **conservation of influence**: Give necessary and sufficient conditions for SEU maximization with risk aversion for a very special preference set, which is relevant in finance: Assume a finite partition $E_1,\ldots,E_n$ of the universal event. One can invest in $1_{E_j}0$, yielding 1 contingent on event E_j, but the price of this is p_j per unit. An agent should optimally allocate some budget B. SEU means that he allocates $(b_1,\ldots,b_n)$ ($\sum_{j=1}^{n} p_j b_j = B$) to maximize $\sum_{j=1}^{n} q_j U(b_j)$, where U is his subjective utility function and the q_j are his subjective probabilities. The authors provide necessary and sufficient axioms that are restrictions of the revealed preference axioms (SARP). Because of risk aversion and the structure of the choice sets considered, they only need to consider the first-order optimality conditions at the point chosen. Hence, the axioms are of cancellation-axiom types, using duality in solving linear inequalities as in Scott (1964). In this way they can apparently escape from the ring inequalities that made Shapiro (1979) so difficult.

A question remaining is the uniqueness of their representation. Given the finiteness of their data, uniqueness will be more ugly than in the usual continuum models. Put differently, to what extent can their data discriminate expected utility from other models. They give some results with necessary and sufficient conditions for state-dependent expected utility and maxmin expected utility, with examples showing that these at least can be distinguished. Maxmin EU cannot be distinguished from EU for two states though, pointing to the problem of nonidentifiability. They also discuss probabilistic sophistication, for which they have no necessary and sufficient condition.

Kübler, Selden, & Wei (2014) obtained similar results with objective probabilities assumed available. This paper can be considered a generalization in the sense that probabilities are not assumed to be objectively available.

A difficulty is that the decision situations considered here in the axiomatization are not very realistic. Whereas in consumer demand theory, the choice from a budget set is somewhat realistic, a situation where one has to spend all of a budget in investing in linearly-priced state-contingent assets is not easy to imagine. Even if such assets are available in finance markets, it is hard to imagine a sitation where one has to spend exactly all of a given budget on this. Such situations occur in experiments, but are rare outside. %}

Echenique, Federico & Kota Saito (2015) "Savage in the Market," *Econometrica* 83, 1467–1495.

{% Axiomatize discounted utility and quasi-discounted utility, but do not take binary preference as primitive but, instead, a general choice function on demand sets derived from prices. Their axiomatization is like Echenique & Saito (2015), only with timepoint instead of state of nature. Constant discounting readily follows as a special case of expected utility with an extra condition, being stationarity.

They throughout assume concave utility. They also consider more general models, such as additive separability over time, and give the corresponding revealed-preference axioms. They nicely take a data set as a finite number of observations. Unfortunately, they try to give a formal meaning to rationality, following bad habits of the revealed preference literature.

Use their model to test data of Andreoni & Sprenger (2012), finding that quasi-hyperbolic does not fit better than constant discounting. %}

{% They consider prospects (my term) (m,p) where $m \in \mathbb{R}$ is income and p is a nonnegative price vector. Every of finitely many agents has a preference relation $\succcurlyeq_i$ over the prospects. The authors consider a model with a function U on prospects and functions u_i on prices, such that $\succcurlyeq_i$ is represented by $U(m,p) + u_i(p)$: a common utility function augmented by individual values of prices (the authors assume that it is indirect utility). A social welfare evaluation takes place through the social $\succcurlyeq$, aggregating the individual preferences $\succcurlyeq_i$. The authors consider a social welfare functional that is additively separable over the agents and takes a particular form, uniquely determined by the individual preferences, with unique inequality aversion. They provide a Pareto axiom and an anonymity axiom to derive the functional. %}

Eden, Maya & Luis Mota Freitas (2023) "Income Anonymity," working paper.

{% P. 7: Jevons distinguishes two dimensions in utility: Intensity and time. Unit of utility for Edgeworth is **just noticeable difference** (minimally perceptible threshold), somewhere brings in evolution. Edgeworth also brings in number of people.

P. 8 seems to write (I suspect typos below):

"You cannot spend sixpence utilitarianly, without having considered then something on number of people. Edgeworth is clearly aware of the unprovability of the axiom of interpersonal comparability. His axiom is that just noticeable difference is comparable across individuals."

P. 9 compares principle of maximizing utility with maximum-energy principles, says that motion in physics can be described as maximizing energy.

P. 14/15: man as a pleasure machine

Most of book sets up some calculations for economics.

P. 53 "settlements between contractors is the utilitarian arrangement of the articles of contract ... tending to the greatest possible total utility of the contractors. … utilitarian settlement may be selected, in the absence of any other principle of selection" continuing on p. 54:

“utilitarian equity.”

{footnote 2:

“Whereof the uconsciously implicit principle is: time-intensity units of pleasure are to be equated irrespective of persons.”

P. 77/78 suggests utilitarian foundation of larger pay for the more agreeable work of the aristocracy of skill and talent, and similarly for “supposed” superior capacity of the man (opposed to woman) for happiness, with some nice text on role of woman not always in 100% agreement with 20th century feminism.

Appendix II is called:

“On the importance of hedonical calculus.”

P. 97/98:

“greatest average happiness, these are no dreams of German metaphysics, but the leading thoughts of leading Englishmen and corner-stone conceptions, upon which rest whole systems of Adam Smith, of Jeremy Bentham, of John Mill, of Henry Sidgwick. Are they not all quantitative conceptions, best treated by means of the science of quantity?”

P. 98 discusses

P. 99 argues for taking “just perceivable increment” (so, **just noticeable difference**) as unit of utility:

“it is contended, not without hesitation, is appropriate to our subject.”

P. 100/101 argues that different perceptions of time should be incorporated in the intensity dimension; i.e., in instant utility.

P. 101 describes the “hedonimeter,” which is a machine to measure instant utility; described nicely the utility profiles and the integration into global utility:

“To precise the ideas, let there be granted to the science of pleasure what is granted to the science of energy; to imagine an ideally perfect instrument, a psychophysical machine, continually registering the height of pleasure experienced by an individual ... From moment to moment the hedonimeter varies; the delicate index now flickering with the flutter of the passions, now steadied by intellectual activity, low sunk whole hours in the neighbourhood of zero, or momentarily springing up towards infinity. The continually indicated height is registered by photographic or other frictionless apparatus upon a uniformly moving vertical plane. Then the quantity of happiness between two epochs is represented by the area contained between the zero-line, perpendiculars thereto at the points corresponding to the epochs, and the curve traced by the index;”

He “destroyed” the fun of Jevons, Walras, Menger, of using an additively

decomposable utility function by suggesting that it should be general. That is, the value of a commodity depends not only on the quantity of that commodity but also on the quantities of the other commodities. Seems to have introduced the technique of indifference curves.

Seems to write:

"if we suppose that capacity for pleasure is an attribute of skill and talent … we may see a reason deeper than Economics may afford for the larger pay, though often more agreeable work, of the aristocracy of skill and talent. The aristocracy of sex is similarly grounded upon the supposed superior capacity of the man for happiness. … Altogether … there appears a nice conciliance between the deductions from the utilitarian principle and the disabilities and privileges which hedge round modern womanhood."

Seems to have written:

"the first principle of Economics is that every agent is actuated only by self-interest."

Seems to have anticipated the ordinalist insight that often ordinal info is enough, by writing:

"atoms of pleasure are not easy to distinguish and discern … We cannot count the golden sands of life; we cannot number the 'innumerable smile' of seas of love; but we seem to be capable of observing that there is here a greater, there a less, multitude of pleasure-units, mass of happiness; *and that is enough*" [italics added]. %}

Edwards, Ward (1953) “Experiments on Economic Decision-Making in Gambling Situations,” *Econometrica* 21, 349–350. (Abstract)

{% **real incentives/hypothetical choice**: seems to investigate effects of real payments and seems to find differences but not counter-balanced, so may be the result of learning.

risk seeking for symmetric fifty-fifty gambles: probability-preference for 0.5 seems to be found. %}

Edwards, Ward (1953) “Probability-Preferences in Gambling,” *American Journal of Psychology* 66, 349–364.

{% A true classic. A marvelous survey of utility concepts in economics, conveying it to psychologists.

P. 380/381: economic decision theory is essentially an armchair method.

P. 381: end of 2nd para states that economists assume homo economicus (called economic man in this paper) to be rational.

P. 381, on infinite sensitivity: putting this nicely down as (too) technical;

P. 382, 2nd column, ℓℓ. 8-13 has a nice, soft, version of Friedman’s (1953) view: “The most useful thing to do with a theory is not to criticize its assumptions but rather to test its theorems. If the theorems fit the data, then the theory has at least heuristic merit." Edwards' thought is typical of empirically oriented people, who (cannot) learn from theoretical thinking and can only learn from what experiments show. It often bugs me if I use theoretical arguments to justify a new experimental measurement method, and meet experimental readers (referees …) who ignore those arguments.

p. 382: Probabilistic choice is not a modern concept. The text here already mentions it. P. 405: here is the special version of probabilistic choice that is sometimes called random utility: given utility, choice is deterministic, but still choice is random because utility is assumed random.

