P. 684 1st para criticizes the Anscombe-Aumann framework for not being natural, citing Kreps (1988) for it, and I fully agree with it. Epstein & Halevy write: "This disconnect in the literature between Anscombe-Aumann acts and descriptive modeling in the field suggests (to us) that tests of preference models that refer only to Savage-style acts are more relevant to the potential usefulness of these models outside the laboratory."

Appendix A.2.4 gives evidence that subjects do not do hedging in RIS in the experiment, which, if it had happened, would be a problem for RIS. The authors used a version of RIS where, prior to the experiment, subjects received an envelope containing the no. of the choice implemented for real at the end, which, as the authors argue, reduces the risk of hedging. The same procedure was used by Loomes, Starmer, & Sugden (1989 EJ), and it is similar to the Prince method of Johnson et al. (2021 JRU). However, it crucially differs and loses several pros of Prince, as explained in my annotations at Johnson et al. (2021 JRU).

P. 675: the authors find evidence that subjects have no color preferences.

P. 675: here and elsewhere, the authors ue the terms ambiguity attitude and ambiguity aversion interchangeably, showing no awareness of insensitity, as with most people in the field.

The authors do both pairwise choice and CE elicitation using choice lists, and find considerable differences between them, which is a bit discouraging (but, again, a thorough job done by these authors!), their explanation being left as topics of future research.

P. 679 footnote 17 explains that predictive prior refers to beliefs about the outcome-relevant state space, and priors to beliefs about the parameters.

testing color symmetry in Ellsberg urn: they confirm it.

P. 680, §5.2 refers to the source method for what it does. But it is a bit different. The authors use sets of priors and multi stages, which is not common in the source method. Here is how I would use the source method:

Take as the universal state space {BB, BR, RB, RR}.

- Source 1 (urn 1) concerns the algebra generated by { {BB, BR}, {RB, RR} }.

- Source 2 (urn 2), not used below, concerns urn 2, and the algebra generated by { {BB, RB}, {BR, RR} }.

- Source 3 concerns the relation between the urns, and concerns the algebra generated by { {BB, RR}, {BR, RB} }.

Take RDU (also known as CEU) with v denoting the weighting function, and v(BB, BR) = v(RB, RR) = 0.4, v(BB, RR) = v(BR, RB) = 0.3. This person is ambiguity averse for the unknown Ellsberg urn, but even more ambiguity averse regarding the relation between the urns. As chosen here, the person considers the event same ({BB, RR}) to be as likely as the event different ({BR, RB}).

It may be argued that this modeling is more accommodating than explaining, but still it gives the terminology and concepts needed, and is way simpler than the models that the authors put forward. It avoids reference to multi-stages which (for me) are highly problematic under nonEU, and it also needs no reference to the (for me) problematic concept of sets of priors containing candidates for the (for me) problematic concept of true existing but unknown objective probability. %}

Epstein, Larry G. & Yoram Halevy (2019) “Ambiguous Correlation,” *Review of Economic Studies* 86, 668–693.
https://doi.org/10.1093/restud/rdy008

{% The authors examine ambiguous signals, and attitudes towards that ambiguity. An ambiguoous urn contains 10 balls, either 1 Red and 9 Black, or 1 Black and 9 Red. First subjects determine matching probabilities (MPs) a priori. Then subjects receive a signal and again give MPs. The ambiguous signal is as follows. N black balls and N white balls are added to a copy of the urn, a signal urn. Subjects know that either N=0 or N=45, but they don’t know which it is. Then a ball is drawn from the signal urn, and its color is told to the subject. Then the subject’s MP is measured again. Of course, if N=0 and the subject were to know so, then the signal would be very informative. If n=45 the signal gives very little information. The authors consider also risky signals, where subjects know what the signal is.

Comparing risky with ambiguous signal gives attitude towards ambiguity of signal. An early equation suggests that the authors do something different: Compare the average MP after good/bad signal with the prior MP. As far as I can judge, this captures ambguity only under the assumption that there are no other deviations from EU, i.e., that we have EU under risk. The authors do indeed state explicitly that they assume EU under risk, which I regret. Another problem is that the signal is contrived, and subjects may dislike it just for that reason.

Important: There is never dynamics in any situation. Dynamics under nonEU are always problematic. Thus, to be sure on this, during the measurent of the prior MP subjects do not yet know that later signals will come.

I did not see a clear conclusion of what the results give.

The authors cite several other papers that investigate ambiguous signals.

second-order probabilities to model ambiguity: Sometimes, when the authors want to generate ambiguity, they do it by using 2nd order probabilities. They argue that this is OK. They argue that regular ambiguity can have problems with symmetry of colors (I think this is unlikely) and being distorted by interaction of the RIS with ambiguity (e.g. hedging). However, the violation of RCLA that they build on, can also have problems with symmetry of colors (also unlikely) and interaction with RIS (not hedging of course but otherwise). %}

{% This paper uses a recursive maxmin EU ambiguity model. It allows for a different set of priors, also within-subject, for domestic stocks than for foreign stocks, thus using ambiguity theory to accommodate the home bias of finance. More generally, they accommodate the difference between more or less familiar. This can be taken as a special case of source dependence, and the authors cite Heath & Tversky (1991) for it. Because they use recursive maxmin EU, they cannot differentiate between aversion and insensitivity/perception. They use the general term "greater ambiguity" for bigger sets of priors.

A citation from p. 1254: "Thus our model can be viewed as a formalization of the suggestion by French and Poterba (1991) that equity home bias may be due to differences in beliefs. They speculate (p. 225) that investors 'may impute extra "risk" to foreign investments because they know less about foreign markets, institutions and Hrms'. They also cite evidence in Heath and Tversky (1991) that 'households behave as though unfamiliar gambles are riskier than familiar gambles, even when they assign identical probability distributions to the two gambles'. The widespread tendency to invest in the familiar has been documented recently in Huberman (2001), with the home country bias being just one instance; see also Grinblatt and Keloharju (2001). We formalize the difference between the familiar and less familiar as a difference in ambiguity." %}

{% Wakker (2008, New Palgrave) gives counterexamples to their definition of unambiguous. The most elementary: for every Anscombe-Aumann model with two ambiguous horses, the horses are unambiguous according to their definition.

The set of unambiguous events is a lambda system. There they impose qualitative probability and probabilistic sophistication à la Machina & Schmeidler (1992). Event T is, therefore, unambiguous if the more-likely-than relation, conditioned on T^c, between two subsets A and B of T^c, with the act on $T^c \backslash (AuB)$ a fixed act h, does not depend on the fixed outcome at T. More likely is defined from bets on, not against, events (e.g., p. 273, 280), as in Sarin & Wakker (1992).

They emphasize much that their definition of unambiguous is not exogenous but endogenous; i.e., derived from preference.

If there are two sources of uncertainty, say two different urns, and we find probabilistic sophistication for both in isolation but, say, a different probability transformation for one than for the other (so, no probabilistic sophistication when joining the two), then it is not clear which source is to be taken as ambiguity neutral. Maybe one is ambiguity averse and the other ambiguity neutral, but maybe the one is ambiguity neutral and the other ambiguity seeking. This paper discusses this issue on pp. 281-282 and 295. Ambiguity of an event depends on the other events available (also visible in the role of A and B in the definition of unambiguous on p. 273). This point, defended by the authors on p. 295, is different, for example, for risk, where risk neutrality (EV maximization) w.r.t. a partition is determined by gambles on that partition and is not affected by the presence of other events.

The authors confound absence of ambiguity and neutrality towards ambiguity. They discuss this issue on p. 283 penultimate paragraph, comparing their treatment of ambiguity with risk. But the comparison is not proper: For risk it IS possible that I really perceive of risk and risk is not absent, but yet I am risk neutral. In the approach of Epstein & Zhang it is not possible that I really perceive of ambiguity but yet am neutral with respect to it. Absence of ambiguity, and neutrality towards it, are really confounded.

The second part of Corollary 7.4(a) on p. 287, claiming a characterization of risk aversion under rank-dependent utility, is not correct. Concavity of u is not necessary. This was pointed out by Chateauneuf & Cohen (1994, JRU, Corollary 2 on p. 86).

Footnote 18, p. 279 is also incorrect because the capacity need only be a transformation of an additive measure, and need not be additive, as one readily verifies. The transformation may very well be nonlinear, making the capacity nonadditive on the algebra mentioned. It implies that, contrary to the authors' claim in 2nd para of p. 279, Axiom 6 need not be satisfied by CEU (Choquet expected utility). Also contrary to the authors' claim, this axiom is rather restrictive, capturing a considerable part of probabilistic sophistication in addition to their unambiguity axiom.

For example, assume that:

S = [0,1] x [0,1]; for f and g probability transformation functions, we have:

for all A x [0,1] capacity W is the f-transform of the Lebesgue measure (the usual additive measure assigning to each interval its length, so that W([a,b]) = f(b−a)); and

for all [0,1] x B capacity W is the g-transformation of the Lebesgue measure.

Let A_1 = [0,1/n] x [0,1] ,…, A_i = ((i–1)/n, i/n] x [0,1], …,

A_n = ((n–1)/n, 1] x [0,1].

Let B_1 = [0,1] x [0,1/n], …, B_i = [0,1] x ((i–1)/n, i/n], …,

B_n = [0,1] x ((n–1)/n, 1].

If f(1/n) = g(1/n), then W(A_i) = W(B_j) for all i,j, and strong-partition-neutrality implies that W of the union of j A-events agrees with W of the union of j B-events, so that f(j/n) = g(j/n) for all j. This is very restrictive. Assume next for some $\varepsilon > 0$ that f and g coincide on $[0,\varepsilon)$. It then easily follows, first for all rational numbers and then by continuity throughout the domain, that f and g coincide throughout their domain [0,1]. Because of the erroneous footnote 18, the authors apparently were not aware of the existence of example as above with nonlinear and different f and g. In a RUD 2006 conference in Paris, Epstein explained in public during my lecture that this paper had been developed to handle the three-color Ellsberg urn and not the two-color urn.

§9.1, p. 293, discusses the case where we have only one urn available, and find probabilistic sophistication satisfied there. The authors argue that intuitively it may not be clear whether the urn is unambiguous, but there is no behavioral evidence for ambiguity and, *hence*, they formally call it unambiguous. If behavioral info can't show if there is ambiguity or not, then I would prefer to leave it unspecified and not to "randomly" choose one option.

P. 269, end of penultimate para writes: "This argument is due to Zhang (1997), whose major finding in this regard we proceed to outline." I criticized this crediting in my annotations to Epstein (1999). %}

{% Find that subjects who express their uncertainties in terms of probabilities, behave worse in a number of cases (e.g., violate dominance more, in Experiment 2). The tasks are somewhat complex, e.g. there is a game in Experiment 1 where they state probabilities over opponents' moves and there are income effects etc. in the lottery choices of Experiment 2, so, it is not very easy to decide on the real causes for the findings.

natural sources of ambiguity: P. 91 last para points out that most of our decisions are taken without knowing probabilities, and knowing probabilities is the unusual situation. It may decrease decision quality. Although the authors only claim more irrationality and not more aversion, they are not far from suggesting what I believe: If anything, people will have more ambiguity seeking than aversion for natural events. Ambiguity aversion happens in situations like the Ellsberg urn, where info is deliberately and artificially kep secret for no good reason that one can think of. This was suggested and found by Wakker, Timmermans, & Machielse (2007). %}

{% %}

Erev, Ido & Alvin E. Roth (1998) "Predicting how People Play Games: Reinforcement Learning in Experimental Games with Unique, Mixed Strategy Equilibria," *American Economic Review* 88, 848–881.

{% **ubiquity fallacy**: This is the text of a lecture and, hence, was not submitted to usual criteria. It is an advertisement of decision from experience (DFE), the topic that Ido Erev worked much on, and in the spirit of the learning that Roth worked much on. As usual, people make their field look broader than it is. I think that DFE is an interesting topic, but just one among many, and as remote from real life as most of the work that we researchers do. However, this paper positions it as an alternative to all of behavioral economics and oversells it too much. The abstract writes: "That is, the assumption of rational behavior is useful in understanding the ways in which many successful economic institutions function, although it is also true that actual human behavior falls systematically short of perfect rationality. We consider a possible explanation of this apparent inconsistency, suggesting that mechanisms that rest on the rationality assumption are likely to be successful when they create an environment in which the behavior they try to facilitate leads to the best payoff for all agents on average, and most of the time ..." That is, they put up a particular finding in DFE as a general answer to the role of irrationalities in general!

P. 1st column writes: "The most basic rational model, the expected value rule, models people as assigning cash equivalents to possible outcomes, and then selecting the option that maximizes their expected return." That is, they take decision under risk/uncertainty (the only thing that EV speaks to) as if all of life.

P. 1 2nd column writes: "It generalizes the expected value rule by adding one psychological parameter: risk aversion or diminishing returns, as axiomatized by von Neumann and Morgenstern (5). Expected utility theory was generalized to subjective expected utility theory by Savage (6) and others. Subsequent modern contributions (e.g., refs. 2 and 7–9) added parameters that capture loss aversion, oversensitivity to rare events, other regarding preferences, and similar psychological tendencies." The authors seem to not understand that other regarding preferences are just a different thing than expected utility, tangential to it.

After these general claims, there is a detailed survey of many findings from DFE. Note that recent (2019) papers challenge the claim that DFE gives underweighting of rare events. %}

Erev, Ido, Thomas S. Wallsten, & David V. Budescu (1994) "Simultaneous Over- and Underconfidence: The Role of Error in Judgment Processes," *Psychological Review* 101, 519–527.

{% Decision from experience (DFE) has been done using past decisions with outcomes received, or with sampling to collect info without outcomes received. This paper considers doing both, and finds strong interactions, with a reduction of effect in Study 1 and even a reversal in Study 2. The authors propose a face-or-cue model for it.

It was interesting for me to read the current general views of the authors in their first pages. Highly interesting was a text on p. 585. The early papers on DFE claimed a reversal of effects claimed by prospect theory (PT) in the sense that rare events were not overweighted, as PT has it, but underweighted. Several recent studies, including Aydogan (2021), found that rare events are not underweighted under DFE, but still overweighted. Only, less so than in other framings, which does not go against PT. The authors now side with that. (**DFE-DFD gap but no reversal**) They write in the main text the still neutral sentence "The term underweighting of rare events refers to a tendency to prefer that option that pays more with higher probability when this option does not maximize expected return." But then there is a footnote that fully explains:

> These definitions imply that the existence of the gap does not imply underweighting of rare events in decisions from experience. for example, consider an experiment that studies decisions between R "10 with probability 0.9, 0 otherwise" and S "9 for sure" using the sampling and the description paradigms. Assume that the R-rate (the choice rate of the option that pays more with higher probability) is 40% in the sampling paradigm, and 10% in the description paradigm. The gap in this example is large (40% - 10% = 30%), but the results do not exhibit underweighting of rare events in the sampling paradigm (as the choice rate of the option that pays more with higher probability is lower than 50%).

I think that this way it cannot be taken as evidence against PT. PT does not say that overweighting of rare events is always the same in different informational circumstances. %}

Erev, Ido, Ofir Yakobi, Nathaniel J. S. Ashby, & Nick Chater (2022) "The Impact of Experience on Decisions Based on Pre-Choice Samples and the Face-or-Cue Hypothesis," *Theory and Decision* 92, 583–598.
https://doi.org/10.1007/s11238-021-09856-7

{% The authors use richness in state space. That is, assume that the grand (Savage) state space is a product of the two issues/sources, issue b with B events and issue a with A events. They take the decomposition as exogenous and not as endogenous as KMM did. So, all events involved are observable. Here is a typical prospect yielding outcome x_{ij} for event A_i-intersection-B_j.

x_{11}	…	x_{1m}	A_1
. …	.		
. …	.		
x_{n1}	…	x_{nm}	A_n
B_1		B_m	

For their basic theorem, I reinterpret their central axiom 5b (a|b strong comparative probability) so as to make clear that in each partition into B-events each single B event is assumed separable (weak separability w.r.t. the B-partition; can do CE substtution for each B event), implying folding back/backward induction for the B events, something that their paper does not state clearly I think. P. 906 has a far-fetched way of saying that backward induction on B's precludes backward induction on the A's. (Otherwise the aggregation theorem, a corollary of Gorman 1968, would give total complete separability and, essentially, EU).

For prospects with outcomes depending only on A events, they impose all the Machina & Schmeidler axioms, giving probabilistic sophistication there. Then they assume all B events separable, i.e., we can do folding back (= backward induction) with respect to those events. !!!This assumption follows immediately from their Axiom 5b by taking event B_2 empty.!!! Such implications of separability have been known since the 1950s at least, with Strotz (1957; not his famous time consistency paper but another pearl he produced) a nice paper on it. Moreover, Ergin & Gul assume that every preference conditional on any B event agrees with the unconditional preference over the A events (also their Axiom 5b). (This also implies in a way that the events of the two sources are statistically independent.) Then we may as well replace all acts conditioned on any B event (such conditioned acts are then acts with outcomes depending only on the A events; i.e., columns in the above matrix) by what I interpret as a fixed outcome. The latter would be a conditional certainty equivalent if there was richness (continuum) of outcomes. The authors do not assume the latter, but they assume richness of events. Then, with a maximal prize X and a minimal prize x, we can replace every act with outcomes dependent on A events by an equivalent X_Ax, which can be equated with the event A conditional on which the big prize is obtained, denoted (A:X). Assume that this way we have $(A_1{:}x_{1j}, \ldots, A_n{:}x_{nj}) \sim (A_{bj}{:}X)$ for each j for appropriate event A_{bj}. The above displayed matrix prospect can then be replaced by the equivalent

$(B_1{:}(A_{b1}{:}X), \ldots, B_m{:}(A_{bm}{:}X))$.

On these acts all Machina-Schmeidler axioms are imposed (mainly Axiom 5b again). A recursive probabilistic sophistication model results.

The authors have thus axiomatized a version of a two-stage Anscombe-Aumann framework where probabilistic sophistication holds for both stages, with subjective probabilities for both stages.

§3 considers axioms concerning second-order risk aversion in some versions that in general are not equivalent but, as the authors show, are equivalent if we impose probabilistic-sophistication rank-dependent utility. Unfortunately, these axioms use probabilities as inputs (as do KMM in their smooth ambiguity aversion). Probabilities are subjective here, so, not directly observable, and conditions that use them I prefer not to call preference conditions. They have the same observability status as conditions that use utility numbers as inputs. So, Theorem 2 (p. 911) in this paper, while mathematically and logically correct, does not really give preference conditions. Papers co-authored by Gul more often have this problem. Another point here is that the authors consider source preference only in an Anscombe-Aumann two-stage setup, whereas it can easily be done for general sources with no need to have a two-stage statistically independent setup.

Theorem 3 shows that if we reinforce the Machina-Schmeidler probabilistic sophistication axioms into the Savage axioms, then we get an axiomatization of recursive expected utility. Theorem 4 gives a result with RDU.

Interesting is the introduction showing that the Ellsberg 3-color paradox can be considered as involving two sources. A nice alternative view of Ellsberg's three-color example: The three balls are numbered 1,2, and 3, with 3 the number of the known color Red. At a first stage there is uncertainty about the color composition of the urn, at the 2nd about the number of the ball drawn. These two

together determine the color. Gambling on known color is gambling on only stage 2 uncertainty, gambing on unknown color involves also stage-1 uncertainty. It does not allow for a completely disjoint source-approach to Ellsberg 3-color. %}

Ert, Eyal & Ido Erev (2008) "The Rejection of Attractive Gambles, Loss Aversion, and the Lemon Avoidance Heuristic," *Journal of Economic Psychology* 29, 715–723.

{% Add further evidence that loss aversion is volatile. The authors go further and seriously question the prevalence of loss aversion, and provide balanced evidence to support their view.