P. 385 explicitly links ordinal revolution in economics to behaviorist revolution in psychology. On Hicks & Allen (1934): "This paper was for economists something like the behaviorist revolution in psychology."

real incentives/hypothetical choice: p. 387: that economists don't like experiments with imaginary transactions.

P. 388 criticizes defense of intransitivity on the basis of **just noticeable difference** because latter is statistical concept

P. 390 suggests that message of Arrow (1951) is that one shouldn't do welfare theory at the ordinal level. (**Arrow's voting paradox ==> ordinality does not work**) I fully agree with this interpretation of Arrow's result.

P. 391 discusses **RCLA** (but not: second-order probabilities to model ambiguity)

P. 393-394: states Markowitz' (1952) reference dependence. So does p. 395 1st para penultimate para, and p. 400 1st column ℓ. −12.

P. 394: **risky utility u = transform of strength of preference v**: "Of course a utility function derived by von Neumann-Morgenstern means is not necessarily the same as a classical utility function … ."

P. 395 2nd column ℓ. 9-18 points out the basic difficulty of testing decision theories that only !one! real choice can be observed; see also p. 405

P. 395, very properly, and little understood in the field, points out that reference dependence is less plausible for nonmonetary outcomes: "This assumption is plausible for money, but it gets rapidly less plausible when other commodities with a less continuous character are considered instead."

real incentives/hypothetical choice: p. 396: Both real incentives and hypothetical choice is done. "It also turned out that on positive expected value bets, they were more willing to accept long shots when playing for real money than when just imagining or playing for worthless chips."

inverse S: for very small probabilities (**(very) small probabilities**), Edwards' following claim goes against it: p. 396: "subjects strongly preferred low probabilities of losing large amounts of money to high probabilities of losing small amounts of money—they just didn't like to lose."

utility measurement: **correct for probability distortion,** P. 396: suggests that measuring utility when nonlinear probability may be difficult. **tradeoff method** of Wakker & Deneffe (1996) show it's not so difficult! Edwards writes: "It may nevertheless be possible to get an interval scale of the utility of money from gambling experiments by designing an experiment which measures utility and probability preferences simultaneously. Such experiments are likely to be complicated and difficult to run, but they can be designed."

Pp. 396-398: S**EU = SEU** is properly discussed

P. 398 (e.g. Fig. 3): **biseparable utility**

P. 398 shows that prospect th. violates stoch. dom? No no no! Only that additivity implies that the probability transformation is the identity function. On basis of that argues that transformed probabilities should be interpreted as decision weights, not as expressions of probability.

P. 398 1st-2nd column: "One way of avoiding these difficulties is to stop thinking of a scale of subjective probabilities and, instead, to think of a weighting function applied to the scale of objective probabilities which weights these objective probabilities according to their ability to control behavior."

P. 400: argues for sign-dependence; i.e., different probability transformation for gains than for losses.

P. 401: the Samuelson game, people prefer sure outcome over gamble, but under 20 repetitions prefer the gamble. Erroneously considers this evidence against EU.

coherentism: p. 401: mentions that Allais and Coombs want to link probability and utility to psychophysical measurement.

P. 404: that intransitivity can be the result of indifference.

P. 405: that transitivity can never be really tested unless repeated [I add: or hypothetical] choice requiring constancy of choice.

game theory can/cannot be viewed as decision under uncertainty: p. 406:

"A scientist in his laboratory may be considered to be playing a game against Nature. (Note, however, that we cannot expect Nature to try to defeat the scientist.)" The last addition properly notes that there is a difference.

P. 409 criticizes maxmin approaches to uncertainty/ambiguity: "A very frequent criticism of the minimax approach to games against Nature is that Nature is not hostile, as is the opponent in a two-person game. Nature will not, in general, use a minimax strategy. For this reason, other principles of decision making have been suggested." %}

{% **risk seeking for symmetric fifty-fifty gambles**: probability-preference for 0.5 seems to be found. %}

Edwards, Ward (1954) "The Reliability of Probability Preferences," *American Journal of Psychology* 67, 68–95.

{% **risk seeking for symmetric fifty-fifty gambles**: seems to find it. %}

Edwards, Ward (1954) "Variance Preferences in Gambling," *American Journal of Psychology* 67, 441–452.

{% nonlinearity in probabilities; Assumes, without further ado, that utility of receipt of N gambles is N times utility of one gamble (p. 203 3rd para). But this amounts to linear utility, contradicting the nonlinear utility assumed in this paper.

P. 201: "If it is reasonable to assume that subjective values of money should be substituted for objective values in Equation 1, it is equally reasonable to make the same assumption about probabilities."

linear utility for small stakes: argues that for small stakes (between −$50 and $50 in those days) utility is about linear, and probability transformation is more important than utility curvature

Edwards finds !!sign-dependence!! of probability weights

P. 209: Finds that people overestimate probabilities (enhancing risk seeking) for gains, and are about linear for probabilities of losing; says that is in agreement with common sense. Note that this is opposite to the current viewpoints.

Seems that no mixed gambles were considered, and that degree of loss aversion was simply positied. %}

Edwards, Ward (1955) "The Prediction of Decisions among Bets," *Journal of Experimental Psychology* 50, 201–214.

{% **updating: testing Bayes' formula** %}

Edwards, Ward (1961) "Probability Learning in 1000 Trials," *Journal of Experimental Psychology* 62, 385–394.

{% P. 120 etc: summary of his probability transformation exps.

P. 109: points out, very correctly, that for the fixed-outcome-probability-transformation model, utility should have a "true" zero; i.e., that location of utility is not free to choose.

SEU = SEU: P. 115 states explicitly that subjective probability !cannot! be function of objective probability alone. The author bases this on unpublished data where different events with same objective probability had different subjective probabilities depending on display etc. Also mentions that there would be logical difficulties; theorem 3 on p. 119, ascribed to Savage, gives a mathematical and appropriate theorem. This work is actually really good material on the **SEU = SEU** question. Savage's influences have clearly been useful here!

P. 116 uses the metaphor when a function (here subjective probability) depends on one variable (objective probability) but also on others, that there is a book with a page for each level of the other variables.

risk seeking for symmetric fifty-fifty gambles: P. 121: In gains, people prefer 50/50 gambles to others with same EV. In losses, subjects prefer small-prob-high-losses to others with same EV: this is all opposite to current empirical findings!

P. 126/127: "An old familiar finding in psychophysics is that the form of any subjective scale depends on the methods used to determine it. The same may be true for SP [subjective probability] and utility scaling." Voila framing, and a bit of the constructive view of

preference, avant la lettre.

P. 128 describes the kind of formulas needed for transformed probabilities. It distinguishes between entirely positive gambles, entirely negative ones, mixed ones. That is, quite already, exactly the distinction of prospect theory ’79!

{% **value of information** %}

Eeckhoudt, Louis, Philippe Godfroid, & Christian Gollier (2001) "Multiple Risks and the Value of Information," *Economics Letters* 73, 359–365.

{% Proposition 1: Assume stochastic background risk ε with only negative outcomes. Adding ε stochastically independent of all else always increases risk aversion iff decreasing absolute risk aversion. My alternative proof: Condition on every outcome of ε. Does not affect else because of stochastic independence, so, all conditional CEs (certainty equivalents) lower, so, unconditional CE lower too. Then result is extended to nonstochastic independence with Ross' (1981) extension, and to second stochastic dominance with prudence coming in. %}

Eeckhoudt, Louis, Christian Gollier, & Harris Schlesinger (1996) "Changes in Background Risk and Risk Taking Behavior," *Econometrica* 64, 683–689.

{% Do prudence, temperance, and so on, in a dual way, for Yaari's (1987) dual to EU. If the classical EU results can be proved on a comonotonic subdomain of acts, then the duality between EU on a comonotonic cone and Yaari's theory of Wakker & Yang (2021, IME) could be used.

The intro and first result of this paper show the following. Although preceding preference conditions in the literature for prudence in Eeckhoudt & Schlesinger

(2006) were presented in a model-free manner, they were still quite targeted towards EU. In particular, if imposed on Yaari's theory, they imply EU, i.e., subjective expected value. The authors write (p. x+2): "This result illustrates that while (primal) prudence and higher order risk attitudes are often presented as being model free, and rightfully so, they may have, at the same time, no specific meaning outside EU."

P. 3 last para: "A positive sign of the third derivative of the probability weighting function is consistent with an "inverse S-shape" ,"

Very unfortunately, the authors do not use the nowadays (1990-2023) common top-down integration, transforming decumulative probabilities ("starting with the best"), but the other way around, bottom-up, transforming cumulative probabilities ("starting with the worst"). Means that concavity of probability weighting in this paper is what is commonly convexity today. Also means that common parametric families such as Prelec's mean a different thing here than what they mean commonly. I encourage everyone to follow the current convention because otherwise citing their work is problematic. %}

Eeckhoudt, Louis R., Roger J.A. Laeven, & Harris Schlesinger (2020) "Risk Apportionment: The Dual Story," *Journal of Economic Theory* 185, 104971. https://doi.org/10.1016/j.jet.2019.104971

{% The title may at first seem to be not nice because praising itself, but it is a clever pun, as someone explained to me. Prudence is about putting two risks together or separate, so, putting them in the right place.

First para says that economists will not likely define risk aversion as a behavioral property. Second says that with prudence it is different and cites Gollier (2001) on a behavioral definition. The paper assumes EU. Although they don't say, [x,y] denotes a lottery (they do say it's equal-probability).

P. 282 (citing others for it): Prudence if $(I-k)_{0.5}(I+\varepsilon) \geq I_{0.5}(I-k+\varepsilon)$, where I denotes initial wealth, k>0 is a sure amount, and ε a random variable with 0 expectation. It is reminiscent of multiattribute risk aversion and is equivalent to $U''' \geq 0$. P. 287 points out that prudence is weaker than decreasing absolute risk aversion. This paper adds similar conditions with more complex ingredients than k and ε to characterize signs of higher-order derivatives of utility. Something like

$(0+B_{n-2})_{0.5}(\varepsilon+A_{n-2}) \leq (0+A_{n-2})_{0.5}(\varepsilon+B_{n-2})$ with all ε independent is equivalent

to alternating signs of derivatives. It is inductively, where An and Bn are defined by adding previously defined random variables. Pretty! %}

{% This paper re-analyzes five of the ten games analyzed in the pretty (but not very innovative) Goeree-Holt (2001 American Economic Review) paper, being the five static ones. It reanalyzes those using the neo-additive ambiguity models. The new approach using those neo-additive ambiguity models can be formulated, and understood, without much knowledge of RDU or neo-additive: Everything as usual, with randomized strategies, the only difference being that in the EU calculations one adds overweighted the minimal and maximal "possible' (specified later) outcomes (also if probability 0 of happening). It is psychologically plausible and gives interesting new equilibria, as the paper shows. So, nice!

Formal details on RDU with neo-additive are: There are two ways to do neo-additive for uncertainty, with different interpretations of "possible." Both use a subjective probability measure. The first is probabilistically sophisticated where a neo-additive probability weighting function is applied. Then all events with probability 0 are ignored. (For infinitely many outcomes one'd have to take infimum and supremum over some minimal support, to be defined properly). The second is the one used in this paper, where the sup and inf outcomes of the whole image of the act are overweighted. Then events of probability 0 that are still logically possible (so, nonempty) do count as regards sup and inf outcome. For general nonadditive weighting functions the definition of support is problematic (decision weight 0 with one rank (or in one comonotonic set) need not be decision weight 0 in another). One can take support maximal (as soon as positive decision weight somewhere, like Savage) or minimal (ony if positive decision weight everywhere), or in a particular rank-dependent way. The problems are a bit less for neo-additive. The authors take support of the subjective probability measure. Equilibrium under ambiguity requires that all strategies in the support are optimal. Now optimal means SEU with extra weight for the sup and inf outcomes, which given finiteness of actions means max and min outcome. (**game theory as ambiguity**) %}

Eichberger, Jürgen, David Kelsey, & Burkhard C. Schipper (2008) "Granny versus Game Theorist: Ambiguity in Experimental Games," *Theory and Decision* 64, 333–362.

{% Allow subjects to express indifference. Use a beautiful incentivization of indifference: They then do not randomize choice (which would bring in risk and thus be a horrible confound in a study of ambiguity), but just give one option to half of the subjects, and another to the other half, and find no significant differences between the two treatments.

Just like Dominiak & Schnedler (2011), they do not find Schmeidler's (1989) ambiguity aversion. Wakker (2010, §11.6) called Schmeidler's equation of ambiguity aversion with preference for probabilistic mixing a historical accident.

ambiguous outcomes vs. ambiguous probabilities: Although the authors interpret uncertainty about outcomes as a different concept of uncertainty than what is captured in state spaces, I interpret this uncertainty as a more complex state space, with uncertainty both about the color of the ball drawn and the type of envelope.

In O (open envelope; subjects see if it contains €1 or €3) and R (random envelope, containing €1 or €3 fifty fifty) the authors find ambiguity aversion as usual, but in S (sealed envelope; €1 or €3 but subjects just don't know) they find less.

In treatment S, there is ambiguity everywhere because of the envelopes. In this treatment, also for urn H there is ambiguity. Given that the envelopes are ambiguous already, urn U does not add much ambiguity to it, and is close to urn H. So, then plausible that subjects are indifferent. In the other treatments, urn H has no ambiguity but urn U does, so, subjects prefer H. %}

Eichberger, Jürgen, Jörg Oechssler, & Wendelin Schnedler (2015) "How Do Subjects View Multiple Sources of Ambiguity?," *Theory and Decision* 78, 339–356. https://doi.org/10.1007/s11238-014-9428-1

{% Jaffray (1989 Operations Research Letters) introduced a beautiful framework for ambiguity, using belief functions. See my annotations there. Good thing that his framework be used more often. Gul & Pesendorfer (2014, 2015) basically used it.

This paper also does so. In particular, it uses different evaluations at various stages than Jaffray did. In the first stage, uncertainty is resolved with known probabilities, i.e., it is risk. Then in the second stage a case results of complete ignorance: one knows the set of possible outcomes, and nothing more.

Jaffray applied his model of complete ignorance in the spirit of Cohen & Jaffray (1980), where such a situation is evaluated by an α maxmin approach: A convex mix of the inf and supp utility, where the mixing weight reflects ambiguity aversion. This paper instead adopts the principle of insufficient reason for complete ignorance, taking average utility over the set of outcomes with utility function denoted $\varphi \circ u$. For the first-stage probabilities Jaffray does "just" expected utility maximization. This paper generalizes in a recursive expected utility (smooth utility) sense, by adding in an extra transformation, denoted φ^{-1}. Jaffray captures ambiguity attitude through α in the 2nd stage, and this paper through how the utility function in the 2nd stage differs from the 1st stage. Whereas in the smooth model ambiguity aversion corresponds with a more concave utility function in the 1st stage, this paper has that in the 2nd stage (Proposition 13).

I think that this paper is an improved version of the smooth model because the events conditioned on in the first stage here have objective probabilities, and such are better suited for conditioning on. This paper is a kind of reversed Anscombe-Aumann framework, as initiated by Jaffray. (**criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**)

P. 11 §2.1 mentions that Jaffray used a monotonicity axiom to axiomatize his α maxmin evaluation in the second stage, but does not discuss it further. Let me explain here how their average utility model violates it. Assume three events E_1, E_2, E_3, giving outcomes (in utility units) 1,8,9, respectively, giving average utility 6. Imagine we improve the outcome under event E_2 from 8 to 9. Now the outcome set is {1,9} giving average 5: monotonicity is violated. %}

{% **violation of risk/objective probability = one source**: Consider how risk aversion is related for subjects across six different contexts, five insurance decisions and one investment decision. Use nice real data (health-related employer-provided insurance coverage decisions) with some N = 13,000 subjects. Find relations, but not very strong.

One analysis, theory-free, considers the ranking of subjects from most to least risk averse in each of the six contexts. That is, to what extent is the most risk averse subject in one context also so in another context? The authors argue that

this way they do not need the many assumptions to be made in theoretical (structural) analyses, such as what are the probabilities and losses for each subject in each context. But I think that this is also relevant for the theory-free analysis where it is now ignored. For example, the apparently most risk averse subject for health insurance may in reality not be risk averse at all there, but simply have bad probabilities there because of bad health.

The other analysis fits EU with CARA (and also CRRA) utility to fit the risky choices, bringing in things such as initial wealth, but I guess not other individual-specific info. For each individual and each context, an interval is calculated for the CRRA risk aversion parameters that accommodate the choices observed. Then it is inspected to what extent these intervals have overlap, so do not contradict each other.

The data set and questions considered are fascinating, but because of lacking info it is hard to interpret the results. %}

{% P. 26 bottom:

"this review has tried to place behavioral decision theory within a broad psychological context"

%}

Einhorn, Hillel J. & Robin M. Hogarth (1981) "Behavioral Decision Theory: Process of Judgement and Choice," *Annual Review of Psychology* 32, 53–88.