They show that six factors can increase risk aversion and, hence, loss aversion: (1) framing safe alternative as status quo (formulating choice as accept/reject lottery rather than binary choice); (2) focusing on probability of gain, 0, and loss; (3) high stakes; (4) high nominal amounts; (5) highly attractive risky prospects elsewhere in experiment creating contrast effect; (6) fatiguing subjects (difficult long experiment and difficult stimuli).

Study 3 finds central tendency effect (tendency to choose answer in the middle) for choice lists.

Relative loss aversion means that gain prospects, after being translated into mixed prospects, give more risk aversion, confirmed by the well-known Payne, Laughhunn, & Crum (1980, 1981). The present paper finds the opposite in several choices, providing the strongest evidence against loss aversion in the literature that I am aware of. Thus, the summary at the end, p. 229, writes that

they find "weaker risk aversion in choice between mixed prospects than in choice between gains."

An explanation can be that this is always in situations where in the gains-choices the risky gain lottery has a possibility of yielding 0, which generates special aversion. Or it can be that the stakes were so small that joy of gambling came in, but this is admittedly not a strong counter because joy of gambling is hard to model or to give predictions.

P. 227 2nd column 2nd para: much risk neutrality for small stakes (**linear utility for small stakes**)

{% **updating under ambiguity with sampling**; 24 subjects chose between risky and ambiguous options the usual way. 32 subjects got the chance to first sample unlimitedly from the ambiguous option before choosing. In the former case we have the usual likelihood insensitivity and a-insensitivity with preference for ambiguous urn if unlikely and opposite if likely. Still the case is different here because if, for instance, the objective probability is 1/10, the ambiguous urn is described just as unknown prob of win or lose, so, dichotomous, so, like ambiguous 0.5 probability, which makes it natural that also Bayesians prefer ambiguous for unlikely and risk for likely.

In second treatment subjects can sample from ambiguous. Then those who happened to have favorable sample will prefer ambiguous, and the others the opposite. Introspective measurements of beliefs suggest that preferences are not due to belief generated by sampling. Hence, it may be due to motivation. %}

{% **PT: data on probability weighting**;
decreasing ARA/increasing RRA: bit less risk seeking for large losses than for small.
concave utility for gains, convex utility for losses: the latter is found;
utility elicitation;
inverse S is found for losses, both large and small; also upper and lower subadditivity are.
No real incentives, but flat payment.
N = 35 subjects. Considers loss outcomes. **tradeoff method**: Uses that to elicit utility for losses. It is mostly convex, but less so than others (p. 224). With utility for losses given, use CE (certainty equivalent) questions to measure the probability weighting function. Does it for small (down to −$1200) and large (down to −$14000) losses. Finds more pessimism/risk aversion for large losses than for small. For small probabilities, significantly more pessimistic for large

losses, for other probabilities no significant differences. That probability weighting does not depend much on outcomes is good news for PT. (**probability weighting depends on outcomes**)

P. 218: nice citation of Allais (1988), that risk is too complex to expect one fixed probability weighting function. %}

Etchart, Nathalie (2004) “Is Probability Weighting Sensitive to the Magnitude of Consequences? An Experimental Investigation on Losses,” *Journal of Risk and Uncertainty* 28, 217–235.

{% **tradeoff method**;

Uses the method of Abdellaoui (2000) to measure probability weighting. N = 30 subjects, all interviewed individually. Flat payment. §3.1 suggests that shallow probability weighting in the middle can, besides cognitive, also be strategic, in cases where the distinction does not matter for decisions. I did not fully understand this because it suggests that probability weighting cannot be identified. Probably it means, differently, that the payoff differences were so small that subjects just did not care at all. Something sometimes called the peanut effect.

Basic treatment is with small losses. Change of level means adding a negative constant to all outcomes (as with constant absolute risk aversion), making losses worse without changing differences. It had little effect except some more underweighting near p = 1. Change of spacing means, roughly, not precisely, multiplying the outcomes by a positive constant > 1 (as with constant relative risk aversion), making all distances bigger. It led to more pessimism and much more sensitivity except at small probabilities. (**probability weighting depends on outcomes**)

Utility is fitted using exponential utility, expo-power utility, or an uncommon inverse S family (the latter may capture that utility can get concave again for very serious losses, often thought to happen near ruin). The utility family chosen may affect the results on probability weighting. For instance, under power utility, subtracting a constant from all amounts leads to more linear utility, forcing probability weighting to capture more risk aversion and pessimism. But then, it is hard to avoid such things.

losses from prior endowment mechanism: properly criticized on p. 51

middle for, for instance, generating house money effect.

inverse S: is confirmed.

§4.2, p. 58, retrospectively gives another interpretation for a deviating finding in her 2004 paper. That paper may have mixed level and spacing effects.

§ 4.2, p. 59, top, again discusses cognitive interpretation of inverse S. (**cognitive ability related to likelihood insensitivity (= inverse S)**)

§4.1, p. 57 bottom, says that TO method assumes that probability weighting remains constant during the experiment. This is common to any theory. If EU is used, then it is not assumed that utility can change halfway the analysis or experiment. %}

{% **losses from prior endowment mechanism**: A beautiful study, of central importance to real incentives for losses. They use RIS. Do a treatment with real losses! So, they really provide the gold standard to assess other incentive schemes. Compare it with hypothetical choice and losses from **prior endowment mechanism**; within-subject, the three measurements at least 15 days apart each. Find no differences. Us choice list for gains, finding CEs (certainty equivalents). Biggest loss was €20.

real incentives/hypothetical choice: They do find differences for gains (also showing that their design does have power) with, as usual, more risk aversion under real incentives. In the real loss treatment, 17 subjects actually lost money. However, there were two other sessions (within subjects it was) where they could make up. In the end, after the three sessions, 2 subjects had really lost money (p. 69 footnote 9). They had small-probability losses and found mostly risk aversion (p. 72).

Use the semiparametric measurement of PT of Abdellaoui et al. (2008).

risk averse for gains, risk seeking for losses: utility is slightly concave for gains and also slightly concave for losses.

inverse S: their nonparametric estimations of probability weighting confirm inverse S for both gains and losses.

convex utility for losses: When they fitted PT (probability weighting and utility) utility was slightly convex but close to linear (p. 75). For gains, utility was concave.

inverse S: this their probability weighting function is both for gains and for losses, based on fitting at p-values 0.05, 0.25, 0.50, 0.75, 0.95.?

reflection at individual level for risk: they have the within-individual data but do not report on this.

They seem to test for order effects of first presenting gains or losses but find no order effects. %}

Etchart, Nathalie & Olivier l'Haridon (2011) "Monetary Incentives in the Loss Domain and Behavior toward Risk: An Experimental Comparison of Three Reward Schemes Including Real Losses," *Journal of Risk and Uncertainty* 42, 61–83.

{% Propose a new preference condition, fatalism. Consider two prospects $\gamma_p\beta$ and $(\gamma-\delta)_{p+\varepsilon}(\beta-\delta)$, the first yielding good outcome γ with probability p and bad outcome β with probability 1–p. δ and ε are posaitive, so the second prospect has worse outcomes but better probabilities. If

$(\gamma-\delta)_{p+\varepsilon}(\beta-\delta) \succcurlyeq_1 \gamma_p\beta \;\Rightarrow$

$(\gamma-\delta)_{p+\varepsilon}(\beta-\delta) \succcurlyeq_2 \gamma_p\beta$

then $\succcurlyeq_2$ is more fatalistic than $\succcurlyeq_1$. $\succcurlyeq_2$ appreciates the improvement in probability less than $\succcurlyeq_1$ does. Under RDU for agents with the same utility functions, the condition is necessary and sufficient for $w_2'(p) \le w_1'(p)$.

While formally different than insensitivity (inverse S), the condition is very similar in spirit. The authors do not refer to insensitivity. They have a nice application: it reflects willingness to invest in prevention. (**inverse S negatively related to prevention**) %}

{% **survey on nonEU**; a useful concise survey; I focus below on details that I see differently.

Survey mostly theoretical models of ambiguity, but no axioms. Review some empirical findings too. They use terms uncertainty and ambiguity interchangeably. My preference is that uncertainty is general, and ambiguity is the difference between uncertainty and risk. The same concept, although with different terminology, is in Cohen, Jaffray, & Said (1987). The authors cite Wald for the deterministic maxmin. Although Wald also introduced maxminEU, characterized by Gilboa & Schmeidler (1989), they do not cite him for it.

P. 242, cumulative prospect theory (I prefer not to write the term cumulative), unfortunately the authors do not reflect the weighting for losses. Hence, what they call the weighting function for losses is the dual of Tversky & Kahneman (1992).

P. 242, §3.2.1 first line: The authors do not know that Wald, Luce & Raiffa (1957 Ch. 13), and Gärdenfors & Sahlin, for instance, and a whole “imprecise probability” community including Walley (1991), extensively discussed α maxmin EU way before Choquet expected utility was introduced. Thus, they call CEU “first generation” in the beginning of §3.2, and multiple priors a follow-up in the beginning of §3.2.1. Multiple priors existed way before CEU!

P. 248: As many do, the authors give priority to Segal for using multistage probabilities for ambiguity. But many did it before (Gärdenfors 1979; Gärdenfors & Sahlin 1983; Kahneman & Tversky 1975 p. 30 ff.; Larson 1980; Yates & Zukowski 1976). §3.2.1 takes multiple priors endogenous, and §3.3 considers multiple priors with priors exogenous. §3.4 cites Chew & Sagi on sources. But Tversky initiated it, with 1995 papers with me (Wakker) and Fox on it. Chew

worked with Tversky in the early 1990s, although they did not finish a paper, and this is how Tversky influenced Chew as he influenced me.

§4.3, p. 254 last para, erroneously claims that Epstein wanted unambiguous to be exogenous. Epstein was very strong on it having to be endogenous (with me disagreeing much).

§§4.5.1-4.5.3 discuss concepts of ambiguity and ambiguity aversion but cannot give a clear picture because they fall victim to what I called a historical accident in my book Wakker (2010, §11.6): As in Schmeidler 1989, they take EU as given, and equate convex (pessimistic) weighting function with ambiguity aversion and Ellsberg. I think that convexity of the weighting function, an absolute property, is better related to the Allais paradox. The Ellsberg paradox and ambiguity aversion concern a relative concept: More pessimism/convexity for uncertainty than for risk. Because they take EU as given, being more convex for uncertainty than for risk happens to coincide with being convex, and the relative and absolute concepts get confused.

P. 259, on rectangularity of Epstein & Schneider (2003): Sarin & Wakker (1998, JRU, pp. 87–119), Theorem 2.1 had it before, calling it the reduced family. %}

{% This paper uses Segal's (1987) two-stage model of ambiguity, which I describe there. It is two-stage with backward induction and the same nonEU risk functional used at each stage ("time neutrality").

P. 286 5th para (“As I noted earlier …”) improves upon many papers by acknowledging the empirical finding of **ambiguity seeking for unlikely**, deviation from the global ambiguity aversion studied in this paper. Then defends against it.

P. 287 3rd para: cites papers studying ambiguity in strategic situations.

P. 287 4th para: A pro of Segal’s ambiguity model is that one can use results for risk attitudes to analyze ambiguity. This it shares with the source method!

P. 287-288 compares Segal’s ambiguity model with the smooth model, similarly as I do in my annotations of Segal (1987).

P. 290, Definition 3, defines more-ambiguity-averse-than as is most common in the literature, being Yaari-like lower certainty equivalents but adding the assumption of identical risk attitudes. This is equivalent to stronger preference for risky options over general (ambiguous) options. Ambiguity aversion means more averse than some ambiguity neutral attitude, which is equated with probabilistic sophistication (with objective probabilities present; this is a crucial specification of Epstein’s definition.)

P. 291, the main result, Theorem 1: Global ambiguity aversion iff negative certainty equivalence (NCI) of Dillenberg (2010), the main axiom of cautious utility (Cerreia-Vioglio, Dillenberger, & Ortoleva 2015). Global ambiguity aversion means that the risk nonEU functional is such that ambiguity aversion, as defined before, occurs for every state space and two-stage configuration. P. 293 top points out that, as NCI is imcompatible with RDU, so is global ambiguity aversion. Gul’s (1991) disappointment aversion can be reconciled.

P. 293, Corollary 1, 3 lines below: Unfortunately, the author and journal did not publish the proof, meaning that we cannot trust this result. One should never drop proofs from publications for the purpose of saving space.

P. 294, §4, discussed increasing ambiguity, using one of several conceivable ways of defining mean-preserving spreads of the 2nd order distribution.

P. 298 end of 1st para of §4.3: “Similarly, it is hard to imagine a satisfactory method that can separate ambiguity from ambiguity attitudes within Segal’s (1987) model.” The preceding para discussed the pro of the smooth model of giving such a separation. Drawbacks of that separation in the smooth model are, first, that it is only based on speculation and, second, that it is unobservable to the extent that the two-stage decomposition is unobservable. 2 paras later: “Obviously, ambiguity attitudes are also

non-separable from risk preferences in Segal's (1987) theory." I can agree with this claim to the extent that one takes the two-stage framework as exogenously given, rather than as endogenous as (formally, although never in practice) in the smooth model. %}

Falk, Armin & Michael Kosfeld (2006) "The Hidden Cost of Control," *American Economic Review* 96, 1611–1630.

{% Thought-provoking experiment on markets eroding moral values.

Here letting mouse live means that an experimental mouse that would normally have been killed, is given a decent life (average: 2 years). It need not be desirable in the sense that other people had apparently decided that this life is not worth living, and the money it takes, but now they get forced to still do it.

TREATMENT 1. A subject can choose individually: (a) €10, but mouse will be killed; (b) the mouse will live but no money;

TREATMENT 2 (bilateral market). A pair of subjects can choose: (a) They let one (one!) mouse live and get no money; (b) They agree on dividing €20 and the mouse will be killed. They can take 210 rounds of bidding.

In this treatment 2, one of the two subjects is called seller and is told "the life of the mouse is entrusted to your care," but this is only framing without any strategic implication; the life of the mouse is in fact a public good and not a consumption commodity.

TREATMENT 3 (multilateral market). 9 subjects are called sellers and 7 are called buyers. Sellers must state a minimum prize x, meaning that they accept any division of x or more for them and 20-x for a buyer. Buyers must state a maximum prize y, meaning that they accept any division of 20-y for themselves and y for the other. Note that the difference is only a matter of framing (whether you should say z or 20-z), and not strategic. Sellers and buyers are coppled by market mechanisms. Whenever a trade is made, a mouse is killed for it. They can take 210 rounds of bidding. Because there is a lack of buyers, with the firmest two sellers left alone, buyers are in a power position and selling prices of sellers (used as index in the analysis) will be relatively low.

As Figure 1 shows, the price for a mouse is highest in Treatment 3, then in Treatment 2, and lowest in Treatment 1.

The authors conclude that markets erode moral values. Points for discussion:

(1) Treatment 2 is in fact a bargaining problem, with mouse surviving the disagreement outcome (which need not be unfavorable). Strategic considerations and fairness play a role. Also, the bargaining distracts from the moral issue, especially if experimenter demand comes in. Here also the tradeoff is between money or HALF responsibility rather than, as in treatment 1, full responsibility. I expect that in Treatment 2 most subjects simply took the fair 10-10 division of money; this number is not reported in the paper.

(3) In Treatment (3), market considerations similarly complicate the case, where further the strategic disadvantage of the sellers complicates. Here the responsibility for a mouse's life is quite small because a seller can think: if I don't sell, then another seller will and the mouse will die anyhow (p. 708 2nd column bottom).

The authors have a control treatment (p. 708 top of 2nd column) with a market for a consumption good where market and individual price do not differ, but this

is very different (e.g. it is zero sum) from the bargaining problem of the public good of the mouse-life.

The authors have a control treatment (p. 710 1st column top) where individuals do not receive €10 for sure, but a 50-50 lottery, but this 50-50 lottery will not distract the same way as the bargaining situation.

The authors have a control treatment (p. 709 3rd column middle) where an individual decides, but not only he but some nondeciding other gets €10 if the money is chosen. Here indeed it is €20 per mouse life in total, and the welfare difference between Treatments (1) and (2) is controlled for, but the shared- versus single-responsibility difference between Treatments (1) and (2) is not controlled for. %}

{% **utility elicitation**; extensive survey for unidimensional utility. For multiattribute, Fishburn (1967 Management Science) and Fishburn (1968 Management Science) are nice companions. The paper assumes risk and expected utility (EU). One can take that as multiattribute utility still, with every state of nature (generating a probability) as an attribute.

The paper uses the old term "chained" measurement for what is nowadays (2024) more often called "adaptive."

Table 1, p. 1285, distinguishes whether one uses certainty equivalents, probability equivalents, indifferences between two risky lotteries, and so on, and whether one varies probability or outcome to get the indifference.

The paper discusses what to do about violations of EU, inconsistencies, detected through crosschecks, with p. 1285 mentioning resolutions through modifications of previous answers. P. 1285 bottom mentions the impact of the decision analyst. Sections 5 and 6, pp. 1288-1293, have more on it.

P. 1286 states already what Loomes, Starmer, & Sugden (2003 EJ) call the shaping hypothesis, and what has also been called "coherent arbitrariness," for coherent choices that are coherent biases rather than coherent genuine preference: "In complicated or unfamiliar decision problems, consistent responses with a single assessment procedure may result primarily from a convenient heuristic rule or from a salient contextual effect."

Table 3 distiguishes different starting positions (status quos). Section 5.2 distinguishes matching ("direct estimation") from choice-based procedures ("convergence techniques" or "bounding techniques"). It does not discuss incentive compatibility, which is no issue in prescriptive applications, the primary interest in this paper.

P. 1289 below Eq. 4 recommends avoiding probabilities near 0 and 1, because they give most deviations.

PE doesn’t do well: p. 1290 2d para, strangely enough, claims the opposite.

Table 3, p. 1294, nicely organizes the many utility measurement procedures.

{% Consider cases where the status-quo health state of people improves and consider health states that originally were above the status quo but are below now. They assume that utility is concave above the status quo and convex below (which, strictly speaking, is not defined for the nonquantitative outcomes considered here; but this problem can be fixed). This aspect of prospect theory, if taken in isolation, would imply that the health states considered have lower utility now than they had before. The authors test this hypothesis for 14 subjects. For 8 subjects they find higher utility now, contrary to the hypothesis, for 6 the same utility, and for 0 lower. They conclude that prospect theory is violated. (**PT falsified**)

It would be interesting to analyze the case considering loss aversion. Loss aversion is stronger than the concavity/convexity effect considered below. If I see things right, loss aversion will decrease the utility of outcomes that originally were closely above the status quo and now are considerably below, but will increase the utility of outcomes that originally were considerably above the status quo but now are closely below. In a complete analysis of prospect theory, also probability weighting would be incorporated. Thus, for a complete analysis of prospect theory it is not clear if the data of this paper confirm or reject it.

There are also intertemporal dependencies different than prospect theory that are effective here. %}

{% **decreasing ARA/increasing RRA**
inverse S: confirm it both for gains and for losses, using Goldstein & Einhorn (1987) two-parameter family

risk averse for gains, risk seeking for losses: find it well confirmed.

reflection at individual level for risk: they have it in their data but do not report it.

Experiment in Bejing 2005 with real incentives for Chinese students (N = 153), and CEs (certainty equivalents) of 56 lotteries, using a finite mixture regression model. Stakes were like 1-hour wage (low-stake) versus 40-hour wages (high-stake). Always choice between sure outcome and 2-outcome prospect in choice lists to get CEs. Use the Goldstein & Einhorn (1987) two-parameter family for probability weighting, and power-utility.

Unfortunately, they implemented two choices for real for each subject, being one for high-stake and one for low-stake (the high-low stake comparison is within-subject), giving an income effect. It will, unfortunately, amplify a contrast effect with subjects simply taking low-stakes not very seriously. Not much can be done about this (other than do between-subject).