{% An impressive paper on ambiguity. Probably the first to seriously put forward the concept of likelihood insensitivity/ **inverse S**, although empirical studies such as Preston & Baratta (1948) had found the phenomenon before (in their case for risk). Those empirical studies did not discuss the concepts though.

They use an anchoring-and-adjustment model for ambiguity. Their theory is explained on pp. 436-439, but I find the details not so interesting. I next give an account that more easily gives the esssence, I think:

There is a first-best-guess probability p_A of the ambiguous event A. It will be modified into a weight, which they denote $S(p_A)$, because of ambiguity, with parameters as follows.

(1) Parameter theta captures the degree of ambiguity.

theta = 0: no ambiguity; theta = 1: maximal ambiguity.

(2) Parameter beta captures under/over weighting.

0 < beta < 1: underweighting; beta > 1: overweighting.

Decision-oriented economists and people exposed to rank-dependent models will now ask: Does the over/under weighting apply to weights of best or worst outcomes? This makes all the difference for the behavioral implications, about whether we get aversion or the exact opposite, seeking. The answer is: neither! The authors did not know about rank dependence. They had in mind the old Edwards-type transformation of separate-outcome probabilities (separable prospect theory), rather than cumulative probabilities. Their decision experiment, Experiment 3, only involves prospects with only one nonzero outcome. There, the old formulas agree with modern 1992 prospect theory, both for gains and losses, so that things are fine there. Their finding of inverse S, likelihood insensitivity, therefore agrees with modern findings. For general prospects, with two or more nonzero outcomes, the behavioral effect of over- underweighting can best be qualified as random. Those old formulas just were no good.

The total overweighting is increasing in theta and beta, as if it was their product, although the actual function is different than a product. If one wants to know exactly how the maths in their model works, one can study their Section “A descriptive model,” pp. 436-439, but I think that this is not worth one’s time. Must say that I found their formulas not very interesting. For completeness, here they are: The authors take $S(p_A) = (1-\theta)p_A + \theta(1-p_A^{\beta})$ (Eq. 6b, p. 437). The parameter θ reflects degree of inverse S (for $\beta = 1$ a large $\theta \leq 0.5$ moves the weight towards 0.5; the authors assume $\theta \leq 1$ but $\theta > 0.5$ does not make much sense, leading to weights decreasing in p_A for $\beta = 1$), and β reflects source preference.

They allow both parameters to depend on both the decision situation and the agent (p. 438 2nd column 2nd para), so, they do not commit to agent-independence of theta and situation-independence of beta, contrary to many ambiguity models popular in 2020, the year when I write this summary of their theory. (I have known this paper since 1989, when I worked in a psychology department in Nijmegen and a colleague recommended the paper to me.) But they do write, p. 437 clumn 1 ℓ. 12-13: "Attitude toward ambiguity is denoted by β,"

The anchoring-and-adjustment procedure makes sense for the stimuli that the authors use, where always an anchoring probability is salient; and it can be put on the x-axis for graphs. It does not hold for ambiguity in general, because in many situations of ambiguity there is no particular anchor probability. For virtually all ambiguity models popular in 2020, probabilities are specified in some sense still.

Inverse S is indeed perceptual/cognitive and not motivational, as confirmed by Hogarth (personal communication, March 9, 2007, 11:55 AM, in Barcelona): **cognitive ability related to likelihood insensitivity (= inverse S)**

P. 434 lines 6-10: the authors' model is descriptive, and not normative.

inverse S is found; **ambiguity seeking for unlikely**: p. 435 cites Ellsberg on it and p. 439 Gärdenfors & Sahlin (1982); their model also has it (e.g., Fig. 2). Tversky criticized this work because the authors do not properly reckon with statistical regression to the mean (e.g., p. 454 2nd column lines 7-9), and their inverse S may be just that.

uncertainty amplifies risk: p. 439: "Thus, although the domain of our theory is different from that of prospect theory [which then only concerned risk with known probabilities], we believe that it is not coincidental that the treatment of uncertainty is so similar." They do not really claim amplification, but, at least, similar spirit.

Their data "confirm" their model, though they don't discuss the issue of **ambiguity seeking for unlikely** explicitly in the results and discussion. That is, the paper does not make clear if there is ambiguity seeking for unlikely. P. 453: Judged probabilities show inverse S-shape, and choices suggest transformation downwards of judged probability.

When they use the term "source" they mean something like an expert, being a source of information about the uncertain states of nature. So, source does not have the same meaning as in the works initiated by Tversky in the early 1990s.

Most of their tests are on non-choice-based data. Experiment 3 tests predictions of their model for prospect choices, but uses a very weak test (whether their model is better than completely random choice).

biseparable utility: they do not clearly specify a decision theory with, for instance, weights related to best and not to worst outcomes or vice versa. They seem to have separate event weighting (like separable prospect theory but with events instead of probabilities) in mind.

event/outcome driven ambiguity model: event driven %}

Einhorn, Hillel J. & Robin M. Hogarth (1985) "Ambiguity and Uncertainty in Probabilistic Inference," *Psychological Review* 92, 433–461. https://doi.org/10.1037/0033-295X.92.4.433

{% **inverse S** is found; **ambiguity seeking for unlikely**: p. 230 states it; their model assumes it (see p. 232/233); for gains, their data don't find it clearly, a majority still prefers the unambiguous urn for p = .001, be it nonsigificantly (60, against 48 preferring the ambiguous urn, p = .144, see Table 1 on p. S237). Still, in the text the authors write as if ambiguity seeking for unlikely has been confirmed. This writing is misleading! For losses they find clear ambiguity aversion for unlikely, weaker but still significant at p = .5 (Table 1), and maybe some preference for p > .5 though only in the buyers paradigm (Tables 2 and 3, p. 242/243); so: mixed evidence on: **ambiguity seeking for losses**. They also repeat in many places that weighting functions should be sign-dependent and properly credit Edwards (1962) for that (e.g. p. S245). Dobbs (1991), footnote 1, points out that what the authors consider an ambiguous probability may be biased upwards. Heath & Tversky (1991) do that too.

reflection at individual level for ambiguity: Experiment 4 has losses, but also asymmetric info, and does not report on it. Dobbs (1991) says they did gain-loss between-subjects. %}

{% **natural sources of ambiguity**: This paper, a followup on Kemel & Mun (224), but published very fast, measures the indexes of Baillon et al. (2018 Econometrica) by measuring matching probabilities of natural events. It also derives beliefs (a-neutral probabilities) as can be done. It uses source theory. A novelty is that it does so both for gains and losses, so that it can investigate sign dependence. It is desirable that beliefs are not sign dependent. The paper indeed does not find sign dependence of a-neutral probabilities. Because they get the a-neutral probabilities, they can see how these are mapped to matching probabilities (gambling-equivalent objective probabilities), and this mapping can be called the ambiguity function, fully capturing ambiguity attitudes (Dimmock, Kouwenberg, & Wakker 2016 Theorem 3.1). The authors find that ambiguity attitudes are not reflected between gains and losses, but that ambiguity aversion for gains corresponds with ambiguity aversion for losses. (**reflection at individual level for ambiguity**) Thus, the source function for losses is found to be the dual of

those for gains. They use the Goldstein-Einhorn family to fit data, which is my favorite parametric family.

The authors consider two different natural sources of uncertainty, but find similar attitudes and source functions between the two, although they are different than for the risky source (otherwise there would be ambiguity neutrality). %}

{% Was presented at RUD 2011 under title; "A Variation on Ellsberg"

Consider Ellsberg 3-color urn, with 20 black chips and 40 red or yellow chips in unknown proportion. I regret that the authors did not follow Ellsberg in letting red be the known-probability color, but instead took black.

They consider correlated ambiguities, where a prize won for instance depends on the composition of then urn. A difficulty is that the results are not easy to interpret, because ambiguity neutral players will not be indifferent between the different stimuli.

Let there be r red balls. They consider ambiguous probability as usual (receive $20 if red), but also ambiguous outcome (receive $r if black), ambiguous time (receive $20 in r days), and positively correlated ambiguity in probability and outcome (receive $r if red). Ambiguous outcome is most ambiguous because the outcome can be anything between $40 and $0, and these outcomes in fact do have unknown probability (we do not know the probability of receriving $40, $39, and so on, because we do not know the probability of r having these values), and it indeed is the ambiguity most dispreferred. Note that here the meta-ambiguity, the uncertainty about r, plays a role. One could say that not only the color drawn, but also the composition of the urn, now is outcome-relevant, so that beliefs and uncertainty and most elementary state space become different.

Ambiguity in time is dispreferred the least. This is not just embiguity about the timepoint of receipt because for ambiguity about timing the timing is always related to the composition of the urn, so that always correlation comes in. Positively correlated ambiguity is specially liked by the subjects but this is no surprise and does not speak to ambiguity attitude: improving outcomes under likely events and worsening them under unlikely events is a good deal by any standard, even for ambiguity-neutral expected utility maximizers. %}

{% A voting theorem where under increasing population size the probability of the right candidate winning goes to 1, assuming SEU, is reanalized using maxmin EU, and then no longer holds.

The conclusion starts with the sentence "Theorem 1 shows that rational but ambiguity averse voters may …" Being a Bayesian, I will never co-author a paper with such a sentence! %}

Ellis, Andrew (2016) "Condorcet Meets Ellsberg," *Theoretical Economics* 11, 865–895.

{% **dynamic consistency**: Gives recent references on the Machina (1989) type dynamic decision principles to imply EU. It presents such a result assuming consequentialism (Assumption 1; like time invariance of Halevy 2015), dynamic consistency (Assumption 2; called time consistency by Halevy 2015), and a richness of domain assumption (Assumption 3; full support) with sufficient overlaps. I assume that the analog of RCLA or collapse independence (independence of reversal of order of events) is implicit. The uncertainty considered concerns the types of players in a game, and acts map type-vectors to outcome vectors. Nature is also there. The richness assumed is enough to get Gorman's (1968) theorem involved. The paper only considers payment vectors for type vectors, and no game-theoretic interactions are examined. P. 242 writes it: "I abstract away from the formal details of the game and equilibrium."

P. 241: "Theorem 1 shows that at least one of these properties [the EU dynamic decision principles] fails in (discretized versions of) nearly all of the literature on auctions and multi-agent mechanism design with ambiguity aversion"

P. 242: "the modeler faces the familiar trade-off between Consequentialism and DC"

P. 242: "while DC has very strong normative appeal, violations thereof are well documented."

Is somewhat: **dynamic consistency**: **favors abandoning forgone-event independence, so, favors resolute choice**.

P. 245: "For instance, if a player engages in forward-induction reasoning (e.g. Kohlberg and

Mertens, 1986), then she violates Consequentialism."

P. 245: "DC requires that no player has an incentive to deviate from her ex ante optimal strategy upon learning her type. This is the property that permits reduction of the strategic form to the normal form." %}

{% **ambiguity attitude taken to be rational**

In the two-color urn the colors are Red and Black, in the three-color urn the known color is Red, and Black and Yellow are the unknown colors. I hope that everyone in the field will consistently use these colors! Is a convenient convention. The common payment for ambiguity is on Yellow and not on black (**suspicion under ambiguity**: just like that it will give the confound of suspicion).

About the works of Savage/Ramsey:

"the implication that—for a "rational" man—all uncertainties can be reduced to risks" (p. 645). This may have contributed to the unfortunate terminology where SEU for unknown probabilities is called risk. (**SEU = risk**)

P. 75 of Keynes (1921) presents the Ellsberg 2-color urns, says there is more probability error (meaning probability being more unknown) in the unknown than the known, but does not relate it to decision making. And not at all points out that those violate Savage's (1954) axioms, those not available at that time. I feel, therefore, that the priority goes to Ellsberg.

P. 645 points out that a problem arises in the distinction between beliefs (called relative expectations by Ellsberg, context shows it's beliefs) and utilities (called relative preferences for outcomes by Ellsberg) in revelations from choices: the **tradeoff method** of Wakker & Deneffe (1996) can do it!

P. 646 middle writes that Ellsberg is less interested in normative than in reflective (sort of prescriptive; decisions after reflection)

P. 646 seems to write, on Savage's axioms, that they gave "a useful operational meaning to the proposition that people do not always assign, or act 'as though' they assigned, probabilities to uncertain events." So, he uses axioms to criticize a model here.

P. 649, footnote 5, points out that the sure-thing principle, in the presence of known probabilities, reduces to the independence condition.

Pp. 651-652: Ellsberg's analysis of the two-urn example is not natural. He does not take the product space as state space, as most do and as is most natural, but he takes an urn that contains the union of the separate urns. Pfff! Here is a different way of showing that the two-urn example violates the sure-thing principle, which I hope is clearer.

P. 656 claims that Savage did the common Ellsberg preferences and, seeing that he violated his axioms, did not want to change his preferences, feeling reluctant about it. I do not believe this. It flies into the face of Savage's writings. Ellsberg writes himself to have been reluctant to ask Savage again and this adds to my disbelief. In a letter to Savage, Ellsberg later seems to write, again confirming my disbelief: "I see from a copy of your letter to Fellner that I haven't convinced you yet." (D. Ellsberg to L.J. Savage, May 21, 1962, LJS Papers, 11, 260.)

P. 657b says that in addition to utility and probability there is a third dimension (ambiguity).

P. 659: An individual … can always assign relative likelihoods to the states of nature. But how does he *act* in the presence of uncertainty? The answer to that may depend on another judgment, about the reliability, credibility, or adequacy of his information.

P. 663: "in situations where I really can't judge confidently among a whole range of possible distributions, this rule steers me toward actions whose expected values are relatively *insensitive* to the particular distribution in that range, without giving up too much in terms of the "best guess" distribution." Ellsberg writes entirely in the spirit of multiple priors, which I disagree with.

P. 664 ℓ. −2: **EU+a*sup+b*inf**

P. 667 uses, for common Ellsberg behavior, the term “pessimism” to refer to belief and “conservatism” to refer to decision attitude.

P. 667 bottom suggests a rank-dependent idea: “He “distorts” his best estimates of likelihood, in the direction of increased emphasis on the less favorable outcomes.” He then elaborates on an example with this. %}

Ellsberg, Daniel (1961) “Risk, Ambiguity and the Savage Axioms,” *Quarterly Journal of Economics* 75, 643–669.

{% Is a reply to Roberts’ comment. Essentially both agree that many emotional factors besides ambiguity attitude (he used the term vagueness which is actually better than ambiguity) play a role, and only disagree somewhat on the extent.

P. 342: “This is not to say that vagueness, as defined, is typically the sole factor underlying deliberate choices in conflict with the Savage postulates, even in the situations that I described, or that such choices reflect mainly a simple aversion to vagueness (though my article may have given those impressions). My own thinking has moved recently toward recognizing the influence of various dimensions of the decision problem under uncertainty that are strongly associated with vagueness but distinct from it;” %}

Ellsberg, Daniel (1963) “Risk, Ambiguity and the Savage Axioms: Reply,” *Quarterly Journal of Economics* 77, 336–342.

{% With an introduction by Isaac Levi and an updated bibliography by Mark Machina.

ambiguity seeking for unlikely: in 1962 version, pp. 268–270 and onwards, clearly and explicitly describes ambiguity seeking.

ambiguity seeking for unlikely: in 2001 version, p. 203 ℓ. 12-14: “… whereas a preference influenced significantly by extreme favorable possibilities is easily stigmatized as “wishful.” … Nevertheless, the deliberated preferences in this example of some individuals—including myself—seem to reflect in a systematic way both favorable and unfavorable positions in an ambiguous situation.” It is about a known urn K with 100 balls of 10 colors, each 10fold present, and an unknown urn A with 100 balls of 10 colors in unknown proportion, where Ellsberg prefers to gamble on not-Green from known to that from unknown, but prefers to gamble on Green-from-unknown to Green-from-known, so that he exhibits ambiguity preference regarding 1/10 probability. Ellsberg repeats his sympathy in footnote 1 on p. 206. He discusses at length on pp. 205-206 that not only the worst conceivable probability distribution receive extra weight, but also the best one. P. 206 2nd para: "…; in their own decision-making they wish to take *some* account also of favorable possibilities in ambiguous situations. These individuals will *not* exhibit a uniform tendency to "avoid ambiguity." "

P. 654 seems to write the same as p. 656 in Ellsberg (1961) on Savage in Ellsberg paradox. See my comments there. %}

Ellsberg, Daniel (2001) "*Risk, Ambiguity and Decision.*" Garland Publishers, New York. Original Ph.D. dissertation: Ellsberg, Daniel (1962) "Risk, Ambiguity and Decision." Harvard University, Cambridge, MA.

{% Ellsberg very explicitly considers the usual Ellsberg paradox behavior to be rational, and the sure-thing principle not to be rational.

P. 222 says that 2-color paradox came first to him, before 3-color. P. 223 writes that he discovered Keynes (1921) only in 1962, before his Ph.D.. But obviously after his 1961 paper. (P. 224: he did not know Allais paradox in 1961, but did in 1962 before thesis.)

natural sources of ambiguity: P. 223 writes, to my joy, what I interpret as a plea for investigating natural events and not to overstudy the Ellsberg urns as the field now (2013) does, with square brackets from the original:

"these urn experiments … it is long overdue to perform experiments that test for other forms of ambiguity. That shouldn't be hard; and they may well turn out to have interestingly differential effects."