P. 154 footnote 5 properly points out that loss aversion does not affect choices between losses under PT; this paper only considers nonmixed prospects.

Point out that measurements of utility and risk aversion, and investigations of whether risk aversion is decreasing or increasing and whether concavity of utility is decreasing or increasing, cannot be settled properly if there is no correction for

probability weighting and other things. Find increase in relative risk aversion for gains, but find that this is primarily driven by different probability weighting for high outcomes than for low. The latter entails a violation of prospect theory (**PT falsified; probability weighting depends on outcomes**). No increase or decrease but constant attitude is found for losses.

Losses with real incentives are implemented in an unconventional way: For each gain-choice there was a corresponding loss-choice that consisted of first a (choice-situation-dependent!) prior endowment and then the losses-choice, such that after integration of the endowment with the loss-choice the loss-choice was the same as the gain-choice. So, differences between gains and losses are a matter of framing, and this is how the authors often refer to it. Discussion of it on p. 170.

P. 151 top references several studies showing that heterogenous models can be really off. They find 1/4 subjects doing EV, and 3/4 PT. %}

Fehr-Duda, Helga, Adrian Bruhin, Thomas Epper, & Renate Schubert (2010) “Rationality on the Rise: Why Relative Risk Aversion Increases with Stake Size,” *Journal of Risk and Uncertainty* 40, 147–180.

{% **survey on nonEU**: well on probability weighting it is. Describes many implications of nonlinear probability weighting.

P. 568 penultimate para gives an unconventional interpretation of disappointment aversion as probability weighting.

P. 571 Table 1 the authors take 1st order risk aversion as desideratum for nonEU (thus arguing against the smooth model although they do not mention it, focusing on risk).

P. C.2, Figure 2, nicely depicts indifference curves of RDU and disappointment aversion in the probability triangle, to show their different characteristics, mosty with the DA indifference curves being linear (but not parallel), as they are for every betweenness model.

P. 576 end of §3.4 mentions some aspects in which the disappointment aversion model is more tractable than RDU.

P. 577 footnote 6 senses correctly that there are difficulties in identifying loss aversion, but incorrectly claims that one will have to add gain prospects to mixed prospects to do it. From mixed prospects one can entirely identify preferences over non-mixed prospects (under continuity), so, nonmixed prospects cannot really help.

P. 578 top rightfully criticizes power probability weighting functions. My main criticism is that they can't accommodate inverse S. The authors point out, right so, that it can't accommodate the common ratio effect, so, neither the certainty-effect version of it as in Allais' common ratio paradox. But it can accommodate the certainty effect in the common-consequence effect and in that version of Allais paradox.

Unfortunately, that the weighting function of T&K'92 is not strictly increasing for their parameter $\gamma < 0.279$ is called a drawback. Every parametric family imposes restrictions on its parameters. Linear-exponential (CARA) utility $U(\alpha) = \mu(1 - \exp(-\theta\alpha))$ under EU restricts its parameter values such that it is strictly increasing too (by requiring $\mu\theta > 0$). Is it a drawback that there are other parameter values ($\mu\theta < 0$) that have it decreasing? The second drawback, that relations between elevation and inverse S are assumed, cannnot be avoided for one-parameteric families, and a negative relation is plausible. (Its main drawback is I think that it overweights small probabilities too much. And, as the second drawback just mentioned, that two parameters are desirable to separate elevation and inverse S, agreeing with the authors claim opening up §3.6.2 on p. 579.)

P. 579 suggests that the intersection point of probability weighting may exceed 0.37. I think it usually is below. They find it to exceed in their experiments, especially with general populations. Thus, they do find strong evidence for **inverse S.**

P. 583 2^{nd} para nicely explains that one-nonzero prospects cannot identify utility and probability weighting (I add: Because their common power is unidentfiable). Then, people may have them identifiable if they assume parameteric families that do not leave the power free. But then the functional assumed a prori, rather than the data, determine the common power of utility. Some people deliberately assumed linear utility for this purpose, not as a confusion but deliberately. (This also often happens in intertemporal choice when estimating discounting with one-time-outcomes.) This annotated bibliography in 2013 signals the problem for Benhabib, Bisin, & Schotter (2010, p. 218 middle the estimate of power utility), Glaser, Trommershäuser, Mamassian, & Maloney (2012, Psychological Science), and Zeisberger, Vrecko, & Langer (2012, see

Figure 1).

§5, p. 586 ff., nicely lists many findings outside the lab that support probability weighting.

Prospect theory/Rank-Dependent Utility most popular for risk: §6 %}

{% Suggests “slanted” (= distorted, or nonadditive) probabilities for ambiguity.

P. 672 suggests that subjective probability judgments relating to different “processes” (Amos would say sources) are not directly comparable. Suggests that there is a probability estimation stage, and next a transformation into decision weights (as in source theory). The estimated probabilities are called “corrected probabilities,” or “true subjective probabilities,” the transformed ones “uncorrected probabilities.”

P. 673 2nd para discusses the Ellsberg two-color urns where the matching probability of an ambiguous color is 0.3.

P. 674/675 discusses in quite some detail that probabilities of gains are more natural entities to be transformed than probabilities of staying in the initial position. A similar argument for losses would suggest that probabilities for losses are to be considered there. These two viewpoints nicely support the method of Choquet integration adopted by Tversky & Kahneman (1992)—top-down for gains and bottom-up for losses—so, symmetric about the origin as the Šipoš (Sipos) integral. Because if only singles out the reference point, it also fits well with 1979 prospect theory.

utility measurement: **correct for probability distortion**: p. 676 points out that, when subjects (pessimistically) transform probabilities of gains downward, then common methods of measuring utility give overly concave utilities and then first the subject’s transforming of probabilities should be incorporated. So, it

pleas for correcting for probability transformation.

P. 676 nicely explains that it is a modeling issue whether the deviation from expected utility is ascribed to probability transformation or to utility: "for pragmatic reasons we may sometimes wish to channel the impurity into the utility concept itself rather than catch it at the level of the weighting system. In this case the distortion of probabilities gives the appearance of a distortion of the utility concept rather than of the probabilities."

P. 679 raises the income effect.

P. 680, **paternalism/Humean-view-of-preference**: "… leaving an otherwise rational person alone who consistently prefers three dollars to *quatre* [four] *dollars*. This latter person needs to be supplied with a dictionary rather than to be assured of our respect for his preference scales."

§II argues that deviations from expected utility generated by psychological costs etc. may be rational.

uncertainty amplifies risk: p. 684 suggests that nonadditivity is more pronounced for uncertainty than for risk.

P. 680 gives a nice argument against consumer sovereignty and for paternalism: "But the question still remains whether leaving him alone is not like leaving an otherwise rational person alone who consistently prefers three dollars to *quatre dollars* [French for "four dollars"]. This latter person needs to be supplied with a dictionary rather than to be assured of our respect for his preference scales. He is making a mistake."

P. 685 suggests correction factor; i.e., how much added probabilities fall short of 1, as measure of degree of "slanting." Is common and, for instance, also used by Schmeidler (1989).

Other than that, §§II (rationality) and III (a little experiment) were not interesting to my current interests. P. 681 tries to defend nonEU, also for risk, and finds little appreciation from a Bayesian like me.

{% The authors tested decision under risk in three monkeys, using many 1000s of choices over extended periods. In particular, they tested common ratio and common consequence violations of expected utility's independence axiom, so, the usual Allais paradox tests. They did data fitting with new 1992 prospect theory (**PT falsified**: not!), i.e., rank-dependent probability weighting. They, properly, do top-down integration in rank-dependence, as is the convention these days (2023).

inverse S: They find that probability weighting better fits and predicts choices than utility. However, the patterns of violation are opposite to those found among humans. (**PT falsified**) They go against the certainty effect and give S-shaped, rather than inverse S-shaped, probability weighting, and more concave than convex probability weighting. They also find convex rather than concave utility. How come this difference they do not discuss much. Reminds me of Decision from Experience, which is what one has to do with monkeys.

They test not only direct violations of independence, which they call preference reversals and of which they do not find much, but also what they call preference changes. Those are the proportion of common Allais-violations versus the reversed Allais violations. Those gave more significant statistics.

I usually use statistical tests that assume between-subject stochastic

independence but not within-subject stochastic independence. Then, with N = 3, only three monkeys, not much statistics is possible. %}

{% **preference for flexibility**: An agent has to select one alternative from a choice set. Can do with as many intermediate rounds as he wants. At each stage, does not know for sure the true preference and may with some probability perceive a random preference instead. At each stage, forgets past and only info is set of alternatives left. If very risk averse, main interest is not to choose the worst alternative. If very risk averse, main interest is to choose the best alternative. Hence (Proposition 1), an extremely risk averse subject at each choice removes only one alternative, being the one perceived as worst; so, takes as many nontrivial rounds as possible. A very risk seeking subject immediately chooses one (the one perceived as best) alternative, so, takes as few nontrivial rounds as possible (Proposition 2, p. 413). %}

{% Duggie Fields (1990 approximately). In 1969 he was a painter and a roommate of Syd Barret, the member of the pop band Pink Floyd from 1965 or so till 1968. Duggie, verbatim, explained the following about Syd’s depressions in a documentary about Syd made around 1990. It describes a preference for liberty of choice, and how this leads to a loss of utility and how it is not optimal from a consequentialist point of view. In the second half of the citation, every word is perfect, such as “limited presence” (**conservation of influence**!).

> I think he spent quite a while lying in bed—I used to be in the next room and, eh, I’d be painting, and it was kind of like the wall in between us would sort of cease to exist. And, I knew he was lying in bed sort of thinking, and my my interpretation was that he was thinking that while he lay there, eh, he had the possibility of doing anything in the world that he chose. But the minute he made a choice he was limiting his possibilities, so, he lay there as long as he could, so, he had this unlimited future. Ah, but of course that’s a very limited presence when you do that, and a very depressing one ultimately. %}

{% **relation age-risk attitude**: see title.

questionnaire for measuring risk aversion: The Columbia card task is a nice

risk taking task, and probably an improvement of the balloon task (BART): There are 32 cards, face down, n among them losing cards, the rest (32−n) gaining cards, a gain G, and a loss L. Subjects can turn around cards (that were not turned around before, so, it is drawing without replacement), one by one. After each gaining card, G is added to their gains, and subjects can choose to continue or stop. (For the next round the loss probability increases.) After a losing card, L is subtracted from subjects' gains and they must stop. Because the data are truncated after a loss, it is probably best to ask beforehand how many cards subjects want to be turned around if the chance (strategy method).

This paper considers both where subjects must announce beforehand how any cards they want turned (the cold treatment), and where they turn around one by one being informed immediately about each result (the hot treatment). The authors conjecture that the former, cold, treatment will trigger our rational system, and the latter, hot, treatment will trigger our emotional system. The hot treatment will usually deliver censored data, after a loss. Therefore, unfortunately, the authors rigged the experiment, letting the losing cards be the last to come. (See p. 713. Among 54 experimental questions, rigged this way, they added 9 tasks with early losing cards deliberately generated.) This is deception, which is unfortunate. (**deception when implementing real incentives**) Comes to it that subjects who try some, will get encouraged to become more risk seeking.

The authors do ANOVAs within subjects (p. 712 bottom of 1st column), apparently assuming independence of choices within subjects. By this collapsing of data per subject into significant or nonsignificant (a sort of median split) much power is lost.

The authors consider both overall degree of risk aversion, being how many cards turned in total, and information sensitivity by seeing how the number of cards turned depends on the number n of loss cards, the gain G, and the loss L.

{% **gender differences in risk attitude**: A meta-analysis.

Prospect theory not cited: They focus on EU-logpower fitting of indifferences, often named after Holt-Laury. But their Footnote 1 at least mentions the point,

starting with providing the readers with the following information: "The application by Holt and Laury (2002) of a multiple price list is not the first to elicit risk preferences in decisions under risk." They then cite Cohen & Jaffray (1987) and Tversky & Kahneman (1992) as alternatives. But then they defend their restriction: "However, at the present time, the HL task constitutes the most widely known implementation of the multiple price list approach applied to risk" However, the Nobel-awarded Tversky & Kaheman (1992) is cited 2.5 times more than Holt & Laury (2002), and it also used choice lists. Kahneman & Tversky (1979) is even the most-cited paper ever in an economic journal.

They find little gender difference. In their study of details and specifics that may interact, in §5, it is a big pity that they do not distinguish utility curvature, pessimism, insensitivity, and loss aversion, but go with only one index, of risk aversion. I did not understand much of, and guess I disagree with, many claims in the discussion of probability weighting on p. 3154. Have the impression that the authors equate risk aversion with utility curvature also if probability weighting is present, a confusion found in many places in the literature. %}

{% **cognitive ability related to risk/ambiguity aversion**: Allais-violation of EU is enhanced by less education and experience. N = 180 farmers. %}

Finkelshtain, Israel & Eli Feinerman (1997) "Framing the Allais Paradox as a Daily Farm Decision Problem: Tests and Explanations," *Agricultural Economics* 15, 155–167.

{% Two monkeys received visual stimuli indicating that they might receive a liquid reward after two seconds. Distinct stimuli indicated probabilities of 0, 0.25, 0.50, 0.75, or 1. The monkeys apparently learned to distinguish the stimuli, for one reason because anticipatory licking was different for them. The brain activities of the monkeys were measured.

Phasic activation of dopamine neurons after receipt of reward decreased with reward probability. After no reward, neuronal activity was suppressed, tending to increase with probability, though hard to measure given the low level of spontaneous activity. So, after both reward and no reward, seems that neuronal activity decreases with reward probability and, thereby, increases with elation (difference between predicted and actual reward), apparently in agreement with earlier findings (p. 1898 last column gives several references).

P. 1898 end of 2nd column:

"It is only through a rich representation of probabilities that an animal can infer the structure of its environment and form associations between correlated events."

And references to support this are given.

New in this study is the measurement of sustained activation between signal and reward. This activation was maximal at p = 0.5, and absent at p = 0 and p = 1. In time it was maximal at time of reward, and in reward it was maximal in discrepancy between good and bad reward.

inverse S: The symmetry of sustained activity of dopamine neurons around 0.5 is reminiscent of inverse S and cognitive factors, although the dependency on reward size makes clear that it is not merely cognitive. (**cognitive ability related to discounting**)

Phasic and sustained activities seem to be independent. All of the observed activities disappeared for motivationally irrelevant activities. In the last two columns the authors speculate on sustained activation playing a role in learning, attention, intrinsic utility of learning, etc. %}

{% referaat Anne Stiggelbout 21 April 1993. **paternalism/Humean-view-of-preference**? Three filosophies:

1. philosophy of basic values (people have only a limited number of simple values and complicated decisions have to be derived from there),

2. philosophy of articulated values (people have sophisticated values, also for complicated things), and

3. philosophy of partial perspectives (intermediate form), are compared.

Imagine that a researcher follows the philosophy of articulated values but reality is partial perspectives, then what goes wrong? Etc. This is a nice enterprise.

For many years, many aspects of the paper escaped me. I felt confusion between the dimension of whether or not values of people EXIST, and the dimension of whether of not people KNOW them given that they exist. In April 2005 people told me that Fischhoff is strictly and exclusively considering the second dimension. That is, he assumes throughout that preferences and values about what is best for a person really do exist. He only considers the dimension of whether or not people know their own values. Thus, the extreme form of the constructive view of preference of people saying that values and preferences (except very basic) simply do not exist; plays no role in Fischhoff's text. With this explanation, I reread and then understood what his sentences are saying.

I think that many nuances of the literature get lost in this paper by not considering nonexistence of values. For instance, economists who believe that true values and utilities exist and also that people know them well ("consumer sovereignty") are lumped together with the extremely different view of psychologists who do not believe that any value exists. These two groups have in common, indeed, that they see no discrepancy between what exists and what is known and, hence, will refrain from paternalism. Decision analysts are put at the other extreme of the continuum, as basic values, which they are only in the sense that they may be more open to paternalism. They believe strongly and extremely that true values do exist, and in this sense are close to many economists and far remote from psychologists.

{% Hupman & Simon (2023 p. 2): "the superb and widely praised book Utility Theory for Decision Making (Fishburn 1970a)". The book indeed is superb.

cancellation axioms: P. 41 Theorem 4.1B gives necessary and sufficient conditions for additive representation of finitely many preferences.

P. 74 ℓ. 6: those recangles don't have to fit together.

p. 76 first para: big step. I do not see what continuity implies what is claimed there. If g is defined on $V \cup V' \cup V''$ and represents on $V \cup V'$ and on $V' \cup V''$, then it does not have to be representing on $V \cup V' \cup V''$.

restricting representations to subsets: P. 74. On April 2, 1990, I sent a letter to Fishburn explaining that I do not see in point 5 on p. 74 how one can be sure that the rectangles as constructed in Figure 5.3 behave as "nicely" as depicted there, having Axiom Q1 only globally not getting indifference curve k directly. I also asked about the reasoning in lines 2/3 on p. 76, deriving global additivity from local additivity on a domain that is not a Cartesian product. I gave further details. In a letter of April 16, 1990, Fishburn answered that he did not really remember how to justify these parts. I also wrote that Debreu's (1960) function g at the end of his proof has the same problems as Fishburn's function g.

strength-of-preference representation: Ch. 6.

P. 82: **risky utility u = transform of strength of preference v, latter doesn't exist**.

Pp. 92-94: Fishburn never gets $\sum_{j=1}^{n} u_i$ in general under continuity. His mixing of continuity assumption present and absent (as in Theorem 7.3) covers this omission up.

Kirsten&I: Theorem 7.5, p. 96, does constant discounted utility for finitely many timepoints.

Section 13.1: Good reference for the modern two-stage horse-race-roulette version of Anscombe-Aumann (1963). Before, it was in the first three paras of §3.8 (p. 1607), of Fishburn (1967 Annals of Mathematical Statistics) and before in Chernoff (1954). It can also be recognized in Arrow (1951 Econometrica pp. 431-432).

criticisms of Savage's basic framework; p. 161, §12.1, describes an example where acts and consequences are naturally given and states of nature are defined from those. P. 166, §12.2, suggests that the case where the consequence sets are conditional on each state are disjoint as "does not seem unusual," for the reason that consequences are complete descriptions of what might occur. P. 168, end of §12.2, again pleas for this model on the basis of residual uncertainty not specified in the states descriptions and describes state-dependent expected utility in Eq. 12.7.

P. 192, §14.1, Fishburn has a somewhat weaker version of P7 than Savage, only taking strict preferences rather than weak as premise. However, the axiom readily implies Savage's. That is, under P1, P2, & P6, Fishburn's P7 implies Savage's P7; i.e., they are equivalent. Liu (2023) demonstrated this point.

P. 193, §14.1, erroneously claims that the state space S in Savage's model has to be countable. When I was a Ph.D. student, I sent a letter to Fishburn writing that it can be countable, giving an example. Ten years later, in a plenary lecture in 1990 in Irvine, Fishburn acknowledged me for this in public. A dear memory!

{% A Nicer version of Theorem 3, Fishburn’s main result, is in Kim (1996). An also nicer, but less so, result is in Border (1992).

Finding representations of expected utility (EU) for risk amounts to solving linear equalities and inequalities, so that duality theorems or, equivalently, separating hyperplane theorems can give necessary and sufficient conditions. Scott (1964) is a beautiful paper showing it for general additive representations, not focusing on risk. This (Fishburn’s) paper, positioned as mostly expository, does a similar thing focusing on EU for risk, not citing Scott. I find it less appealing, although still useful. In particular, this paper does not make the step towards cancellation axioms. Theorem 3 seems to offer a characterization of EU-maximization for a finite collection of weak and strict preferences. But it uses heavy notation and is not presented nicely. Fishburn just states the duality condition with no attempt to give a nice preference interpretation. He also has results for incomplete preferences with several EU functionals and then unanimous representations by those, and lexicographic representations. %}

{% Preface (p. 4/5) says that Edgeworth's Mathematical Physics "has gone far astray" on one point; i.e., in taking **just noticeable difference** as unit of utility.

P. 11 §I.I.1, dissociates itself from psychology.

P. 67 seems to explain that, in absence of additive representability, the total utility curve of milk, and the tradeoffs of milk, will not be the same or even proportional for different levels of beer or bread.

Fisher does assume in Part I that utility of each commodity is independent of all other commodities. It is never really specified (in terms of preferences) what that means. But it can be seen from the analysis of marginal utility that it must mean additive decomposability. Thus, §4 of Ch. 1 defines marginal utility of bread through tradeoffs with other commodities (oil). However, it considers infinitesimal tradeoffs, so, derivatives. It shows how the quotient of marginal utilities of two commodities can be measured by tradeoffs with a third commodity.

questionnaire versus choice utility: Fisher does not want Benthamite utility, see for example end of §1.5.

Uses the nice terms competing and completing goods.

P. 102 in 1937-book: proposed consequentialistic approach to commodity bundles in sense that for articles of fashion such as diamonds one incorporate quantities consumed/produced by all persons in the market.

"This limitation has many analogies in physics. The attraction of gravity is a function of the distance from the center of the earth. A more exact analysis makes it a function of the revolution of the earth, of the position and mass of the moon (theory of tides) and finally of the position, and mass of every heavenly body."

P. 18 of 1937 book, on arbitrary scale: "Any unit in mathematics is valuable only as a divisor for a second quantity and constant only in the sense that the quotient is constant, that is independent of a third quantity. If we should awaken to-morrow with every line in the universe doubled, we should never detect the change, if indeed such can be called a change, nor would it disturb our sciences or formulae."

Edn. of 1892/1962 seems to write on insurance, not ascribe it to risk aversion in pure sense but also to argument of planning budget: "To buy too much or too little, to sell too cheap or too dear will be equally sure to diminish gain. Herein lies the virtue of insurance and the vice of gambling."

risky utility u = transform of strength of preference v, haven't checked if latter doesn't exist: Doesn't relate it to risk but writes, on p. 23, end of §14 of Ch. 1: "Utility" is the heritage of Bentham and his theory of pleasures and pains. For us his *word* is the more acceptable, the less it is entangled with his *theory*. [Italics from original]

§II.IV.8, p. 89, already stated concisely and perfectly, ordinalism (note the premise that puts it all in the right perspective!!!!). It is the whole Part II, Ch. IVC, §8.

"Thus if we seek only the causation of the *objective facts of prices and commodity distributions* four attributes of utility as a quantity are entirely unessential, (1) that one man's utility can be compared to another's, (2) that for the same individual the marginal utilities at one consumption-combination can be compared with those at another, or at one time with another, (3) even if they could, total utility and gain might not be integratable, (4) even if they were, there would be no need of determining the constants of integration." %}

Fisher, Irving (1892) “Mathematical Investigations in the Theory of Values and Prices,” *Transactions of Connecticut Academy of Arts and Sciences* 9, 1–124. Reprinted as book in 1965 (1st edn. 1925), Yale University Press, New Haven.

{% %}

Fisher, Irving (1916) “Is ‘Utility’ the Most Suitable Term for the Concept It Is Used to Denote?,” *American Economic Review* 8, 335–337.
Reprinted in Alfred N. Page (1968), *Utility Theory: A Book of Readings*, Wiley, New York, 49–51.

{% On the possibility to use interpersonal comparisons of utility he seems to have written, p. 179-180: “To all these questions I would answer ‘yes’—approximately at least. But the only, or only important, reason I can give for this answer is that, in actual practice human life, we do proceed on just such assumptions.” And then some later comes the, beautiful: “Philosophical doubt is right and proper, but the problems of life cannot, and do not, wait.” Reminds me of I often point out to philosophers and ivory-tower researchers that I worked eight years in a hospital. The next para on that p. 180: “So economists cannot afford to be too academic and shirk the great practical problems pressing upon them merely because these happen to touch on unsolved, and perhaps unsoluble, philosophical problems. The psychologist has set the example by becoming a “behaviorist.” [new in 1920s] He can thereby deal practically with phernomena the essentialnature of which he confesses he cannot fanthom.”

P. 159 cites J. Willard Gibbs:

“The whole is simpler than its parts.”

Obtains cardinal utility by imposing additive decomposability.

Assume oddland and evenland, with different prizes and budget for two families with identical pref. rels. Assume two commodities, one and two. Assume (y_1,x_2) is what a family in evenland buys. The marginal utility of money spent on first commodity must be equal to that spent on second, there; it is the marginal utility of money there. In oddland we have two observations for different prize/budget combinations, leading to (x_1,x_2) and (y_1,y_2), respectively. Comparing the prize ratios of the 2nd commodity at (x_1,x_2) in oddland and (y_1,x_2) in evenland shows the ratio of marginal utility of money in those two cases, comparing the prize ratios of the 1st commodity at (y_1,y_2) in oddland and (y_1,x_2) in evenland shows the ratio of marginal utility of money in those two cases. So, we obtain the ratio of marginal utility of money at (x_1,x_2) and (y_1,y_2) in oddland, so, at two different levels of wealth, having used evenland as a measuring rod/yardstick. P. 187 says that these observations can be extended to more levels: give the family in evenland budget/prices so that it buys (z_1,y_2), in oddland so that it buys (z_1,z_2), and the marginal utility of money at (z_1,z_2) can be related to the others; etc.

Pp. 175-176 nicely explains how the group of food commodities may be separable.

Discussion on pp. 179-181 is in fact a nice discussion of the many assumptions underlying a preference relation.

Seems to assume also comparability of utilities for different persons, in order to achieve concrete results applicable to income taxation.

P. 181 seems to argue that individual data on utility contains too much noise.

P. 180, about people who doubt about cardinal utility: "Philosophic doubt is right and proper, but the problems of life cannot, and do not, wait."

P. 181:

"Even the philosophic doubter, if himself taxed unfairly, would be apt to know it!"

P. 187 etc. looks similar to standard sequences and TO method, with p. 189 l. 3 mentioning yardstick, but it looks like not and the text is too complicated for me to find out further. %}

{% **risky utility u = transform of strength of preference v**: This paper does not consider risky utility, but considers the history of cardinal-ordinal utility in welfare theory. In particular, to what extent Arrow' impossibility theorem was a death sentence to ordinal welfare theory (**Arrow's voting paradox ==> ordinality does not work**). Samuelson and others argued otherwise.

The basic issue is as follows. Assume two agents. We only know their *ordinal* utilities U_1 and U_2. We define a social welfare function $W(x) = w(U_1(x),U_2(x))$. Assume $w(U_1(x),U_2(x)) = w(U_1(y),U_2(y))$. Can we say that we made an interpersonal comparison of utility difference, with $U_1(x)–U_1(y) = U_2(y)–U_2(x)$? Strictly mathematically speaking, we can just deny it. %}

{% Aumann & Serrano (2008, JPE) define a measure of riskiness of a prospect (lottery) g that has both positive and negative outcomes as the risk tolerance (reciproke of measure of absolute risk aversion, which has the nice property of having monetary unit as its unit; in other words, of being a money amount) at which the person is indifferent between taking the prospect or the 0 prospect. That is, with $U(x) = 1–\exp(-\alpha x)$, $EU(g) = EU(0) = 0$, and then α is the index.

This paper does the same thing but with a different utility family, being the logarithmic family defined by $U(x) = \log(\alpha + x)$, where α is the parameter. The authors show this definition of their measure only in Section VI.B, following Eq. 5. Their defining Eq. 1 is equivalent, as readily follows from substitution. They denote the measure by R(g). They interpret α as wealth level, as this is often done. Beause log(0) is $-\infty$ (we approximate for x to 0 from above), this should always be avoided and dominates all else, and R(g) should exceed the minimal outcome. If I understand right, this simply means that R(g) is the liminf of the support of g. Thus, if there is a minimal outcome and it has positive probability, then R(g) is this outcome.

The authors put this interpretation, of avoiding bankruptcy, central in many discussions in the first part of the paper. They derive many properties in Section V Proposition 1, such as homogeneity, which follows from CRRA, subadditivity, and so on. It reminds me of the Kelly criterion (Kelly 1956), maximizing logarithm of wealth, which is optimal if in repeated investment decisions one want to minimize the risk of ruin/extinction.

P. 800 3rd para criticizes Rabin (2000) on the ground that the extreme risk aversion that Rabin derives agrees with the authors' criterion of R(g). R(g) is indeed the most pessimistic and risk averse one can think of. The authors judge R(g) and its extreme risk aversion to be plausible (I disagree). Hence, they disagree with the implausibility claim that Rabin assigns to extreme risk aversion. %}

{% **survey on nonEU**
Focuses on decision under risk with a bit on ambiguity.

Not primarily a complete survey but rather a didactical account giving the main ideas, with some nicely written sentences. For example, p. 51, on Rabin’s paradox: “by way of analogy, if one could perceive the curvature of the earth by walking the length of a football field, then the earth must be implausibly small.”

loss aversion: erroneously thinking it is reflection: This paper of course does NOT make this mistake. It usefully lists it as the first of some misunderstandings (top p. 55): “A few points of common confusion are worth highlighting at this juncture. First, loss aversion is not the same as risk seeking for losses. …Second, decision

weights are not generally interpreted as a measure of belief. … Third, the concavity (convexity) of the value function is not the same as risk aversion (risk seeking), and overweighting low-probability gains (losses) is not the same as risk seeking (risk aversion)."

P. 58 brings up the two-stage model of PT for ambiguity, in the spirit of Tversky that I know well, having discussed it so much with him: There is belief and risk-probability weighting in the first para, with no space for the typical Ellsberg source preference. The latter is considered a relatively unimportant phenomenon much driven by contrast effects beyond individual choice, and reluctantly showing up in the 2nd para. Tversky convinced me of this and it has underlied my work on ambiguity ever after. Tversky mostly discussed these things with Craig and me.

PT falsified: Pp. 59-63 lists violations. The 2nd part of this paper is on external validity from lab to field, giving procedures to work on this.

P. 79 (conclusion) (**Prospect theory/Rank-Dependent Utility most popular for risk**):

"Despite its limitations, we find that prospect theory is the most successful general purpose model currently available for predicting, describing, and interpreting decisions under risk; to our reading alternative models that we reviewed outperform prospect theory only under specific conditions."

{% **PT: data on probability weighting**; **natural sources of ambiguity**
ambiguity seeking for unlikely; **inverse S** Option traders do EV for given probabilities, and subadditivity for unknown probabilities; ascribe it to subadditivity in judged probability.

P. 7: "Note that risk can be viewed as a special case of uncertainty where probability is defined *via a standard chance device* so that the probabilities of outcomes are known," [italics added] Important: the italicized part shows that risk (I add: Ambiguity neutrality) refers to a neutral emotionless implementation of risk. The same statement is in Tversky & Fox (1995).

The value function is elicited by asking for equivalences
(p, x; q, c; 1–pzq, 0) ~ (p, a; q, b; 1–p–q,0),
x > a > b > c,
where all values except x were set by the experimentor and subjects should provide x. For example, this paper took a = \$100, b = \$50, b = \$25. Expt. 1: p = q = 1/6. The median answer found was x = \$125.

The authors conclude that that implies a linear value function under cumulative prospect theory (p. 8, ℓ. 15–18). However, that need not be true in general. It will depend on p and q chosen and, no matter what p and q are, on the probability weighting function (which may be different for different individuals).

linear utility for small stakes: their findings remain unaffected if they assume linear utility.

real incentives: **random incentive system** %}

{% %}

Fox, Craig R., & Yuval Rottenstreich (2003) "Partition Priming in Judgment under Uncertainty," *Psychological Science* 14, 195–200.

{% They introduce monadic testing for the Ellsberg urn test of ambiguity aversion. That is, they do not let subjects choose between known and unknown urn, but present each in isolation and ask for evaluations (certainty equivalents), thus avoiding contrast effects. Ambiguity aversion may not be genuine, but may be just a contrast effect. They indeed find that ambiguity aversion then disappears, although later studies primarily by Chow & Sarin (2001, 2002) suggested that the truth is in the middle: ambiguity aversion is reduced but does not disappear under monadic testing.

ambiguity seeking: The paper finds source preference for betting on football over chance, but less sensitivity for football. So, source sensitivity and preference do not always covary.

Study 4 compares WTP both for event and for its complement. But they do not test uniform dominance (source preference), but only sums of WTP, so that it is not really **source preference directly tested**. P. 893 mentions cases where there is uniform dominance (both the event and its complement have higher CE (certainty equivalent)) for medians. So, this is at the median level but not directly at the individual level.

Studies 2 & 3 have real incentives, studies 1,4,5,6 are hypothetical.

P. 600: "the conclusion that the Ellsberg phenomenon is an inherently comparative effect." The next para argues that it is not clear which is more rational, the finding of the comparative test shows or of the monadic test.

inverse S: Argue that nonadditive models can describe source sensitivity but not so easily source preference because the latter may be a comparative effect, see P. 601: "This suggests that models based on decision weights or nonadditive probabilities (e.g., Quiggin [1982]; Gilboa [1987]; Schmeidler [1989]; Tversky & Wakker [1995, Econometrica]) can accommodate source sensitivity, but they do not provide a satisfactory account of source preference because they do not distinguish between comparative and noncomparative evaluation."

This paper shows Amos' preference to use the term chance for known probabilities.

P. 601 footnote 1 emphasizes the importance to control for "subjective probability" (their term) before drawing inferences about ambiguity attitudes.

P. 602 criticizes Dow and Werlang [1991] and Epstein and Wang [1994] for treating source preference in a noncomparative manner. %}

Fox, Craig R. & Amos Tversky (1995) "Ambiguity Aversion and Comparative Ignorance," *Quarterly Journal of Economics* 110, 585–603. https://doi.org/10.2307/2946693

{% **PT: data on probability weighting**; **inverse S**; **ambiguity seeking for unlikely**; **coalescing; natural sources of ambiguity**

The model for uncertainty in this paper, called the two-stage model, assumes introspectively based belief judgments, on which the probability weighting function of prospect theory for risk is applied. This assumes that everything of ambiguity is cognitive, i.e., comes from belief! I like this interpretation of ambiguity, although it deviates from the prevailing views these days (2021). Beliefs are assumed to be captured by support theory. This implies binary additivity (Eq. 2): The belief in an event and in its complement add to 1. It precludes source preference.

The model predicts that matching probabilities are identical to introspective beliefs (Eq. 5).

The value function is elicited by asking for equivalences

(.25, x; .25, c; .50, 0) ~ (.25, a; .25, b; .50, 0),

x > a > b > c,

where all values except x were set by the experimentor and subjects should provide x. They conclude from that that, for value function v, v(x) + v(c) = v(a) + v(b). This is correct !because! they do this only if expected utility is assumed. It would not be true had they claimed this under cumulative prospect theory! The abstract is confusing in writing that they assume prospect theory for risk. (It would also be correct under original 1979 prospect theory, which deviates from the new 1992 version here.)

P. 879 1st column claims: "the classical theory [axiomatic decision theories] .. does not correspond to the common intuition that belief precedes preference." I disagree. Axiomatic theories take no stance on what precedes what, decisions or beliefs/attitudes. I agree on the plausibility of belief preceding, being prior to, preference.

1998, p. 883, first column, third paragraph, opening sentence, suggests that what they do is independent of probability weighting. This is not correct. (Other parts of the text also suggest this incorrect claim but less explicitly than the sentence on p. 883.) What follows, in particular the identification of risk attitude with utility, is correct only under expected utility.

real incentives: Do **random incentive system** in study 1, not in study 2 it seems.

P. 885: They use the terms risk averse / risk neutral /risk seeking as equivalent to concave / linear / convex utility. This is, again, only because they are doing the analysis in the context of expected utility there.

P. 893 penultimate exhibits the usual enthusiasm about own results, focusing on this journal Management Science: "The two-stage model may have important implications for the management sciences and related fields." %}

{% **value of information**: The paper is on that. It takes value of information from the posterior perspective, after actual receipt of the info. It takes the instrumental value, being how much more (conditioned on the info received!) expected utility one gets by choosing optimal thanks to the info relative to the perceived optimum without that info. It then formulates some abstract mathematical properties, endowed with the strange name validity, and proves some theorems on it.

Because the topic interests me much, I tried to understand this paper, but I failed. I failed immediately in the definitions in §I.A on p. 3652. When the authors write that a belief is a distribution I gamble that they mean a probability

distribution. A signal realization is what I would call a signal, and what they call a signal is the corresponding prior anticipation/ random variable (?). After quite some thinking about the first three lines of the 2nd para, I came to understand that signal is as follows: (1) There are finitely many possible signal realizations $r_1, \ldots, r_m$. One takes a finite partition of the state space $\{E_1, \ldots, E_n\}$. For every E_j there is a conditional probability p_{ij} of receiving signal realization r_i conditional on E_j. Therefore, after receiving the signal realization, one can update the probabilities of E_j by Bayes formula.

However, I got lost at the last sentence of that para. A signal is a random variable. Is S the image or (I guess) the range (set of images)? But what is the domain? [0,1]? If it is S x [0,1], then the domain has not been endowed with a probability measure yet, so one cannot use the term random variable. I gave up trying to really understand.

P. 3653: At first I did not understand the first displayed formula because p and q were not explained. Only 8 lines below they get explained.

If we can quantify the value of info, then we can define the degree of nuncertainty in a situation as minus the value of perfect info, and we can readily define value of info conversely. The authors make a big point of this relation.

P. 3656 defines validity of a measure of info as the EXISTENCE of a decision situation such that the measure of info is the value of info there. This is a strange definition because the decision situation may be weird and practically irrelevant. There is a corresponding definition of validity of measure of uncertainty. Theorem 2 will show that validity of a measure of uncertainty holds iff the measure is (regular and) concave, further showing that this is just a mathematical property. What the authors call validity is something like a very minimal requirement for validity. %}

{% I took from Wikipedia in Dec. 2022:

In a 1772 letter to Joseph Priestley, Franklin laid out the earliest known description of the Pro & Con list, a common decision-making technique, now sometimes called a decisional balance sheet: ...

"my Way is, to divide half a Sheet of Paper by a Line into two Columns, writing over the one Pro,

and over the other Con. Then during three or four Days Consideration I put down under the different Heads short Hints of the different Motives that at different Times occur to me for or against the Measure. When I have thus got them all together in one View, I endeavour to estimate their respective Weights; and where I find two, one on each side, that seem equal, I strike them both out: If I find a Reason pro equal to some two Reasons con, I strike out the three. If I judge some two Reasons con equal to some three Reasons pro, I strike out the five; and thus proceeding I find at length where the Ballance lies; and if after a Day or two of farther Consideration nothing new that is of Importance occurs on either side, I come to a Determination accordingly." %}

{% **paternalism/Humean-view-of-preference**: nice discussion. More than that, it is one of the nicest papers I ever read on this topic. (Another nice paper on this topic is Tversky & Kahneman (1981), my no 1 paper in all of decision theory.)

Paper considers simple cognitive test (with clearly correct/incorrect answers) and correlates these with choices. Pp. 26/27 starts nicely with a simple question where subjects with correct answer discounted clearly less. Pp. 28-30 gives references. The paper nicely on each occasion challenges the unfruitful “De gustibus non est disputandem” and consumer sovereignty by taking examples of overly extreme discounting (rather $3400 this month than $3800 next month; p. 31) and overly extreme risk aversion (rather $500 for sure than (0.15: 1 million;

0.85: 0)) that are so clearly over-extreme that the consumer sovereignty people will have a very hard time.

cognitive ability related to discounting

cognitive ability related to risk/ambiguity aversion: p. 32: Fewer studies have been done for risk than for intertemporal choice on correlations with cognitive tasks, but then cites some for risk. This paper finds, strangely enough, that intelligent people not only are more risk seeking when this means going for expected value (which can be taken to be rational), but also when this means going against expected value (which can be taken to be irrational). Unfortunately for me, no data/discussion on inverse S, and only on risk aversion.

gender differences in risk attitudes: p. 38: "expressed loosely, being smart makes women patient and makes men take more risks."