P. 223 writes that Savage and Raiffa (two Bayesians) are the most clever people he ever met.

P. 225 does what many do today: Ambiguity is automatically equated with the multiple prior model where there are more than one possible probability measures: "ambiguity (where, one might say, more than one probability distribution over events seems reasonable)." I find this unsatisfactory, because there can be situations where there is nothing like a probability distribution in the mind of the agent, and the whole concept of "true" but unknown objective probability is questionable.

ambiguity seeking: P. 225 mentions that ambiguity seeking is to him as rational and normative as ambiguity aversion, also in his own urn examples, and that he has thought so from the beginning. He discusses it much for unlikely events (**ambiguity seeking for unlikely**), but not for losses.

ambiguity seeking: p. 226 gives a long plea against universal ambiguity aversion (italics added):

"I should have emphasized the last clause in the QJE article, but my failure to do so doesn't fully explain to me why nearly all later research has focused only on "ambiguity aversion," nor why most expositions have wrongly attributed the same *preoccupation* to me. It is as if the comments noted above—noting the occurrence of patterns of choice that clearly contradict "ambiguity aversion" even in these particular, frequently-replicated examples—had never appeared in the article. My long-term complaint is not about the mischaracterization of my own exposition but about the *general failure to explore this phenomenon* in subsequent experiments and analysis.

That is especially frustrating to me, because I happen to believe that this latter pattern will be much more frequent than the reverse in certain circumstances of payoffs and events other than the ones that were addressed explicitly in the QJE article and *almost exclusively investigated later*. Because these other circumstances (discussed in RAD, especially pp. 199–209) often characterize high-stakes political or economic decisions, I see it as being at least as significant empirically as "ambiguity aversion," if not more so; hence, certainly deserving of much more experimental and theoretical investigation than it has received." [Italics added here]

For reasons unclear to me, Ellsberg does not like the term ambiguity seeking for what I call ambiguity seeking for unlikely, but prefers something like hope, which may be something like optimism (he does not use this term). I will probably be imposing my views on his thinking if I conjecture that he is searching there for Tversky's concept of insensitivity, but does not grasp it. Here is his text that I am now referring to:

P. 225 (italics added): "What to call this pattern? "Ambiguity seeking" would be misleading; it doesn't relate to the subjective considerations of the decision makers, who reasonably don't see themselves as "preferring ambiguity" but simply as giving special weight in situations of ambiguity to more hopeful possibilities. Some would criticize this as "wishful," which may be why it has received less or no attention in discussions of normative criteria (*though that doesn't excuse the neglect of it as an empirical phenomenon*)." [Italics added here]

He goes on to argue for something like α-maxmin, which he calls restricted Bayes-Hurwicz criterion.

P. 227 very clearly argues for ambiguity seeking for unlikely, which he already expects with one of 10 colors, and expects more strongly with 1 of 100 or more colors.

uncertainty amplifies risk: I did not see this idea in his paper. %}

{% This paper opens with discussions of regression models with errors in the independent variables. It then uses this to analyze choice lists. Mostly, when choice lists are used, subjects are forced to be consistent in having only one switch, and in the right direction. This is easier for subjects and gives cleaner data. However, there are also pros to allowing for multiple switches: Those give info about the degree to which subjects are understanding. One can then, for instance, remove subjects with too many choice switches. This paper also allows for multiple switches and uses those to get better estimates of the errors in the regressions. %}

{% **updating under ambiguity with sampling**; In a first experiment, risk and ambiguity aversion are measured. For the risk attitude, consider lotteries L_j = $\big(0.5{:}(13-j\times 3), 0.5{:}(13+j\times 4.5)\big)$, $j = 0,\ldots,4$. Choice situation j gives a choice between L_{j-1} and L_j, $j = 1,\ldots,4$. Note that, under EU, a subject with utility function $U(\alpha) = (\alpha-13)^r$ has the same preference in all four situations, exhibiting constant relative risk aversion w.r.t. outcomes $\alpha-13$. For the ambiguity attitude, subjects chose five times, each time between L_j and an ambiguous version of it, where the probability 0.5 is replaced by an unknown two-color Ellsberg urn. Subjects could choose the winning color (p. 77 1st para; **suspicion under ambiguity**). The authors seem to suggest that subjects only once switch from risky to safe, and from ambiguous to risky, or vice versa, as j increases, but I do not understand why, and neither which direction of switch the authors have in mind. But this point is not important for the rest of the paper.

P. 78, §2.6: The authors took the number safe vs. risky choices as index of risk aversion, and number of risky vs ambiguous choices as index of ambiguity aversion. These are atheoretical indexes, with all the pros and cons of those. (For example, no need to commit to a theory, but no direct comparability with other experiments or existing indexes.) It is not clear to me why the authors restrict to

expected utility for risk, or the smooth model for ambiguity, in the first part of their paper, because their indexes are atheoretical. For the smooth model they assume that the second-order distribution is uniform over all probability compositions.

In a second experiment done a month later, the same subjects could play a game with ambiguous choices where they could pay to receive extra info, I think a drawing from the unknown distribution. Ambiguity averse subjects are willing to pay more. I would of course be interested in a relation between a(mbiguity)-generated insensivitity and willingness to pay for extra info, but the experiment, with only 05-05 uncertainties, does not give the data to investigate this. It would accrdingly have interested me much if ambiguity attitudes had also been measured with a(mbiguity)-neutral probabilities 0.1 and 0.9. %}

{% This paper, together with Bénabou & Tirole (2016), is the first I read on motivated reasoning. As a novice reading this literature, I have many difficulties.
1. Everything we ever do is motivated (say by evolutionary procedures), including rational beliefs we seek to have objectively. Probably the field means: beliefs that deviate from the info we have because we feel interests in believing different things than what is the truth.
2. It seems to be assumed that our beliefs are distorted in the direction of what we like. But pessimists systematically believe bad things, and insecure doubting persons believe too much opposite info.
3. Much of the utility of info is not utility of the info itself, but of its content. The authors in their 2nd para give as example a researcher having as much impact as Kahneman. However, I would not want this as info/belief about myself, but as fact about myself.
4. If I speak too positive about a candidate I vote on, this is not my belief, but my communication to convince others (p. 135 2nd para).
5. The field faces the danger of the **ubiquity fallacy**: erroneously thinking that one’s field can explain everything. %}

{% **restrictiveness of monotonicity/weak separability**: When dealing with time and risk, Andreoni & Sprenger (2012; A&S) implicitly first aggregated over timepoints (conditioning on risky events). This implies a sort of weak separability, i.e., separability of each single risky event which, in particular, precludes hedging considerations across different timepoints (called "intertemporal diversification" in this paper). It also requires correlated lotteries for different timepoints, and A&S's mistake was that in their experiment they instead implemented the lotteries stochastically independently.

This paper analyzes correlations/dependencies to properly reckoning with hedging possibilities, and first aggregating over risky events rather than over timepoints. Thus, things can well be reconciled with prospect theory and probability weighting, contrary to A&S's claims. The authors write in the closing para: "Overall, RDU can explain all of the major findings in CTB experiments and provides the most convincing explanation of the evidence. The model respects first-order stochastic dominance, it can handle general boundary effects aside from the certainty effect, and correctly predicts behavior under different correlation structures. Thus, RDU and its cousins are an attractive modeling choice not only in atemporal, but also in intertemporal situations."

{% Propose a model with risk and time where for all future timepoints there is a probability of dying before, so that all future outcomes are risky, a variation of Baucells & Heukampt (2012). They assume rank-dependent utility with probability weighting as model for risk. Then standard models, with a central role for subproportionality of probability weighting, can very efficiently accommodate a large number of anomalies. They accommodate reduction of certainty effect due to delay, reduction of present bias due to risk, that the order of integration over time or risk first matters, and many other things. Regarding order of integration, they have nonzero outcomes at only one timepoint, which, under normal circumstances, would imply that the order of aggregation, first over time or first over risk, would not matter. However, the authors in fact have three levels, because the survival probability is treated as an extra level, and it works differently in one order of integration than in the other. %}

{% Seems to considers EU where consequences are streams of outcomes. In this framework, gives conditions implying that the utility function over outcomes is constant discounting. %}

Epstein, Larry G. (1983) "Stationary Cardinal Utility and Optimal Growth under Uncertainty," *Journal of Economic Theory* 31, 133–152.

{% Nice survey of the recursive betweenness literature;

dynamic consistency (= constant tastes).

P. 1 defines risk in the traditional way where probabilities should be known: "…individual behavior under risk where, following Knight (1921), risk is defined as randomness with a known probability distribution."