I like in particular the very balanced discussion section (p. 38 ff.). The author makes clear that he prefers what I call the paternalistic approach of decision theory, however without ever crossing the line of just shouting out own opinions as other less-nuanced authors may do (am worried that I may belong to the latter category sometimes). Nice discussion with many references to people discussing that de gustibus EST disputandem (so, I dropped the "non" from the known saying).

P. 41 explains that it is good to follow your brilliant neighbor on mortgage choice, but not necessarily so to follow Einstein in preference for apples over oranges. I like in particular the discussion that the preference

$500 > (0.15: 1 million; 0.85: 0)

most probably does not signal that utility is way flatter above $500 than below, but rather that it is "more reasonable" (the author's words) that this choice is to be overridden. The concluding sentence (whatever stance on paternalism, the correlation between intelligence and decision attitude calls for some explanation) nicely gets back the consumer-sovereignty readers.

A detail: P. 40 suggests that Savage (1954) coined the term reflective equilibrium, but I am not aware of this term appearing in Savage's book. Rawls (1971) is usually credited for having coined it. %}

P. 406, last para: "a concept used in the interpretation of observable phenomena has no meaning independently of the operations specified for measuring it."

P. 409:

"Science is science and ethics is ethics; it takes both to make a whole man;" %}

Friedman, Milton (1955) "What All Is Utility?," *Economic Journal* 65, 405–409.

{% A classic paper because it is about the first to try to use utility in the expected utility model seriously, to capture nontrivial phenomena beyond risk aversion.

They posit utility function that has convex regions, so that EU can explain the co-existence of gambling and insurance.

Markowitz (1952) discussed that their utility curve makes many wrong empirical predictions. F&S themselves also pointed out such predictions, not yet knowing they are wrong but saying they are things to be tested. See the comments on their pages 282/301 below.

The authors argue that the common thinking has been that marginal riskless utility is meaningful, that it is diminishing, and that the expectation of this utility is to be maximized under risk (EU), which implies universal risk aversion. They argue that this reasoning is incorrect because, first, marginal riskless utility is not meaningful anyhow and, second, if it were, it need not be vNM utility. Therefore, their partly convex vNM utility does not violate the intuition of diminishing riskless marginal utility.

P. 282 says about their conjectured utility function that it has predictions beyond the phenomena considered and then, very appropriately, "Further empirical work should make it possible to determine whether or not these implications conform to reality."

P. 282 seems to write (**coherentism**)

"asserts that individuals behave as if they calculated and compared expected utility and as if they knew the odds ... the validity of this assertion does not depend on whether individuals know the precise odds, much less on whether they say that they calculate and compare expected utilities or think that they do, or whether psychologists can uncover any evidence that they do, but solely on whether it yields sufficiently accurate predictions about the class of decisions with which the hypothesis deals"

P. 301 indicates, correctly, that their curve predicts risk seeking for small gambles at specific levels of wealth. That this does not hold has later been taken as empirical refutation of their utility function. So, F&S themselves very correctly pointed out a critical test of their theory.

P. 283 cites Vickrey who identifies marginal utility with vNM utility in a critical manner.

P. 298 gives nice description of EU as an as-if model.

!not! **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)** because they assume that riskless utility is only ordinal and not cardinal; the famous paper; one of the early papers to state that risk aversion iff u concave, referring to Marshall for it. %}

Friedman, Milton & Leonard J. Savage (1948) "The Utility Analysis of Choices Involving Risk," *Journal of Political Economy* 56, 279–304.

{% A verbose discussion of Baumol's (1951) reaction, and a correction of a mathematical mistake in the EU derivation in their 1948 paper (I think that they only used betweenness and not full-force vNM independence there).

This paper seems to have been the first to formulate the sure-thing principle. About it, p. 468:

"practically unique among maxims for wise action in the face of uncertainty, in the strength of its intuitive appeal. The principle is universally known and recognized; and the Greeks must surely have had a name for it, though current English seems not to." At a young age I was puzzled by this claim, until Peter Fishburn pointed out to me that they wrote this tongue-in-cheek.

P. 473 seems to write:

"The failure of these experiments [i.e. those aimed at making riskless utility cardinally measurable] should be interpreted neither as a consequence of the nonmeasurability of utility in some absolute sense nor as showing that utility is not measurable. . . . It may be that future experiments along the same general lines will be more successful." %}

{% **Conservation of influence**: Below follows a famous poem. One can recognize decision theory principles. The choice of the less trodden road can be taken as a plea for ambiguity seeking (☺: why not?). The one taken having the better claim but still being essentially equivalent in every respect can be taken as lexicographic preference. The justification of the choice in retrospect (if the last

line can be interpreted this way, which is debatable) can be taken as cognitive dissonance. The last sentence can also be taken as definition of influence (**conservation of influence**), with “all the difference” taken as identifying the agent with his actions. Nice is that “sigh” and “all the difference” can equally well be positive as negative. The title refers to the essential role of counterfactuals in analyzing preferences, decisions, and free will, which distinguishes social sciences from natural sciences.

The Road Not Taken

TWO roads diverged in a yellow wood
And sorry I could not travel both
And be one traveler, long I stood
And looked down one as far as I could
To where it bent in the undergrowth;

Then took the other, as just as fair
And having perhaps the better claim
Because it was grassy and wanted wear
Though as for that the passing there
Had worn them really about the same;

And both that morning equally lay
In leaves no step had trodden black.
Oh, I kept the first for another day!
Yet knowing how way leads on to way
I doubted if I should ever come back.

I shall be telling this with a sigh
Somewhere ages and ages hence:
Two roads diverged in a wood, and I—
I took the one less traveled by
And that has made all the difference. %}

{% Subjects choose between sure outcomes and two-outcome lotteries. The authors show that risk attitudes in an experiment depend on the stimuli faced before; i.e., there are carryover effects. For instance, one group received lotteries with big variation in outcomes. The other with small variation. The latter group then is more sensitive to changes in outcomes. Or, one group has received lotteries that are getting better and better during the experiment, and for the other group they are getting worse and worse. Then the former are more risk seeking. Such

dependencies have been found in many papers before, for instance in papers by Neil Stewart who developed a good model (decision-by-sampling model) for it, and the authors cite such literature. Just one early reference: Poulton (1968). This issue is central for good implementations of the random incentive system, where one tries to minimize them. The authors propose a model of bounded rationality where efficient coding can explain things. (**calculation costs incorporated**) The utility shape of prospect theory can be "rationalized" this way.

For every irrational bias in decision attitudes, one can imagine an environment with wrong information for the agent so that the bias best neutralizes the wrong information and therefore is best to do. van den Steen (2004 AER) is a good example. Steiner & Stewart (2016 AER) also tried to do this. Question is to what extent the imagined environment is realistic/interesting. I did not study the environment and coding theory of this paper enough to judge on this. %}

{% Izhakian (2024) wrote a reply.

This paper criticizes Izhakian's (2020 JET) mathematical analysis. It claims that his 2nd order probability distribution cannot serve as an index of ambiguity at least not in the way he claims. The paper crticizes Izhakian's Theorem 1 which connects perceived probabilities and Izhakian's index of ambiguity. The authors provide alternative versions of Izhakian's Theorems 1 and 2. They are more critical of Izhakian's Lemma 3 (separating risk and ambiguity attitudes), for which they see no easy fix. The problem seems to be most serious for continuous distributions (§5.2). It would then invalidate later results in the paper, which all depend on Lemma 3. (In my annotations I already indicated that the ambiguity comparisons require same a-neutral probabilities μ.) The authors point out, p. 2 2nd para, that the index may still work in an ad hoc manner and that it has served empirical work. But they claim that it does not have the properties claimed. In particular, it is not independent of risk attitude. §5.3 proposes an alternative measure which, unlike Izhakian's, is invariant under monotonic transformations, although it does not have several other properties.

The conclusion, p. 18, writes on ambiguity in general, and I agree: "Ambiguity research has been mostly restricted to theoretical work for far too long. Finding ways of taking the theory to the data is a timely and important topic." %}

Fudenberg, Drew & David K. Levine (2006) "A Dual Self Model of Impulse Control," *American Economic Review* 96, 1449–1476.

{% Use the dual model of their 2006 American Economic Review paper, where for decisions within a day the emotional self plays the biggest role, and cognitive load does so too; with the cost function of self-control convex. Increasing stakes and probability of winning reduces the importance of cognitive load and enhances rational choice, and reduction of paradoxes such as Allais'. This model suggests that in the usual Allais paradox the irrational emotional choosing occurs with the small-probability choices and, hence, that the certainty effect plays less of a role as irrationality. In their model, discount rates ranging 1-7% and relative risk aversion (they assume EU) of 2 fit some existing data sets well. They also predict that violations of stationarity will reduce if the intertemporal choices are risky, which has been confirmed by Keren & Roelofsma (1995) and later papers. This can be taken as a violation of generalized stochastic dominance (**restrictiveness of monotonicity/weak separability**).

In the conclusion the authors argue that their model may be better in explaining a wide range of phenomena across different contexts with a limited number of parameters than, for instance, prospect theory. But they, nicely, also mention problems for their theory. %}

Fudenberg, Drew & David K. Levine (2011) "Risk, Delay, and Convex Self-Control Costs," *American Economic Journal: Microeconomics* 3, 34–68.

{% This short note briefly summarizes a longer working paper. They propose what they call simplicity theory, which can be combined with any other risk theory. What it does is add to the other theory a term C(|support(P)|), i.e., a term depending only on the number of outcomes in the support of the lottery P. (If the absolute values of the outcomes of P are very small then readily violations of stochastic dominance follow.) For that other theory they consider expected utility, 1979 original prospect theory, and the new 1992 prospect theory. Remarkable, simplicity theory joint with new prospect theory does best and with original prospect theory it does worst (p. 422 2nd column). Unfortunately, the paper only cites a few papers that find what they call complexity aversion (dislike of large supports; actually a misnomer), and not the more papers that find complexity seeking, which is the prevailing finding. {% **tradeoff method**:

Bleichrod, Cillo, & Diecidue (2010) showed a way to quantitatively measure regret theory which, given its intransitivity, is not easy to conceive. This paper extends their technique to multiattribute. It considers the following evaluation, for a state space S, the outcome space an n-fold product space, acts f mapping S to outcomes, and $f_i(s)$ the ith attribute of outcome f(s) $(1 \le i \le n)$:

$$f \succcurlyeq g \iff \int_S \varphi\Big(\sum_{j=1}^{n} \tau_i\big[v_i(f_i(s)) - v_i(g_i(s))\big]\Big)dp(s) \ \ge\ 0$$

Here v_i is the attribute-dependent utility of the ith attribute $f_i(s)$ of outcome f(s), $\tau_i[v_i(f_i(s)) - v_i(g_i(s))]$ is the regret of getting $f_i(s)$ instead of $g_i(s)$, there is an additive and separable summation over the attributes, and then, finally, a sort of EU-type probability-weighted average of φ-transformed regret is taken. The authors axiomatize the model, using preceding axiomatizations of regret-type models by Fishburn, Sugden, and Nakamura. Karl Vind also gave related axiomatizations, but his work is not used. The authors show how the functions

can be measured empirically in a deliberately small experiment only to illustrate. They also consider and axiomatize special properties of the functions. Attribute-dependent regret is captured by τ, and holistic regret by φ. %}

{% This paper provides basically the same ideas as Gaifman & Liu (2018; cited). Detailed annotations are given there and, therefore, mostly pertain to this paper as well. This 2015 paper also adopts the 2CA assumption, correctly criticizes Savage for not explicitly defining domain, but itself does not do either, by apparently assuming closedness w.r.t. cut-and-paste for instance, but doing so only implicitly and never saying so explicitly. The authors assume probability μ (their symbol), derived from qualitative probability as done by Gaifman & Liu (2018), available. This paper then sets out to derive the EU representation, but does not really do it. As explained in my annotations on §4 of Gaifman & Liu (2015), they only show how utility can be defined from preference if EU holds, which is the easy first step in proving preference axiomatizations, but they do nothing to prove that the definition is consistent or would really represent preference.

There is yet another problem. The paper is confusing on whether utility is state-dependent or not. Its claim to do Savage suggests state independence. Several parts in their text do so too. Below Eq. 2.13 they write (where P refers to an event from a partition) "where $u(P_i,x_i)$ is the utility of consequence x_i given P_i. As it will be shortly shown, in all cases in which $\mu(P_i) > 0$ this value depends only on the consequence x_i." But they do not prove any of what is promised here. Their footnote 6, to the contrary, explicitly states that they take utility state-dependent. Several formulas such as Eq. 2.13 and 2.16 indeed take utility state-dependent. In the title of §2.3, and other places, they use the term context-dependence, which, per footnote 6, refers to state dependence. However, doesn't Savage's P4 preclude state-dependence in the author's model, as it does in Savage's? It can of course happen that some consequences are never associated with some states, but don't they have the same utility for every state where they appear?

With all these holes and gaps in their analysis still open, the proof suddenly closes and the final sentence before Theorem 2.7 comes out of the blue: "The rather straightforward proof is omitted." In particular, their announcement "As it will be shortly shown, … this value depends only on the consequence x_i" (below Eq. 2.13) has never been

taken up. Whether the functional would imply the axioms is never discussed either. I think P4 is not implied. As for that matter, how is it defined here!?

And yet another question: The authors take two arbitrary constant acts, which they seem to treat as state-independent. Couldn't utility of these two be state-dependent, with the probabilities μ and the whole model depending on which two constant acts were used for this purpose!? Wakker & Zank (1999 MOR) study state-dependent EU functionals. For such a functional one can always fix two arbitrary nonindifferent outcomes, scale their utilities as 0 and 1 for every state, and then use them to identify the probability measure. But this probability measure depends entirely on the two outcomes chosen. For nonsimple acts, one then will also need some absolute continuity to ensure that the whole functional is writable as an integral of the probability measure obtained, which in absence of countable additivity is complicated.

§3 considers extensions to infinitely many outcomes. The authors consider countably many outcomes, and countably infinite summations of terms $\mu[f(s) = x_i]u\big(f^{-1}(x_i), x_i\big)$. They apparently are totally unaware of the complications of finite additivity here. One can't just do countable addition under the absence of countable additivity. The authors assume every event $\mu[f(s) = x_i]$ nonnull. It can well happen that the above sum does converge (even absolutely) but the sum of probabilities $\mu[f(s) = x_i]$ is strictly less than 1, for instance. It then gives violations of monotonicity. %}

Gaifman, Haim & Yang Liu (2015) "Context-Dependent Utilities: A Solution to the Problem of Constant Acts in Savage." *In* Wiebe van der Hoek, Wesley H. Holliday, & Wen-Fang Wang (eds.) *Proceedings of the Fifth International Workshop on Logic, Rationality, and Interaction*, vol. LNCS 9394, 90–101, Springer, Berlin.

{% This paper provides basically the same ideas as Gaifman & Liu (2015; cited).

The authors, correctly, point out that Savage (1954) is vague on what the set of acts in the preference domain is. Fishburn (1970) puts it right by immediately writing "F is the set of all functions of S into X" (§14.1, p. 192), and this is how we should take Savage's theorem. Yet, I disagree with many details in this paper, and also with the main ideas and results. In particular, I think that this paper is also

guilty of not clearly stating its assumed domain.

P. 4208 writes: "Savage insists however that we should not require the subjective probability to be σ-additive." It is only a matter of subjective interpretation of nuance, but I think that Savage rather insists that we should not care, and should not commit one way or the other. He is more saying that it should not matter rather than that we should do one thing or the other. But my interpretation here is open to debate.

The paper in particular criticizes Savage for assuming all constant acts present (implying that every consequence can be assigned to every state). It cites many who criticized Savage for the same reason. I have always been surprised by this. Savage's model involves many unrealistic acts, and the constant ones are just one special case. Well, they are a clearcut case, that is true.

The authors assume only for two nonequivalent consequences that the constant acts are available. This assumption is denoted 2CA on p. 4210. This is enough to do qualitative probability theory and get the subjective probability measure μ as is well known. CA denotes the assumption that every constant act is available in the preference domain.

P. 4209: Proposition 1.1, is claimed to hold under P1-P6 and CA. However, it needs more, such as the presence of sufficiently many simple acts. It seems that the authors throughout implicitly assume that the preference domain is closed under their cut-and-paste operation defined on p. 4211. That would be enough in the presence of CA to generate all simple acts.

P. 4210, footnote 10: The definition of null event is problematic because it uses the concept of preference given an event, which has not yet been defined there. But it could have been, in the presence of Savage's P2. The page argues that we should only consider "feasible" consequences, i.e., consequences that for some acts occur under nonnull events: "It is not difficult to see that the name is justified and that unfeasible consequences, while theoretically possible, are merely a pathological curiosity." However, I disagree. For example, in finance one may want to work with continuous probability distributions where each single consequence always has probability 0.

P. 4210, Proposition 1.2 claims SEU for all simple acts under P1-P6 and 2CA. But surely more is needed. The authors will implicitly use closedness under cut-and-paste: for two acts f and g and an event E, the act that agrees with f on E and with g on E^c is the result of cut-and-paste.

P. 4211 writes: "Savage takes it for granted that the acts are closed under cut-and-paste. Although the stipulation is never stated explicitly, it is obviously a property of A." That is, they criticize Savage, but themselves aloso never state explicitly whether or not they assume it. Their Proposition 1.2, preceding the def. of cut-paste, needs closedness under cut-paste to be correct, but it is not stated.

P. 4212 has a mysterious sentence: "The σ-algebra assumption can lead to even more extreme cases in a different area: the foundation of set theory. We will not go into this here, since this would require too long a detour."

P. 4214 incorrectly claims that Savage's state space should be uncountable; it need not be. First the page, correctly, writes that Savage's sigma-algebra must be uncountable, an immediate consequence of its μ-image being the uncountable[0,1]; μ denotes the subjective probability. However, it then incorrectly claims that the state space should be uncountable. We can take for S the rational numbers in [0,1], have μ([a,b] intersection S) = b-a for all rational a,b, and then take any finitely additive extension to the collection of all subsets. Such an extension cannot be countably additive, but finitely additive is well possible. We also have P6 and convex-rangedness (the authors use the term complete instead of convex-rangedness). For instance, for irrational numbers c,d in [0,1], μ((c,d) intersection S) = d-c. Btw., this countable example is easier than the case the authors present in their Theorem 3.34. Fishburn (1970) also incorrectly claims that Savage's S must be uncountable. Being a Ph.D. student end of the 70s, I sent a letter to Fishburn pointing out his mistake. He kindly replied and thanked me, and got it right in his follow-up writings. Strangely enough, the authors write on p.4216 middle that there exist "countable models that satisfy all the required postulates of Savage", where it is unclear what "model" means. The authors then seem to cite a Theorem 3.3.5 of Savage that, however, does not exist.

Section 3, the main part of the paper, considers qualitative probability theory. It shows that with P6´, which is equivalent to fineness and tightness, the derivation of μ, done for Savage for a σ-algebra, can also be done on an algebra. This was demonstrated before by Wakker (1981, Annals of Statistics). Wakker used fineness and tightness but, as these authors point out on p. 4216 bottom, this is equivalent to their P6´. That convex-rangedness then need not be satisfies is also well known (e.g., P_1 in Example 3 of Wakker 1981). These results also follow from Kopylov (2007 JET).