Expresses a strong preference for betweenness theories over other

nonexpected utility models such as rank-dependent theories, prospect theory, etc. for normative and tractability reasons. See, for example,

(1) P. 6:

"There are a number of alternative axiomatically based generalizations of expected utility theory that have been developed, but the one which seems to me to strike the optimal balance between generality and tractability, at least for the applications that I will consider, is the *betweenness* theory due to …" and references follow [italics from original]. §4 considers applications to consumption and asset returns, §5 to sequential choice and game theory. Endnote 2, concerning the text just cited and given on p. 52, writes: "rank-dependent expected or anticipated utility …, the nontransitive regret theory … these alternative models are not particularly useful for the applications in §§4 and 5. The same comment applies to prospect theory (Kahneman & Tversky, 1979). The latter also suffers, in comparison with expected utility and the other models mentioned, from more ambiguous predictions because of the lack of a precise theory of the framing and editing processes."

(2) §3.4 on normative considerations on p. 24 2nd paragraph suggests normative appeal and also tractability.

(3) End of §5.1 also for sequential choice (no physical time)

P. 21 defines stationarity.

(4) p. 48 for applications to game theory.

On dynamic decision principles, this paper strongly favors the approach that keeps forgone-event independence (mostly called consequentialism) and update-consistency (mostly called dynamic consistency) and abandons **RCLA**, in the context of "intertemporal utility" where intertemporal means that there can be consumptions at intermediate nodes, so there is physical time:

(a) P. 19, ℓ. 10-13: "The route corresponding to the middle branch … has been by far the most productive to date and will be the focus of the remaining discussion of intertemporal utility and applications. Here the middle branch designates what I described above.

(b) d**ynamic consistency: favors abandoning RCLA when time is physical**: "Introspection suggests that one might care about the temporal resolution of risk even in the absence of any implications for planning."

In sequential choice where there is no physical time, the paper considers RCLA to be natural (p. 43).

§2.4 is on first-order risk aversion

P. 18 writes on violation of forgone-branch independence: "Such dependence is not irrational, ... disappointment or relief"

P. 25 top points out (for recursivity) that verification of a condition at the individual level does not imply the same condition at the aggregate level. Then writes: "We are left with the familiar "excuse" for representative agent modeling, namely the current lack of a superior alternative."

P. 44 suggests that Hammond (1988) and Machina (1989) use the term consequentialism in the same sense (which they don't).

P. 50: **quasi-concave so deliberate randomization** %}

{% This paper explains the author's views on ambiguity. It reflects impressive, deep, and consistent thinking. However, I disagree with many intuitive directions chosen. The "finishing touch" for the author's aims, endogenizing the definition of unambiguous events, is given later by Epstein & Zhang (2001, Econometrica), but most of the ideas, concepts, and interpretations are here. I will use the term ambiguity hereafter for what the author often calls uncertainty.

The author considers it to be desirable to endogenize many things such as probabilities.

On p. 582, bottom, Epstein tries to push his student Zhang, writing: "… Each of {R,B} and {G,B} is unambiguous, but {B} is ambiguous … This important insight is due to Zhang (1997) ..." However, this elementary point had been known longtime to specialists, and I have known it since the 1980s. It every now and then came up in my conversations with Rakesh Sarin who had a "flip-flop" example to illustrate it. It is too elementary to be credited.

P. 583, Eq. 2.2, describes the "standard" definition of risk neutrality (and, hence, risk aversion) and the expectation involved therein not with respect to given objective probabilities as is common, but with respect to endogenous probabilities (Eq. 2.2), because there is a "for some" quantifier for the probability measure m. m is called subjective. In several places, for instance p. 585 below Eq. 2.5, the author equates "risk" with subjective rather than objective probabilities (**SEU = risk**). There are many economists who have done so since Savage (1954), including prominent ones. However, I think that this is an unfortunate and still minority terminology, and that risk better be related to objective probabilities only. By the way, in the latter way it was also defined by the author himself in Epstein (1992, p. 1)!

P. 584 1st para equates indifference-to-ambiguity with absence-of- ambiguity.

P. 584, Eq. 2.3, defines between-person more ambiguity averse as less favorable comparisons of ambiguous acts to unambiguous ones. If for every act a certainty equivalent exists then the condition amounts to same certainty equivalents for unambiguous acts and lower certainty equivalents for other acts. So, the comparison is defined only for people with same unambiguity preferences, Yaari-type.

Ambiguity neutrality is defined as probabilistic sophistication. I argued in Wakker (2001, Econometrica, pp. 1051-1052) that such endogenous definitions are not tractable; they are hard to observe empirically. The same criticism holds for the definition by Ghirardato & Marinacci (2001, 2002), where not probabilistic sophistication but subjective expected utility is taken as ambiguity neutrality. They have the same basic problem as Epstein. All of them can't take the right, straight, road of going to exogenous probabilities. Epstein then goes too broad by taking probabilistic sophistication, and Ghirardato and Marinacci go too narrow by taking subjective expected utility, where they are explicit, but not as much as I would have wanted, on their extra assumption that they have expected utility for risk. Epstein argues on p. 585 that his definition is consistent with common practice, but this is not so. Surely everyone who did experiments knows that common practice is that non-ambiguity is exogenously given (so, directly observable!), by known probabilities/compositions. What may add to the confusion is that some authors (still a minority) confusingly argued that Savage (1954) is risk, rather than uncertainty. See my keyword **SEU = risk**. From this terminology Epstein's and Ghirardato & Marinacci's desire becomes more understandable. Dean & Ortoleva (2017, Theoretical Economics, Footnote 31, especially last sentence) will nicely and properly point out that ambiguity neutrality means probabilistic sophistication *when also objective probabilities are* *present*. The implied agreement with objective probabilities (an exogenous concept) is the bigger half of it, and probabilistic sophistication the smaller half.

Epstein then goes on to define ambiguity aversion as EXISTENCE of a hypothetical ambiguity neutral (= probabilistic sophistication) person who is less ambiguity averse than the real agent considered. Again, this existence clause makes the concept hard to observe. The probability measure of probabilistic sophistication is interpreted as index of belief. In general this need not be unique. It worries me that ambiguity aversion is a necessary prerequisite for defining beliefs. It also assumes that beliefs must still be quantifiable through Bayesian objective probabilities.

The author is well aware of the desirability of making ambiguity aversion observable. He provides impressively deep results on event differentiability to mitigate this problem. If a person satisfies event-wise differentiability of preferences, then eventwise local linear approximations of the preferences exist, which are probabilistically sophisticated. If this derivative is the same at every event ("coherence"), then ambiguity aversion holds if and only if it holds with respect to the derivative mentioned (Theorem 4.3, p. 599). Given the difficulty of observing probabilistic sophistication, and the depth of the ideas, this is an admirable achievement. However, it is not a complete solution to the observability problem because deriving event derivatives from preferences is hard work, and the requirement that this derivative be the same at every event is very restrictive.

Another difficulty with the definition of belief is that it is completely ordinally driven. I think that in many situations there is more-than-ordinal information on beliefs, such as if we know that Choquet expected utility holds and we know the capacity at a more-than-ordinal level. Then we want to use that non-ordinal info for beliefs, rather than confine ourselves to the model-free ordinal info.

Under Choquet expected utility, a person is commonly (though not by me) taken to be ambiguity averse if the CORE of the capacity is nonempty, and each element of the CORE can serve the purpose of index of belief in the probabilistically sophisticated model. In the multiple prior model, any prior in the set of priors can serve this purpose. It shows that under these models, the indexes of belief and ambiguity neutrality are not unique.

Nonuniqueness will give conceptual problems when endogenizing unambiguous (as in Epstein & Zhang 2001). If there are two sources of uncertainty (say urns), and the agent is probabilistically sophisticated with respect to both, then which is to be taken as ambiguity neutral? It may matter for what we designate as ambiguity averse or not. This issue is discussed more in Epstein & Zhang (2001, Econometrica), pp. 281-282.

Section 5 seeks to criticize the Anscombe-Aumann framework, and Schmeidler's (1989) definition of ambiguity aversion through convexity, but remains too vague, probably because the author wants to be diplomatic. %}

{% A short, critical, summary is in Baillon, Driesen, & Wakker (2012) p. 486:

“Epstein (2010) started by criticizing the problematic empirical status of the endogenous two-stage decomposition of KMM. His first example shows that KMM is not able to model ambiguity *within* a stage, which is related to our criticism of KMM’s use of expected utility within each stage. Epstein’s second example shows that KMM is not able to model different degrees of ambiguity within a stage, which naturally follows from his first example. His §3 criticizes KMM for deviating from multiple priors.“

I next give details:

This paper criticizes the famous KMM model (Klibanoff, Marinacci, & Mukerji 2005, Econometrica) of smooth ambiguity. I first list some weak points of the KMM model:

1. The status of the two-stage decomposition.

1.1. If it is endogenous, as suggested by most of the KMM paper and needed for its interpretations, then it is almost impossible to observe, for one reason because it brings too much richness.