Section 4, supposedly, derives EU for simple acts. But the analysis does almost nothing of it. The authors show how utility can be defined from preferences if EU holds, using what Abdellaoui & Wakker (2018) call conditional SG equivalents. This is common as the first step in deriving preference axiomatizations, and is the easy step. Next steps are to show that the definitions are consistent, not depending on the particular stimuli chosen (e.g., the two constant acts assumed present), and then that the functional is of the kind claimed and does really represent preference. The authors do nothing beyond the first step, but then simply claim that they are done. Or should it be the vague sentence "The proof is straightforward." at the end of §4.1, p. 4236? P. 4210 end of penultimate para writes: "In Sect. 4, we take up the problem of CA. We argue that, as far as realistic decision theory is concerned, we need to assign utilities only to simple acts. Then we indicate the proof of Proposition 1.2. To a large extent this material has been presented in Gaifman and Liu (2015), hence we contend ourselves with a short sketch." It suggests, contrary to fact, that Gaifman and Liu (2015) would provide the proof. As I explain in my annotations to that paper, it does not do so. %}

{% Preferences between (x,C) and (x´,C´) where x and x´ are acts and C, C´ are sets of priors. C and C´ can be different and are exogenously given. Thus, the data set is very rich. The agent evaluates each (x,C) using the maxmin EU model where the set of priors is a subset of C. C reflects state of information and its subset reflects decision attitude. The paper generalizes some preceding papers on similar models by (subsets of) these authors.

Section 4 has a convenient subfamily of multiple priors: To define the subjective family of priors, we start from an objective set of priors denoted P, which is assumed given as it is assumed throughout this paper. s(P) is its midpoint (center of gravity; Steiner point), and $0 \leq \varepsilon \leq 1$ is a subjective parameter reflecting perceived ambiguity. The subjective family of priors to be used then consists of all convex combinations

$(1-\varepsilon)s(P) + \varepsilon Q$ for any Q from P.

This theory can be called contraction EU. A generalization would consist of allowing s(P) to be different than the midpoint of P.

Show that aggregation, if existing, must be linear, and that nonEU models such as RDU and maxmin EU cannot deliver belief aggregation. %}

Gajdos, Thibault, Jean-Marc Tallon, & Jean-Christophe Vergnaud (2008) "Representation and Aggregation of Preferences under Uncertainty," *Journal of Economic Theory* 141, 68–99.

{% Relative to the JME-2004 paper of the same authors, they drop the anchor. %}

Gajdos, Thibault, Jean-Marc Tallon, & Jean-Christophe Vergnaud (2004) "Coping with Imprecise Information: A Decision Theoretic Approach,"

{% The authors consider expert aggregation, comparing disagreement between precise predictions (one says 1/3, and the other says 2/3) with agreement between vague predictions (both say that it is either 1/3 or 2/3). Motivation is on pp. 420-421: "Therefore, the first step for making policy decisions in complex situations (such as, for instance, climate changes) is to *elicit* experts beliefs."

They introduce a theoretical decision model for it, building on ambiguity models of these authors (Gajdos, Hayashi, Tallon, & Vergnaud 2008 JET). Novelties in modeling are described on p. 431. Agents can choose between options that have different informations: For instance, they can choose between [a with experts saying A and B] or [b with experts saying C and D]. This cannot readily be modeled through Savage's state space, but the authors solve this problem by giving up on any interpretation of the state space, and they write: "state space … It is for us a mere coding device, without any substantial existence." (p. 421). The provide results on more averse to imprecision (Proposition 2, p. 437). Because now info provided by two experts is considered, and this can be different for different acts considered, the model is very general.

If one expert says that the true probability is in A, and the other says in B, then one could consider taking the intersection of A and B!?

However, Axiom A2 presented as-if dominance or Pareto, is not intuitive to me,

and seems like a form of not caring about conflict. For example, assume that P1 = Q1 = Q2 consisting of only one single probability, so that (f,P1), (g,Q1), (g,Q2) actually concern risk. Assume that P2 is different and also contains a singleton, so that (f,P2) is also risk. And assume that all four (f,P1), (f,P2), (g,Q1), (g,Q2) are indifferent. The authors' axiom implies

(f,P1,P2) ~ (g,Q1,Q2).

But this is not plausible because (f,P1,P2) comprises conflict and ambiguity and (g,Q1,Q2) does not. The axiom seems to imply indifference toward conflict and ambiguity. It treats P1 and P2 in a way as separable, not considering how they are related and agree or differ. This goes against the interpretations given. %}

{% Considers consequentialism and dynamic consistency under ambiguity. Says that one of these must be violated under ambiguity deviations from SEU, apparently taking reversal of events (analog of RCLA) implicitly. Relates dynamic consistency to positive value of info. (**value of information**) %}

Galanis, Spyros (2021) "Dynamic Consistency, Valuable Information and Subjective Beliefs," *Economic Theory* 71, 1467–1497. https://doi.org/10.1007/s00199-021-01351-y

{% **utility elicitation**: Asked for direct assessment of utility of money. Found that x to the power 0.43 fitted well for gains. Seems to find that subjects find it very difficult for losses. %}

Galanter, Eugene (1962) "The Direct Measurement of Utility and Subjective Probability," *American Journal of Psychology* 75, 208–220.

{% Seems simple. %}

Galanter, Eugene (1990) "Utility Functions for Nonmonetary Events," *American Journal of Psychology* 103, 449–470.

{% **utility elicitation**, p. 65: "But all of the data are sketchy, and the field is more populated with theory and derivations of a variety of models than it is with a wealth of empirical information"

P. 75: "The remarkable consistency of the power function as a representation of data that show how people judge events that have a quantitative character is once again supported in these studies."

P. 75 suggests loss aversion using nice words: "On the basis of intuition and

anecdote, one would expect the negative limb of the utility function to decrease more sharply than the positive limb increases."

concave utility for gains, convex utility for losses: Power for gains is 0.45 (Experiment 1, p. 68), for losses it is 0.59 (Experiment 2, p. 70). So, utility is concave for gains and (less) convex for losses.

Cross-modality matching means comparing subjective evaluations of different continua with each other. This paper does it with money and loudness. For example, is the value of this amount of money the same as the loudness of this tone? Power transformations seem to fit the data well. The method can be compared to the VAS that asks to relate lengths of lines to value of money/lifeduration, be it that length of a line is objective.

More pessimistically, it can be argued that this kind of research demonstrates that subjects answer to all questions no matter what the questions are. One may be measuring stable response modes without anything underlying it. I haven't yet made up my mind on the validity of this viewpoint.

Christiane, Veronika & I: cross-modality matching seems to measure numerical sensitivity more than intrinsic value. %}

{% Primary/secondary quality distinction:

"I think that tastes, odors, colors, and so on are no more than mere names so far as the object in which we locate them are concerned, and that they reside in consciousness. Hence if the living creature were removed, all these qualities would be wiped away and annihilated."

John Locke discussed it extensively. Leibniz argued that it is gradual. Berkeley argued that only secondary (subjective) we can know for sure. %}

Galilei, Galileo (1623) *The Assayer*.

{% Seems that the character Sagredo says, on the water-diamond paradox:

What greater stupidity can be imagined than that of calling jewels, silver and gold "precious," and earth and soil "base"? People who do this ought to remember that if there were as great a scarcity of soil as jewels or precious metals, there would not be a prince who would not spend a bushel of diamonds and rubies and a cartload of gold just to have enough earth to plant a jasmine in a little pot, or to sow an orange seed and watch it sprout, grow, and produce its handsome leaves, its fragrant flowers and fine fruit. It is scarcity and plenty that make the vulgar take things to be precious or worthless; they call a diamond very beautiful because it is like pure water, and then would not exchange one for ten barrels of water.

This is apparently in Dava Sobel (1999) "*Galileo's Daughter: A Historical Memoir of Science, Faith, and Love.*" Fourth Estate, London, p. 152. %}

Gamut, L.T.F. (1991) *Logic, Language, and Meaning* (Vol. 1. Introduction to Logic, Vol. 2. Intensional Logic and Logical Grammar). The University of Chicago Press, Chicago.

{% Mehrez & Gafni, end 1980s, introduced their so-called healthy years equivalent (HYE) as an alternative to QALYs in health economics. Unfortunately, their papers have many logical errors, and many have criticized it, including Johannesson, Pliskin, & Weinstein (1993, MDM), Loomes (1995, JHE), and myself (Wakker 2008 MDM). This paper is a follow-up, worthy of the traditions, because again it is full of logical errors. The basic new model, Eq, 2 p. 1210, is not well defined because a utility function of (x,x_2) (wiggle above x and arrow above x_2 I do not write here) he lets depend on other things than just (x,x_2), being a distribution $L(u_2(x))$ of x of which it has never been specified formally where it comes from. L should by the rules of logic have been expressed as an argument of the utility function then. But then the theory becomes very different from traditional QALY models that first take utility of outcomes without regarding any distribution and only then look at distribution and see how the utilities are to be aggregated, using a probability-weighted mean as in EU or some other aggregation formula. In particular, it loses the tractability of QALYs where evaluation of outcomes is separated from the aggregation of distribution. It now also is unclear if the utility as the author defines should be maximized using an EU aggregation, or otherwise. The author sometimes (p. 1211 top and also 2nd para) explicitly writes that he is deviating from EU. So, in what theory is this function to be used? There he seems to take his model as just taking certainty equivalents without even EU, so that his model is not much more than continuity and transitivity, leaving almost no predictive power.

Many positive claims about HYE are based on nothing other than that HYE is, here, apparently, taken as nothing other than a certainty equivalent (with health assumed perfect) under general EU. Then little wonder that no empirical violations (other than general EU), but problem that little predictive power (mentioned on p. 1210 4th para but not properly incorporated in the rest of the text). Then little wonder that the particular case of SSUF and HYE coincide whenever the model of SSUF holds (pp. 1209-1210).

P. 1210 makes the mistake criticized in Comment 2.6.5 of my 2010 book (p. 63), of not realizing that the utility unit already comprises risk attitude, and that speculating on risk attitudes w.r.t. util units is double counting.

P. 1211 surprises us with the claim that the risk theory of EU would imply the intertemporal restriction of time consistency. New to me!

The second para seems to present, as a positive feature of the theory, that we don't "need to" elicit its separate parameters. I would put this more negatively: These parameters are not identifiable because the theory is of almost complete generality. P. 1211 end of 2nd-to last para writes that the only assumption is monotonicity in life years in full health. (Let us give the author continuity and weak ordering for free.)

equate risk aversion with concave utility under nonEU: P. 1211 penultimate para then equates risk aversion with concave utility, which only holds true under EU, a theory explicitly abandoned here.

One thing the author and I share is admiration for the appealing idea (SSUF) of Guerrero & Herrero (2005). %}

{% Seems to have introduced psychological game theory. Unfortunately, also this term, taking psychology—a field broader and more diverse than economics—as one concept. It is like psychologists using the term "economic game theory" because games involve money, or "mathematical game theory" because on page 2 they used a formula. %}

Geanakoplos, John, David Pearce, & Ennio Stacchetti (1989) "Psychological Games and Sequential Rationality," *Games and Economic Behavior* 1, 60–79.

{% 12 subjects chose repeatedly (768 times), 24 blocks of each 32 times, between two fifty-fifty gambles yielding a gain or loss of x for x = 5 or x = 25 cents. So, they must choose whether x = 5 or x = 25. They received sum total at end of each block. As William explained to me on August 21, 2002, in an email, the latter happened only if that total was positive. If the total was negative it was not subtracted. 52% of the choices were risk seeking, so, x = 25 instead of x = 5. Given that the incentive system enhances risk seeking, it is not amazing that there was some more risk seeking.

Brain-activities for losses were qualitatively different than for gains. After a preceding loss people became more risk-seeking than after a preceding gain. In the first quarter of blocks, there were 58% risky choices (x = 25), in the last 48%.

Because subjects could also see what their alternative choice would have yielded, they could feel regret. But, regret did not do much. I did not find it mentioned what percentage overall was risk seeking (choose x = 25 cents) or risk averse (choose x = 5 cents). How the real incentives were implemented (did they have to pay really if the lost?) is not explained. %}

{% **foundations of statistics**

P. 973 describes the essence of the paper: "we propose to replace, wherever possible, the words 'objectivity' and 'subjectivity' with broader collections of attributes, namely by transparency, consensus, impartiality and correspondence to observable reality, all related to objectivity, awareness of multiple perspectives and context dependence, related to subjectivity, and investigation of stability, related to both." This sentence lists the seven criteria displayed in Table 1.

A good old discussion on statistics with many (53 it seems) discussants writing after. I read many such discussions in the 1980s. The authors focus on the distinction objective-subjective, which is related to the distinction frequentist-Bayesian. They consider it to be counter-productive. Instead, they put up a useful Table 1 with seven desiderata for statistical analyses.

P. 969: "Researchers often rely on the seeming objectivity of the $p < 0.05$ criterion without realizing that theory behind the p-value is invalidated when analysis is contingent on data (Simmons et al., 2011; Gelman and Loken, 2014)."

P. 970: "Some Bayesians (notably Jaynes (2003) and Berger (2006)) have advocated an objective approach, whereas others (notably de Finetti (1974)) have embraced subjectivity."

P. 972: "science should be guided by principles that at the same time aim at stable and reliable consensus as usually associated with 'objectivity' while remaining open to a variety of perspectives, often associated with 'subjectivity', exchange between which is needed to build a stable and reliable scientific world view."

P. 974: "For example, Bayesian statistics is commonly characterized as 'subjective' by Bayesians and non-Bayesians alike. But, depending on how exactly prior distributions are interpreted and used (see Sections 5.3–5.5), they fulfil or aid some or all of the virtues that were listed above. Priors Beyond Subjective and Objective 975 make the researchers' prior point of view transparent; different approaches of interpreting them provide different rationales for consensus; 'objective Bayesians' (see Section 5.4) try to make them impartial; and if suitably interpreted (see Section 5.5) they can be properly grounded in observations."

P. 976 gives Table 1, reproduced here:

"**Table 1.** Virtues

V1. Transparency

(a) Clear and unambiguous definitions of concepts

(b) Open planning and following agreed protocols

(c) Full communication of reasoning, procedures, spelling out of (potentially unverifiable) assumptions and potential limitations

V2. Consensus

(a) Accounting for relevant knowledge and existing related work

(b) Following generally accepted rules where possible and reasonable

(c) Provision of rationales for consensus and unification

V3. Impartiality

(a) Thorough consideration of relevant and potentially competing theories and points of view

(b) Thorough consideration and if possible removal of potential biases: factors that may jeopardize consensus and the intended interpretation of results

(c) Openness to criticism and exchange

V4. Correspondence to observable reality

(a) Clear connection of concepts and models to observables

(b) Clear conditions for reproduction, testing and falsification

V5. Awareness of multiple perspectives

V6. Awareness of context dependence

(a) Recognition of dependence on specific contexts and aims

(b) Honest acknowledgement of the researcher's position, goals, experiences and subjective point of view

V7. Investigation of stability

(a) Consequences of alternative decisions and assumptions that could have been made in the analysis

(b) Variability and reproducibility of conclusions on new data"

Even if one does not fully agree with such a table and even if one feels more disagreements than agreements, then still, where it takes much work to create such a table, it is very useful.

P. 979: "with the Bayesian fitting algorithm being stuck going through remote regions of parameter space that corresponded to *implausible or unphysical parameter values*." [italics added here]

P. 980: "The point is not that our particular choices of prior distributions are 'correct' (whatever that means) or optimal, or even good, but rather that they are transparent, and in a transparent way connected to knowledge. Subsequent researchers—whether supportive, critical or neutral regarding our methods and substantive findings—should be able to interpret our priors (and, by implication, our posterior inferences) as the result of some systematic process, a process which is sufficiently open that it can be criticized and improved as appropriate." This may be the idea of objective Bayesianism. If we take some standardized (say, noninformative) prior that is transparent (so, everyone knows it), then everyone can back it out and put in their own preferred prior. In other words, then it can serve just as a convenient way to just convey the likehood function.

P. 984: "In doing this, we deviated from classical significance test logic in several ways, by not using a test statistic that was optimal against any specific alternative, by not arguing from a single p-value and by using a null model that relied heavily on the data" They "admit" here that they chose the test after seeing the data.

P. 987, §5.2, discusses works by Mayo et al. who defend frequentist approaches.

P. 989: "Dawid (1982b) discussed calibration (quality of match between predictive probabilities and the frequency of predicted events to happen) of subjectivist Bayesians inferences, and he suggested that badly calibrated Bayesians could do well to adjust their future priors if this is needed to improve calibration, even at the cost of violating coherence."

P. 989 §5.4 is on objective Bayesianism, and on Jaynes who favors he logical view of probability.

P. 990: "Jaynes (2003) admitted that setting up objective priors including all information is an unsolved problem. One may wonder whether his ideal is achievable at all."

P. 990 ff.: The authors seem to favor falsificationist Bayesianism, which seems to combine Bayesian ideas with frequentist interpretations of probability. Oh well.

P. 1004, comment by Bartholomew, criticizes the sufficiency concept:

" 'Sufficiency', for example, is an important concept which is often too limited for situations in which it is used."

P. 1004, comment by Bartholomew, is related to the stopping rule paradox: "In this connection it is readily recognized that all so-called frequentist inferences involve a degree of subjectivity. For example, although the sample size may be treated as fixed, this may not actually be so. The choice may, in fact, have resulted from the resolution of conflict between competing interests, or the data may actually be the outcome of a sequential experiment with ill-defined and often unrecognized stopping rules. Conditioning on the sample size we ignore some information which may be relevant. Such 'objective' inferences may thus easily conceal an unacknowledged subjective input."

P. 1020: comment by Stephen M. Stigler is very critical.

P. 1023: comment by Eric-Jan Wagenmakers at the end uses emotionally-loaded terms to plead for Bayesianism.

P. 1020: comment by Winkler: "The subjective–objective dichotomy in statistics has its roots in the Bayesian–frequentist debate that seemed most heated when Bayesian methods were starting to gain traction in the 1950s–1970s."

P. 1025, the authors' reply cites formalizations of exploratory data analysis. %}

{% **dynamic consistency**: **favors abandoning time consistency, so, favors sophisticated choice**: does so descriptively; **updating under ambiguity with sampling** A follow-up paper, analyzing the same data set, is Georgalos (2021).

This paper uses Hey's bingo blower, with a ball to be drawn with three possible colors but unknown probability, to generate ambiguity. Subjects can allocate money to the three colors by state-contingent exchange rates that can change between different choice situations. They also do so after updating, being informed only about whether one particular color did or did not obtain. For nonEU one has to make problematic assumptions about updating. This paper maintains SEU's consequentialism and gives up dynamic consistency (p. 58; §4), which I think is empirically most plausible here. The data will indeed give many violations of dynamic consistency (p. 58 footnote 12). Georgalos (2021, p. 30 top) confirms that this paper assumes, and does not test, consequentialism. That is tested by Georgalos (2021).

The paper considers α maxmin, Choquet expected utility (CEU), prospect theory through Abdellaoui et al.'s (2011) source method (implemented as in Kothiyal, Spinu, & Wakker 2014 JRU), the Chateauneuf et al. (2007) neo-additive model, and SEU. Given that there are no losses, prospect theory through the source method is in fact a particular specification of CEU. So is the neo-additive model. As an aside, also α maxmin (implemented here as in Hey et al. 2014), in fact is so, as can be seen. I assume that what the authors call CEU means that no parametric assumption is made about W. For utility it takes CRRA throughout.

The paper does not consider the smooth model because the author writes that consequentialism then is problematic. I do not fully understand this. At least the basic smooth model that I know satisfies dynamic consistency and consequentialism, but violates reduction of compound lotteries. My difficulty with the smooth model is that the second-order distribution to be chosen is too general a parameter, of too high dimensionality, and essentially unobservable. The paper also considers various parametric families, and various update rules. For multiple priors it uses the same family of priors as Hey et al. (2014) do.

The paper uses predictive power as criterion. The best performing model is the source method, with Choquet expected utility as close second.

P. 57 last para defends the RIS against the hedging-for-ambiguity argument, mostly arguing that subjects cannot know beforehand the choice situations occurring in the experiment.

P. 58 Eq. 1: note that the author will allow the weights w to depend on the outcomes, e.g., as under rank dependence.

P. 76: **ambiguity seeking for unlikely**: the author finds likelihood insensitivity, but it concerns general uncertainty and not only ambiguity because no risk attitude is taken out. %}

Georgalos, Konstantinos (2019) "An Experimental Test of the Predictive Power of Dynamic Ambiguity Models," *Journal of Risk and Uncertainty* 59, 51–83. https://doi.org/10.1007/s11166-019-09311-7

{% **updating under ambiguity with sampling**

Georgalos (2019, GEB) considered dynamic choices under ambiguity, with updating, assumed consequentialism (I guess), and then tested several models, finding that Abdellaoui's (2011) source method performs best. This paper further analyzes the same data set, but now critically considers consequentialism. It distinguishes between resolute choice, sophisticated choice, and naïve choice. It is close in spirit to the marvelous Cubitt, Starmer, & Sugden (1998) for risk, although the conditions tested are not exact analogs. For instance, the conditions tested here involve repeated choices and this was not so in Cubitt et al. Some more than half of the subjects are not ambiguity neutral. Of them, most are sophisticated, some are naïve and very few are resolute. (**dynamic consistency**: **favors abandoning time consistency, so, favors sophisticated choice**; however, descriptively, with no normative position taken).

One general observation: In the ambiguity literature, researchers usually assume EU for risk, and then ambiguity neutrality is equivalent to SEU and (under some minimal assumptions) can readily be made to satisfy consequentialism, dynamic consistency, sophistication, resoluteness, and everything. However, empirically, people violate EU for risk, and then ambiguity neutrality does not give SEU, and still means that some of the dynamic principles are violated. This paper assumes α maxmin and, therefore, has this problem. For instance, p. 35 ℓ. -3 writes: "The resolute type is dynamically consistent but has ambiguity non-neutral preferences." In reality, a resolute agent can be ambiguity neutral but still violate consequentialism and sophistication, already in her risk preferences.

Finding 3 confirms **inverse S** for ambiguity and **ambiguity seeking for unlikely**. In general, the paper finds as much ambiguity seeking as aversion, once again confirming the fourfold pattern of ambiguity and that ambiguity aversion is not at all as widespread as was once thought.

P. 57 last para defends the RIS against the hedging-for-ambiguity argument.

{% Bouchouicha et al. (2019 JRU), in a big empirical study, tried to estimate loss aversion, but found completely opposite results depending on parametric specifications and specific definition of loss aversion. This paper presents a detailed study, also of collinearity of prospect theory parameters. Wakker (2010 §9.6) noted a problem of a definition of loss aversion with the popular logpower (= CRRA) utility, being that the loss aversion found depends much on the unit of money chosen. He also noted that that problem does not arise if we take the same power of utility for gains and losses. This paper finds that this way, taking logpower utility, works best, giving consistent estimates of loss aversion. %}

{% With belief functions, model with subpartition describing all that is observed and acts are correspondences; to them Savage's axioms are applied, leading to a probability distribution over subsets of outcomes, which, in turn, is uniquely related to a belief function over outcomes, being its Möbius inverse. Is similar to Jaffray & I, generalizing it in an appealing manner. %}

Ghirardato, Paolo (2001) “Coping with Ignorance: Unforeseen Contingencies and Non-Additive Uncertainty,” *Economic Theory* 17, 247–276.

{% **updating: discussing conditional probability and/or updating**: Uses **dynamic consistency** and consequentialism to model Savage’s SEU plus Bayesian updating. Not very new (in a lecture Paolo called the result a folk theorem), but done neatly and maybe the nicest paper to demonstrate how dynamic principles imply EU.

The only choice options are static functions from state space to outcomes; i.e., the static analogues of strategies. This automatically implies RCLA. Paolo clearly and explicitly says so two paras above Axiom 1. For each event A, a conditional pref $\succcurlyeq_A$ is given. Can be interpreted as anticipated-conditional, or ex post. Paolo explicitly leaves both open. In this setup, a choice f $\succcurlyeq_A$ g, such as considered in DC (dynamic consistency) (axiom 2) for f and g disagreeing outside of A, is not easily depicted in a conventional decision tree. It is therefore easier to first assume consequentialism (axiom 7). This axiom does not refer to de novo decisions, such not occurring in the model, but says that $\succcurlyeq_A$ ignores the counterfactual part (so that de novo decisions can be meaningfully defined, independently of what counterfactual part is assumed). With that given, Paolo’s DC reduces to the usual DC that [$\succcurlyeq$ if agreement outside of A] agrees with [$_A$ if agreement outside of A]. Paolo’s DC also requires agreement of [$\succcurlyeq$ if agreement outside of A] with [$_A$ if no agreement outside of A] which is a bit hard to interpret. %}

{% **event/outcome driven ambiguity model: event driven**

The authors refer to unpublished work by Nehring for similar ideas. They consider a representation

$$f \dashrightarrow \alpha(f)\inf_{P\in C}\int_S U(f(s))dP + (1-\alpha(f)) \sup_{P\in C}\int_S U(f(s))dP$$

where f is an act mapping S to outcomes, C is a set of probability measures on S, $\int_S$ is the integral over S, U is utility, and $0 \le \alpha \le 1$. Arrow-Hurwicz is the special case of α constant and C the set of all probability measures.

Without any restriction, this model has little predictive power because of the generality of α depending on f in every possible way, apart from the EU evaluation of risk and the required certainty equivalence. We can always let C be the set of all probability measures, so that inf is the worst outcome of f and sup the best, and with $\alpha(f)$ we can get whatever is the desired midpoint between their utilities. The authors impose the following restriction on C. Let ≥´ be the preference relation. They define as the unambiguous part ≥´* the preferences f ≥´* g whenever $\lambda f + (1-\lambda)c$ ≥´ $\lambda g + (1-\lambda)c$ for all λ from [0,1] and acts c (by taking λ close to 0, they can let the decision take place in the comonotonic set with rank-ordering or whatever circumstances as dictated by c, so, whatever they want it to be). ≥´* is a nice and valuable idea.

As regards the mixing operation on acts, they assume the Anscombe-Aumann structure on S, amounting to a convex space of outcomes with linear utility U and statewise mixing for the acts. So, the unambiguous preferences are those that reflect vNM independence and behave according to EU. ≥´* is like an EU preference, only it is not complete. Then they use the appealing representation by Castagnoli, Maccheroni, & Marinacci (2003), and others, that f ≥´* g if and only if there is unanimous agreement that $\int_S U(f(s))dP \ge \int_S U(g(s))dP$ for all P from a set C. They take the set C above to be this set. This makes the representation operational, although I would not call it observable because it still is an existence result not fundamentally different from the existence result of for instance Gilboa & Schmeidler (1989).

The sup of expected utilities above turns out to correspond to the lowest sure outcome x^* that has $x^* \geq'^* f$, and the inf of expected utilities above corresponds to the highest sure outcome x_* that has $x_* \leq'^* f$. So, the value of f is between x^* and x_*, and $\alpha(f)$ is derived from this. The set C turns out to be the smallest set that could be used.

$\alpha(f)$ is constant (independent of f) if and only if x^* and x_* completely determine the preference value of f (Proposition 19). This gives the famous α maxmin model, which the paper is mostly cited for. This result would have been appealing and the main result of this paper because for tractability reasons it is desirable that α not be very general. However, Eichberger, Grant, Kelsey, & Koshevoy (2011, JET) later showed that it is not correct. For finite state spaces the α maxmin model can only exist, under the axioms of this paper, if $\alpha = 1$ or $\alpha = 0$, that is, when it is maxmin or maxmax as known before.

The authors interpret $\geq'^*$ as unambiguous preferences, C as reflecting the state of belief and of ambiguity of the agent, and $\alpha(f)$ as reflecting attitude towards ambiguity. It means that for the special case of maxmin EU they take the whole set of priors as reflecting belief, and not decision attitude. For example, if there is DUR with known probabilities, the agent does RDU with convex probability transformation w, so that we have CEU (Choquet expected utility) with convex nonadditive measure $w(P(.))$, then this model can be written as maxmin EU (the priors are the CORE of $w(P(.))$), and then the authors consider this to reflect ambiguous beliefs.

The authors discuss the point just raised. First, p. 137 next-to-last para discusses that absence of and neutrality towards ambiguity cannot be distinguished in their approach, and that they equate SEU with unambiguous. P. 138 then mentions the big problem that what they call ambiguity also comprises the part of risk attitude that deviates from expected utility (see above example of RDU with convex w). Amarante (2009, §3.1) criticizes the interpretation.

The authors emphasize that they do not want to use objective probabilities as given, based on non-preference info, because they do not want to use such info. (p. 138 ℓ. 12-13). Problem is that the Anscombe-Aumann framework uses (such?) probabilities. The authors defend (p. 138 3rd para) by saying that such probabilities, and the corresponding mixing operation, can be obtained subjectively, justifying it by referring to Ghirardato, Maccheroni, Marinacci, & Siniscalchi (2003, *Econometrica*). Big problem is that such subjective probabilities are not directly observable, but must be derived from preferences. There is a rule of the game in preference axiomatizations that one does not use such inputs in axioms, just the same as one does not use utilities in preference axioms. %}

Ghirardato, Paolo, Fabio Maccheroni, & Massimo Marinacci (2004) "Differentiating Ambiguity and Ambiguity Attitude," *Journal of Economic Theory* 118, 133–173. https://doi.org/10.1016/j.jet.2003.12.004

{% I first describe what the theorem in the paper, Theorem 1, does mathematically. Then I describe the interpretation that the authors give to it, which I think is incorrect. It also obscures the mathematical result of Theorem 1. Clearer statements of some results may be in Sokolov (2011) (I did not check out exactly now).

Theorem 1 is as follows. S is a state space, finite or infinite. Acts map S to an interval $K \subset \mathbb{R}$ and have finite range. (The authors interpret these real numbers as utility units; see below. But this interpretation does not play any role for the maths. All of their maths is only about those "utilites" and in no way involves where those utilities may come from or what they are.) I prefer for now to call these real numbers outcomes. One can endow S with an algebra and restrict to measurable acts. Outcomes α are identified with constant acts. $\succcurlyeq$ is a preference relation over acts. It is a nontrivial weak order that is monotonic (in the weak sense: $f \geq g$ statewise $\Rightarrow$ $f \succcurlyeq g$). We assume a certainty equivalent I(f) for each f.

I is *constant affine* if $I\big(\lambda f + (1-\lambda)\alpha\big) = \lambda I(f) + (1-\lambda)\alpha$ for all acts f, $0 \leq \lambda \leq 1$, and $\alpha \in K$. For $K = \mathbb{R}$ it is equivalent to *constant linearity*: $I(\lambda f + \mu) = \lambda I(f) + \mu$ for all $\mu \in \mathbb{R}$ and $\lambda \geq 0$. It readily follows that for a two-element S this is equivalent to I being a rank-dependent (=biseparable) functional with linear utility, and in general it implies biseparable utility with linear utility.

In my terminology, *constant absolute risk aversion* (called homotheticity in more general contexts beyond uncertainty) holds if $I(f+\alpha) = I(f) + \alpha$ for all acts f and real α such that all involved are acts (outcomes in K), and *constant relative risk aversion* (more generally called homogeneity (of degree 1)) holds if $I(\lambda f) = \lambda I(f)$ for all acts f and $\lambda \geq 0$ such that all involved are acts.

In Theorem 1, Statement (i) is readily seen to be equivalent to constant relative and constant abolute risk aversion. Theorem 1 then says that it is equivalent to I being constant affine (Statement ii) and it is also equivalent to Statement (iii): certainty independence $\left(f \succcurlyeq g \iff \lambda f + (1-\lambda)\alpha \succcurlyeq \lambda g + (1-\lambda)\alpha \text{ for all } 0 < \lambda < 1\right)$. These things imply that I is biseparable with linear utility and, for two elements in S, it characterizes biseparable utility (= rank-dependent utility) with linear utility. (This special case I have known since my youth because Chew Soo Hong told me. But I don’t know any place other than here where it is written in the literature.) If S had three or more nonnull elements then we have biseparable utility with linear utility but with the extra restriction that I is constant affine for all acts.

The authors state Statements (i) and (ii) in a more complex manner by letting transformations v intervene, but this is readily seen to be equivalent to my above statements by referring back to certainty equivalents.

I next turn to the interpretations that the authors give to the result. As written above, they interpret elements of K as units of a utility function u. They further assume that u results from a representation where it is an interval scale, i.e., it is unique up to scale and location. (This interpretation already complicates the readers’ understanding, because they have to understand that this whole framework underlying u in fact does not play any role in the mathematical meaning of Theorem 1. Sokolov (2011) may be clearer.) But u is now used for some further purpose, through I. The typical case is the Anscombe-Aumann (AA) framework, where u results from representing risky choices (between probability distributions over what will now be called prizes) through the expected utility formula, and is next used in I to capture ambiguity attitudes. The authors have this AA framework in mind, where they interpret I as capturing beliefs, although they express proper reservations about this interpretation. Next comes the mistake in interpretation.

The authors assume, erroneously, that functional I should "respect" the interval scale property of u, implying that I should be compatible with affine transformations of outcomes = u-values, i.e., satisfy constant absolute and relative risk aversion in my above terminology, or, equivalently, certainty independence. However, there is nothing in the world why this should be so. An example to clarify: Assume that the agent does expected value maximization for risk. Thus, changing the unit of money from cents to dollars (multiplying all prizes by 100) does not matter for the risk attitude. Then this multiplication may still very well affect the ambiguity attitude. For gains, the agent may be ambiguity neutral as long as all prizes are below $1000, but become ambiguity averse if prizes exceed $1000. For instance, in the KMM smooth ambiguity model, with u the identity function, φ (the second-stage function transforming u due to ambiguity) may be linear up to 1000, but become concave above. Put differently, for ambiguity attitudes we know exactly what the prizes are and may use more info about prizes than what risk attitude they generate. (If the authors defend by saying that I depending on utilities means that the info about the underlying prizes is lost: this is a completely unrealistic assumption in any application. One knows the underlying prizes more than their utilities.) Put yet differently, whether a function is an interval scale, is not an absolute property of that function, but depends on what we want to do with that function. Scale type is a "meta-property," depending on our wishes. Thus, u may be an interval scale when representing risky choice, but not when giving ambiguity attitudes.

The authors could argue that they want I to reflect belief and, if it is different for prizes below $1000 than above, then I is not just belief. However, more formalization then remains to be done, to explain more how beliefs are or are not supposed to depend on prizes, events, and so on. The authors can go circular and say that this is how they define beliefs, but then the result is circular and trivial. I have the same basic objection against Nash (1950). See my annotations there. %}

Ghirardato, Paolo, Fabio Maccheroni, & Massimo Marinacci (2005) "Certainty Independence and the Separation of Utility and Beliefs," *Journal of Economic Theory* 120, 129–136.

{% Decision under uncertainty. Assume that a Choquet expected utility representation exists for all binary acts. CE denotes certainty equivalent. Then, under appropriate rank-ordering,

CE(CE(x,y),CE(v,w)) ~ CE(CE(x,v),CE(y,w)) follows from substitution; this is bisymmetry. They define a midpoint operation x*z = y, assigning midpoint y to x and z, by CE(CE(x,x),CE(z,z)) ~ CE(CE(x,y),CE(y,z)), for x > y > z. Substitution shows that y is the midpoint of x and z in utility units. By repeated procedures we can, thus, get (where mixing is always in utility units) x/4 + 3z/4, 3x/4 + z/4, etc., so, ax + (1-a)z for a dense subset of a's in [0,1] (all dyadic a's). By limit taking, or approximately, we can get it for all a in [0,1]. Note that eliciting all these mixtures amounts to the same as eliciting the utility function itself.

The authors argue that now the mixing operation is observable, behavioral as they call it, and that it can be used as a primitive in axioms. They subsequently reformulate preference axioms in the literature in this manner for extraneous mixing à la Anscombe-Aumann (1963).

derived concepts in pref. axioms: A difficulty is that the mixture operation becomes observable only after a long elicitation procedure. Preference axiomatizations in terms of this are in fact very complex axioms, not easily testable. For instance, f ~ g $\Rightarrow$ f/3 + 2h/3 ~ g/3 + 2h/3, mixture independence for mixture weight 1/3, can never be verified exactly, because weight 1/3 can never be obtained exactly; it can only be verified approximately or in the limit. When Hübner & Suck (1993) similarly used a preference condition in terms of observables that involves infinitely many preferences, they explicitly mentioned this as a weak point on p 638.

The axioms could have been stated directly in terms of utility as well as in terms of the mixing operation, because utility can be elicited as easily, in fact through the same observations, as the mixture operation. (Sugden, *Journal of Economic Theory* 1993, similarly demonstrated how utility can be elicited and then used it as a primitive in axioms. I would not call that behavioral for the same reasons.) I consider this approach derived measurement. While their axiomatizations are logically true, they do not have the behavioral status and appeal of preference axiomatizations that can be stated directly in terms of a small number of preferences. The results of this paper are logical equivalences between two statements in theoretical terms. The authors could have avoided these problems for Choquet expected utility by imposing their axioms only for .5/.5 mixtures, which given continuity will imply the whole axiom. They have such, more appealing, results in the 2003 extended version of this paper.

Besides Choquet expected utility, the authors also characterize maxmin EU, and Bewley's (1982, 2002) model under the special assumption that there is an event E for which subjective expected utility holds, implying that all probability measures in the set of priors assign the same probability to E. This rules out, for instance, probabilistic risk attitudes with RDU with the probability weighting strictly convex.

Köbberling & Wakker (2003 *Mathematics of Operations Research*) use a tradeoff consistency axiom and show in their §7 that the axiom is weaker than the bisymmetry axiom used in this paper, so that most theorems in this paper are immediate corollaries of the K&W theorms. Unfortunately, this paper does not cite K&W.

P. 1897 writes negatively about the Anscombe-Aumann (AA) framework: "In the AA setting, payoffs are lotteries contingent on the output of a randomizing device, or 'roulette wheel.' Postulating the existence of such a device, characterized by objective probabilities, is generally considered unappealing and philosophically debatable (cf. the references cited in Section 4)." The authors are critical of using objective probabilities here. %}

Ghirardato, Paolo, Fabio Maccheroni, Massimo Marinacci, & Marciano Siniscalchi (2003) "A Subjective Spin on Roulette Wheels," *Econometrica* 71, 1897–1908.

{% **criticizing the dangerous role of technical axioms such as continuity**: Krantz et al. (1971 §9.1), and other works, explain that "technical" axioms such as continuity are dangerous because they add implications to intuitive axioms, and we don't know exactly what those are. The authors refer to Krantz et al. for this point, and illustrate it by other examples, regarding the technical assumption of solvability (range convexity as they call it) of a capacity.

The main point is that under CEU/RDU and convex-rangedness, the existence of one symmetric event such as implied by complement-symmetry preference axioms for that event (betting on or betting against the event gives same likelihood ordering) and convexity as implied by what is often interpreted as ambiguity aversion, together imply additivity and SEU. It is like a continuous strictly increasing function w from [0,1] to [0,1] with w(0) = 0 and w(1) = 1, if it is convex and if there is a p with w(p) + w(1–p) = 1 (implying that not both w(p) and w(1–p) can be below the diagonal), then w must be linear. The authors argue, on p. 609 end of §3, that the existence of such an event (or such a p) is a weak assumption, and then put the blame on convex-rangedness. %}

Ghirardato, Paolo & Massimo Marinacci (2001) "Range Convexity and Ambiguity Averse Preferences," *Economic Theory* 17, 599–617.

{% **event/outcome driven ambiguity model: event driven**

That preferences satisfying CEU (Choquet expected utility) on binary (two-valued) acts can be useful and interesting has been observed before (Miyamoto & Wakker 1996 OR; Luce 2000 Ch. 3; Miyamoto 1988 for risk), as it has been that such acts suffice to identify utility and the capacity. But no one used this insight as clearly and thoroughly as this paper does. The results obtained apply to all theories that agree with CEU on binary acts, such as maxmin EU, Gul's disappointment aversion theory, prospect theory only for gains or only for losses, and α-Hurwicz.