1.2. If it is exogenous (not derived from preference but just imposed by the experimenter, often explicitly to subjects or otherwise imposed when analyzing), as assumed in virtually all applications, then it is simply a two-stage model with a Kreps & Porteus’ (1978) representation; i.e., it then is recursive expected utility.

2. It assumes EU within each stage, which surely for empirical applications is subject to EU violations such as Allais’ paradox.

3. It models ambiguity attitude through (utility of) outcomes, but ambiguity attitude should primarily depend on the events considered, and not on the outcomes, as per the fourfold pattern of ambiguity (Trautmann & van de Kuilen 2015).

4a. It commits to violation of RCLA, which is controversial.

4b. It commits to the dynamic principles of backward induction for nonexpected utility, similarly do all models that use the Anscombe-Aumann framework. However, this is controversial for nonEU with, for instance, Machina

(1989, JEL) strongly arguing against it. KMM do not discuss this point.

5. Their condition of smooth ambiguity aversion is not directly observable and is not a preference condition because it takes !!subjective!! probabilities as input, which is the same regarding observability as taking utility as input.

6. Their whole model is targeted towards aversion to ambiguity, as are most models today, but it does not consider the empirically important likelihood insensitivity. It cannot do the latter because one then has to distinguish likely from unlikely events, which one cannot do if going by outcomes rather than by events.

Epstein targets the first two points 1. and 2. explicitly, and the 3rd somewhat implicitly (in a lecture at HEC, April 2009, Paris, he once explicitly stated the 3rd point, so, he also agrees with it). He does not discuss the other points.

So, I agree that these points deserve criticizisms. But I do not agree with the way in which Epstein's paper does so.

The paper starts with an example of an exogenous two-stage case where the 2nd stage has Ellsberg events, making the EU model there questionable (hence, also, that second-order acts are evaluated by EU that cannot capture the ambiguity within that stage, which Epstein then contrasts with the modeling of ambiguity for Savagean acts depending on the 1st stage). I think that in essence Epstein is right here, and there is no reason for KMM to assume EU for the 2nd stage. But KMM can try a defense, being that they can handle Ellsberg in 2nd stage as they do it everywhere: By adding a stage on top, which here would lead to 3 stages. (So, for descriptive purposes, Allais would be better to criticize EU within a stage.) But then Epstein, replying to this defense in §2.3, goes on to argue that then they take their model endogenous making it unobservable. He could have made this point immediately, skipping the path through Ellsberg's example. The presence of the Ellsberg example in his paper can be further explained by the history of this paper:

> HISTORY. In a first version of this paper (July 6, 09) it reacted to the defense mentioned by saying that then he could assume Ellsberg events in a 3rd level. That, always if KMM resort to an n-level model, Epstein could assume Ellsberg events in the nth level. That always KMM have to add 1 level. That, continuing this way, it could become very complex with many levels. Then, however, Epstein would consider that

complexity to be an argument against KMM. I would say that it is an argument against Epstein's example. In the published version of Epstein's paper this discussion has been dropped but the Ellsberg paradox has remained as a left-over.

Obviously, if KMM cannot handle ambiguity within the 2nd stage, then they can neither distinguish between different degrees of ambiguity in the 2nd stage. This is the topic of Epstein's example in §2.4. I don't see what it adds to the first example.

In the reply of Klibanoff, Marinacci, & Mukerji (2012, Econometrica), KMM12 henceforth, KMM12 indeed defend by adding the extra, I would say 3rd, stage. They next collapse what I would call the 1st and 2nd stage into what usually is their 1st stage state space. Weak point in their defense is, at this point, how can users of the KMM model know whether we should remodel or not? KMM12 argue, p. 1307, citing Marschak & Radner, that "all relevant info" should be incorporated into the (1st order) state space. I think that KMM12 interpret this requirement too strictly. Meta-info about what the proper probabilities over the state space are, for instance, should not be part of the state space. (What I write here is often violated, for instance, by Aumann, who took Savage's unfortunate requirement of the state space specifying all info too literally, leading to circular definitions.) KMM12 use similar reasonings to reply to Epstein's §2.4. Their footnote 8 p. 1309, again shows this overly strict interpretation of the Marschak & Radner citation, as does their final sentence in §2.3.

§2.5 presents a nice thought experiment: Imagine we have the KMM model with the two-stage decomposition and μ endogenous. Then the subject is informed that there is a, now exogenous, two-stage decomposition with the same μ, but now μ objectively given. Would the subject change behavior? I think that KMM would say "yes" because it now has changed into a regular two-stage model with no ambiguity perceived at all. But Epstein argues that behavior then should not change.

§3 is strange. It presents a thought experiment with two indifferent Anscombe-Aumann acts f_1 and f_2 generated by mutually independent ambiguous events. It argues that then the probabilistic mix $½f_1 + ½f_2$ should be indifferent to f_1 and f_2. I expect that most readers will find $½f_1 + ½f_2$ on p. 2095 less ambiguous and less aversive than f_1 and f_2, in agreement with the intuition of KMM cited by Epstein. (KMM12 also argue for this, and cite an experiment where it is apparently shown.) Epstein disagrees. Very strangely, the only argument he puts forward is that, apparently, "the" multiple prior model (MP) (and its restricted way of modeling hedging) implies his claimed indifference. Epstein here and throughout seems to assume as self-evident that the MP model is the gold standard. This is also suggested by the citation of Epstein & Schneider (2010) on pp. 2096-2097 who survey a "growing" literature on "fruitful" applications of MP in finance. So, KMM are being criticized here for not being MP ...

§4, with concluding remarks, suggests that MP is "tighter" than KMM, but it only shows that the MP model uses fewer parameters than KMM, not that it is a subset. %}

{% This paper considers a new kind of ambiguity: Ambiguity about correlations (term in title), or let me write relations (term used in paper). Assume two 2-color Ellsberg urns with black and red balls of unknown composition. A ball is drawn from each independently. Hence, the aforementioned relation does not concern the drawings themselves, which are independent as they always are. Instead, the relation concerns the composition of the urns. These compositions may be related and, althouh subjects know that there may be such a relation, they do not know how it is. Maybe, the two urns have the same composition, or opposite, or anything in between. This relation between the compositions, while known to possibly exist, is unknown and ambiguous. Whether the relation comes from related drawings or from related compositions is not fundamentally different for one single draw (although it gives different updatings under repetitions). But, anyway, the relation is assumed to concern the compositions here. If a subject

prefers (in betting sense)
(Red from urn 1) > same color from both urns
and
(Black from urn 1) > different color from both urns
then the subject has what I call source preference for a single urn over the relation.

A special case of the topic of this paper occurs when each urn in isolation is unambiguous with known composition, so that there also is no relation between the compositions, but the drawings are related in an unknown ambiguous manner, so that intersections of drawings are ambigous. So, then, red from each urn has objective probability 0.5, but their intersection is ambiguous. That this can happen, and that the collection of unambiguous events is not intersection-closed, was pointed out by Zhang (2002), but had been known long before.

The authors do careful experiments. P. 673: They have a nice way of observing indifferences versus strict preferences, by not only asking for bets with equal stakes but also when the stake for one event is raised by $1 but for the other event not. Assuming symmetry of events such as Red/Black, these choices give upper and lower bounds on indifferences and strict preferences. Raising the stakes a bit for the ambiguous urn to rule out indifference was also done by Oechssler & Roomets (2015).

P. 668 writes: "distinction between risk (where information is perfect and confidence is complete) and ambiguity is". This is typical of mainstream thinking today. I have an opposite opinion: In Ellsberg 2-color, the known urn is the LOWEST state of information. Oh well.

P. 669, and also abstract and conclusion, suggest that uncertainty about relations is a third kind of uncertainty, besides risk and ambiguity, but I think that it is only a particular kind of ambiguity and should not receive its own separate class.

Pp. 669-670 (and again §6.1 later) writes on economic implications, but I find these texts uninteresting. It is clear enough that ambiguity about relations is worthwhile and relevant. For instance, hedging is all about such relations. Virtually all uncertainties faced in real life are joint, and in this sense the topic of this paper is important with wide implications. But this broadness can also be a drawback. We cannot expect to find very general rules or insights. The experiment only studies how subjects expect one unknown urn, organized for an experiment by some researchers, is related to another unknown urn organized by that same team of researchers. It does not say much about how people think about joint uncertainties in a market and the corresponding (im)possibilities to hedge, for instance.

P. 672 footnote 5: The experiment used jars and blue and green marbles. Fortunately, the paper writes about Ellsberg urns and black and red marbles. It is a good convention to stick with Ellsberg's stimuli, making the reading of papers easier.