In most places the paper interprets the capacity (= weighting function), nicely, as willingness to bet. Sometimes, however, it interprets the capacity as belief (claiming a separation of tastes and beliefs), which is questionable. They point this out in §5.2, p. 879.

Like Epstein, the authors do not want to use objective given probabilities. Then it is hard, or impossible, to separate out the risk attitude component from the capacity (and take what remains as ambiguity component). However, this does not justify the assumption of the authors that there be no risk attitude in the capacity, and that the capacity consists merely of ambiguity attitude. In the terminology that the authors use, probabilistic risk attitude ends up in the wrong place. It should be part of risk attitude, not of ambiguity attitude as it now is. In the authors' terminology, "risk attitude" refers merely to utility. By not wanting to use objective probabilities for the study of ambiguity, the authors have the same basic problem as Epstein (1999). I discuss the case in my annotations to Epstein (1999).

biseparable utility: Emphasized much and a central topic in this paper. They use the term biseparable for it. They impose the Chew & Karni (1994) CEU axioms on binary acts only, giving the CEU representation only there. Show that results on utility, such as u_2 being concave transform of u_1 iff certainty equivalents for u_2 smaller than for u_1, can be derived in their model as well; i.e., if SEU on a comonotonic subset for two states of nature. However, they make the nonbehavioral assumption of equal capacity for the two agents (they suggest they have an axiom for that but don't give it). For real outcomes, they adapt preference for diversification and quasi-convexity characterizations of concave utility to their model.

binary prospects identify U and W;

§5.1, on probabilistic beliefs for binary acts: this is also in Pfanzagl (1959).

%}

Ghirardato, Paolo & Massimo Marinacci (2001) "Risk, Ambiguity, and the Separation of Utility and Beliefs," *Mathematics of Operations Research* 26, 864–890. https://doi.org/10.1287/moor.26.4.864.10002

{% **tradeoff method**: use it on p. 264 and elsewhere to characterize identity of two utility functions in their cardinal symmetry.

I think that a better title of this paper would have been:

"A Separation of Utility and Uncertainty Attitude."

They consider CEU (Choquet expected utility) (or, similarly, maxmin EU) for two-outcome gambles. Interpret utility U as "cardinal" risk attitude, and capacity as ambiguity attitude. A problem is that all of risk attitude outside expected utility, such as Allais paradox, probabilistic risk attitude (probability transformation in RDU), thus ends up in ambiguity attitude and not in risk attitude. The authors signal and discuss this problem on p. 257, 274-275, and several times in the Discussion section. They don't want to use given probabilities (usually described broadly as "extraneous device"), which is why they don't isolate probabilistic risk attitude from ambiguity attitude. They provide arguments against probabilistic sophistication as ambiguity-neutrality in the Discussion section, arguments that I agree with. (But my solution is different: I recommend using ("extraneously-")given probabilities as ambiguity neutrality.) By not wanting to use objective probabilities for the study of ambiguity, the authors have the same basic problem as Epstein (1999). I discuss the case in my annotations to Epstein (1999).

Sometimes (p. 256 ℓ. 7) they interpret the capacity as belief. Mostly they, nicely, interpret it as willingness to bet.

P. 257 ℓ. 12-14 is misleading because Savage did not consider ambiguity as a normatively compelling argument against expected utility.

derived concepts in pref. axioms: p. 265 discusses a preference condition that would require the whole elicitation of a continuum of a utility scale: "This extension requires the exact measurement of the two preferences' canonical utility indices, and is thus "less behavioral" than the one we just anticipated." P. 276 states it as: "Nonetheless, this ranking requires the full elicitation of the DM's canonical utility indices, and thus is operationally more complex than that in Definition 7." Exactly these criticisms apply to the endogenous mixture operation used as behavioral in Ghirardato, Maccheroni, Marinacci, & Siniscalchi (2003, Econometrica).

They use the Yaari-definition of higher certainty equivalents. Call a second agent more uncertainty averse than a first if the second always has lower certainty equivalents. Under identical utilities (implied by their cardinal symmetry) they then call the first more ambiguity averse. It implies, and under CEU is equivalent to, the capacity of the second being dominated by the first. They define SEU as ambiguity neutral and define ambiguity aversion in an absolute sense as *existence* of SEU with same utility that is less ambiguity averse. The latter holds iff the capacity is pointwise dominated by an additive probability, in other words, has a nonempty CORE. This is an axiomatization in the sense of necessary and sufficient, a logical equivalence between two statements about theoretical concepts. It is not a decision-axiomatization because both conditions are not stated in terms of directly observable choices: The *existence* of the less ambiguity averse SEU is not directly observable (**derived concepts in pref. axioms**). The authors signal this problem on p. 256, saying that their definition of ambiguity neutrality is behavioral but computationally demanding. Their definition of ambiguity aversion had been proposed before by Montesano & Giovannoni (1996 Def. 1 p. 136). The authors do not sufficiently credit this priority, and only write on p. 258: "Montesano and Giovannoni [21] notice a connection between absolute ambiguity aversion in the CEU model and nonemptiness of the core, but they base themselves purely on intuitive considerations on Ellsberg's example."

It is troublesome that they can handle ambiguity attitudes, ambiguity neutrality etc., only if there is either ambiguity seeking or ambiguity aversion, and not for more general attitudes towards ambiguity. For insensitive symmetric weighting functions, for instance, their definitions do not detect the ambiguity present. (**Ambiguity = amb.av = source.pref, ignoring insensitivity**) %}

Ghirardato, Paolo & Massimo Marinacci (2002) “Ambiguity Made Precise: A Comparative Foundation,” *Journal of Economic Theory* 102, 251–289. https://doi.org/10.1006/jeth.2001.2815

{% **biseparable utility violated**: they consider a direct generalization.

The authors use a generalization of the endogenous utility-midpoint operation of GMMS (Ghirardato, Paolo, Fabio Maccheroni, Massimo Marinacci, & Marciano Siniscalchi 2003, *Econometrica*). They generalize it by not assuming biseparable utility to hold throughout, but only for one event E and the E-dependent binary acts, or for some events. This they call local biseparability. One such event E suffices to define a utility midpoint operation. Then they proceed as GMMS, first defining subjective mixtures for weights different than ½ by repeatedly taking midpoints and then taking limits. Note that this can involve infinitely many repetitions, for instance for weight 1/3. And as in GMMS, they can then define the Anscombe-Aumann framework endogenously. Because they do not assume biseparable utility, as did GMMS, but only local biseparability, then can handle more models. They don’t need the, for nonEU debatable, monotonicity axiom of Anscombe-Aumann, or the certainty independence axiom, because there are no exogenous mixtures.

One drawback that the authors share with GMMS is that their utility midpoint operation is complex, and hard to implement empirically because it involves many certainty equivalents. Using Wakker & Deneffe’s (1996) tradeoff technique, two indifferences $\alpha_E\sigma \sim \beta_E\tau$ and $\beta_E\sigma \sim \gamma_E\tau$ ($\alpha \preccurlyeq \beta \preccurlyeq \gamma \preccurlyeq \tau \preccurlyeq \sigma$) more easily give an endogenous utility midpoint, as pointed out by Köberling & Wakker (2003). Another drawback that the authors share with GMMS is that their general mixture operation is very complex empirically, and may even require infinitely many observations. Such a concept should not be used in a preference axiom. It in fact amounts to just measuring the utility function, and using it in axioms is like using utility in axioms. %}

Ghirardato, Paolo & Daniele Pennesi (2020) “A General Theory of Subjective Mixtures,” *Journal of Economic Theory* 188, 105056.

{% Consider general multiple prior models, explicitly NOT assuming uncertainty aversion or certainty independence. Use the Anscombe-Aumann setup. They do not explicitly refer to it, but it is because they assume a convex set X of outcomes, preferences over which are represented by an affine function u (their term Bernoullian refers to this being like EU).

Show that sets of priors, as from the pretty unambiguous subpreference of Ghirardato, Maccheroni, & Marinacci (2004), are obtained as union of Clarke differentials. The latter are a kind of multidimensional analog of derivatives, but can also be used if a functional is not differentiable. Thus, they relate priors to local optimizations. Although it can be called an operationalization of sets of multiple priors, unions of Clark differentials and local linear approximations of preferences are too complex to be used for empirical calibration. This paper is an analog for uncertainty of what Machina (1982) did for risk. %}

{% **questionnaire for measuring risk aversion**: use it and give references in mid p. 87;

uncertainty amplifies risk: find that. They use subjective general questionnaires to assess risk aversion and ambiguity aversion of people. Also use a Kachelmeier (1993) list of risky choices to assess risk attitude (which, unfortunately, gave risk neutrality for all 39 subjects so that it was not sufficiently discriminating). Then let N = 39 students decide on how many inspections to carry out in a supposed manufacturing plant where, subjects, however, received real performance-contingent payments. For high risk and high ambiguity they find aversion, for low risk no aversion and for low ambiguity also no aversion. (p. 86 when in the five hypotheses H1-H5 they write "explain" they mean that aversion is exhibited). %}

Ghosh, Dipankar & Manash R. Ray (1997) "Risk, Ambiguity and Decision Choice: Some Additional Evidence," *Decision Sciences* 28, 81–104.

{% Provide many results on risk aversion in RDU, and cite many papers. The authors consider weak risk aversion, and a composition of the risk premium into a probability weighting premium (if utility were linear), taking the remainder as utility premium (note: the latter depends on probability weighting). Hilton (1988) considers a similar separation. They give many necessary and sufficient conditions, for instance for weak risk aversion. However, the conditions are not preference conditions but they involve theoretical constructs (u and w), so that the axiomatizations are not preference axiomatizations. Thus, a preference axiomatization of weak risk aversion remains as the main open mathematical question in RDU.

Warning: Unfortunately, the authors do not the top-down integration as nowadays (1990-2023) convention, but bottom-up. Also unfortunate: they use the inefficient term RDEU. %}

{% The paper considers belief functions via the Möbius inverse, as in Dempster's random messages. It provides a detailed comparison beween a model by Jaffray & Wakker (JW) and one by Giang & Shenoy (GS). The latter considers only (partially) consonant belief functions (Def. 6 p. 42) their Möbius inverse lives on disjoint groups that are all telescopically nested, which means nested (for each pair one is a subset of the other) and in this sense is less general. But JW deal only with Dempster-type setups where the mixture weights used in Möbius inverse are exogenously given objective probabilities ("disambiguate the foci of belief;" p. 50) and in that sense are less general. The paper considers a sequential consistency condition as in Sarin & Wakker (1998) that is violated by JW but satisfied by GS. %}

Giang, Phan H. (2012) "Decision with Dempster–Shafer Belief Functions: Decision under Ignorance and Sequential Consistency," *International Journal of Approximate Reasoning* 53, 38–53.

{% Presents a model similar to Jaffray (1989 ORL), but does not know or cite Jaffray.
Assumes that risk with known probabilities is one extreme, complete ignorance is another (here he does cite Cohen & Jaffray 1980), and (§3) considers also cases in between where, unlike most of the modern ambiguity Anscombe-Aumann frameworks, the roulette precedes horses, which I think is better (Wakker 2010 §10.7.3). Uses Arrow-Hurwicz to model complete ignorance, where only minimal and maximal possible outcomes matter. Uses an Anscombe-Aumann multi-stage setup, and relaxes the collapse-event assumption. It does hold within one source (my term) but not between. So, in Anscombe-Aumann, roulette before horse is different than horse before roulette. Derives comparative results as being more tolerant for ignorance from Yaari-type certainty equivalent comparisons. Discusses Ellsberg, maxmin EU, and belief functions. Does not discuss modern (2015) ambiguity models although as an aside it cites the smooth KMM (2005) paper. %}

{% This paper contains the nice observation that under RDU (= CEU (Choquet expected utility)) the decomposition W = f(P) with f strictly increasing amounts to exactly the same in a mathematical sense as imposing the qualitative probability axioms (having a P that orders events the same as W). So, probabilistic sophistication comes here from only qualitative probability and does not need the stronger conditions that Machina & Schmeidler (1992) had to impose for general probabilistic sophistication. The paper does try to formulate axioms, but, as Gilboa (1986, personal communication) pointed out there is something missing. Convex-rangedness of W does imply solvability of the more-likely-than relation, but not the Archimedeanity that is needed to get P. In other words, although W is quantitative and satisfies some sort of Archimedeanity in its ordinal class, it does not satisfy the additive Archimedeanity that is needed to give P. It does not exclude infinitely many equally likely disjoint nonnull events in terms of P. %}

{% **criticisms of Savage’s basic mode**: in several places.

Text on decision under uncertainty based on what Gilboa teaches. The text pays much attention to methodological issues, based on Gilboa’s philosophical background, and is more oriented towards the probability-uncertainty part than towards the utility part.

Part I. Ch. 2 **free will/determinism**. §2.6: “The distinction between the acts, over which the decision maker has control, and states, over which she hasn’t, is one of the pillars of rational choice.” **foundations of probability**
Chs 3-5 (§5.3 on classical vs. Bayesian statistics).

Part II. §6 on **one-dimensional utility**, using this as the initial model to introduce terms such as normative. The author lets terms such as normative-descriptive and framing refer not only to agents, but also in a meta-sense for theorists developing theories. §6.4 introduces cardinal utility through **just noticeable difference**s and semi-orders.

Ch. 7 (where the author indicates that its location is somewhat ad hoc) argues that to some extent theories need not be so correct but need only be good tools (conceptual frameworks) for us researchers to find good conclusions. Ch. 8 has vNM EU preference axiomatization, with §8.3 sketching three ways of proof, Ch. 9 de Finetti’s SEV theorem with preference axiomatization, and Ch. 10 has Savage’s SEU theorem. Ch. 11 discusses the definition of states of nature. Ch. 12 discusses Savage’s axioms critically, with §12.3 discussing P1 (completeness) and P2 (sure-thing principle) jointly. For the author problems of completeness (P1) lead to multiple priors and then to violation of P2. Ch. 13 distinguishes between weak and strong rationality, with a big role for objectivity. (**ambiguity attitude taken to be rational**)

natural sources of ambiguity: §3.3.3: “David Schmeidler often says, ‘Real life is not about balls and urns’. Indeed, important decision involve war and peace, recessions and booms, diseases and cures. In these examples there are no symmetries and no natural priors, and the principle of indifference cannot lead us very far.”

(strong means you can convince others). Ch. 14 has Anscombe-Aumann. Ch. 15 brings CEU (Choquet expected utility), Ch. 16 has a digression on prospect theory in the new 1992 version, however doing it only for given probabilities and not giving the complete definition. Ch. 17 discusses CEU versus multiple priors. Part IV briefly brings the case-based model, presenting it as a model with cognitive inputs and not just **revealed preference**. %}

Gilboa, Itzhak (2009) "*Theory of Decision under Uncertainty*." Econometric Society Monograph Series, Cambridge University Press, Cambridge.

{% P. 3: Gilboa defines rationality as follows, as it had been done in preceding papers by him and Schmeidler:

"a mode of behaviour is rational for a given decision maker if, when confronted with the analysis of her behaviour, the decision maker does not wish to change it."

It is an interesting concept, worth studying and discussing. But it is absolutely not how I would define rationality. A heroine addict may not wish to change preferences, but I still call it irrational. In general, rationality has a natural-language meaning that is very important for decision theory. And that, I think, cannot be formalized, or expressed in mathematical terms. Many things can't be captured by mathematics, contrary to the thinking of some mathematicians subject to the ubiquity fallacy. Given the importance in our field of the natural-language word rational, I have always objected to any formalization of the concept, and here I do again. I guess that Giboa's condition is necessary for being rational because a rational agent will, I guess, be consciously aware of things, and therefore will not want to change, so that in that sense not-wanting-to-change is necessary for rationality. But it surely is not sufficient. Gilboa's concept becomes subjective, and an empirical concept. (My, vague, meaning of rationality does not.) Fellner (1961 p. 680) nicely stated my point: "But the question still remains whether leaving him alone is not like leaving an otherwise rational person alone who consistently prefers three dollars to *quatre dollars* [French for "four dollars"]. This latter person needs to be supplied with a dictionary rather than to be assured of our respect for his preference scales. He is making a mistake."

Gilboa then argues that we can "preach" rationality conditions. If we think that transitivity is necessary for rationality, which I do, then we can try to convince others that they should satisfy it. If we succeed then we are happy, but if not and an agent prefers to violate rationality, then for that agent transitivity is not rational in Gilboa's terminology.

P. 4 writes: "What are the merits of this definition then? We are equipped with the phenomenally elegant classical decision theory and faced with the outpour of experimental evidence à la Kahneman and Tversky, showing that each and every axiom fails in carefully designed laboratory experiments.4 What should we do in face of these violations? One approach is to incorporate them into our descriptive theories, to make the latter more accurate. This is, to a large extent, the road taken by behavioral economics. Another approach is to go out and preach our classical theories, that is, to use them as normative ones. For example, if we teach more probability calculus in high school, future generations might make less mistakes in probability judgments. In other words, we can either bring the theory closer to reality (making the theory a better descriptive one) or bring reality closer to the theory (preaching the theory as a normative one). Which should we choose?" The answer is easy, and already given in the cited text: for descriptive work we bring the theory closer to reality and for prescriptive theory the other way around.

P. 5: "The final judge of rationality is the decision maker herself." %}

{% **CBDT**;

This paper relates case-based decision theory to statistical techniques, in particular kernel methods. Thus the decision-theory axioms of CBDT, in particular the combination axiom, can be related to statistics. Model: To estimate y_t of a subject with variables $(x_t^1,\ldots,x_t^d)$, we observe n subjects with values y_i related to $(x_i^1,\ldots,x_i^d)$, i = 1, …, n. The paper does not use regression estimates, but normalized similarity-weighted averages of the y_i based on the similarities of the x vectors. %}

Gilboa, Itzhak, Offer Lieberman & David Schmeidler (2011) "A Similarity-Based Approach to Prediction," *Journal of Econometrics* 162, 124–131.

{% **ambiguity attitude taken to be rational**: Consider two preference relations as primitives. The first is objectively rational in the sense of being justifiable to others. The second is subjectively rational in the sense of not being justifiably wrong. The first is incomplete, and the second extends the first (imposed by their axiom with the vague name consistency on p. 761) into a complete relation (we also have to choose if no decisive objective arguments). A similar idea is in Greco, Mousseau, & Slowinski (2010).

The authors use the Anscombe-Aumann framework. The authors impose preference conditions, mainly the usual vNM independence in the Anscombe-Aumann setting, for the objective preference relation. They argue that the usual argument for vNM independence is convincing for objective rationality. For incomplete preference relations this leads to a multiple prior Bewley (1986, 2002) incomplete model with preference f > g iff EU-unanimous (EU(f) > EU(g) under all probability measures in the set of priors).

To axiomatize the subjective relation, the authors impose a very ambiguity averse axiom (caution, p. 761): If f is constant (assigning the same outcome to each state of nature, where outcome can be sure prize but also probability distribution over prizes with risk involved; at any rate no ambiguity involved) and g is not constant, and g is not objectively preferred to f, then already f is subjectively preferred to g. So, subjective preference is in favor of certainty (in sense of no ambiguity but maybe still risk) as much as at all possible given the objective preference relation. Then ambiguous acts are evaluated as negatively as can be; i.e., it is maxmin EU w.r.t. the same set of priors as used in Bewley model. So, caution then characterizes maxmin.

The authors argue that it is natural that subjective preference violates Anscombe-Aumann independence because of hedging. I disagree with this in the sense that I disagree with the very Anscombe-Aumann framework to model ambiguity. I think that independence with respect to prior probabilistic mixing is just as convincing here as it is for objective acts. Independence with only posterior mixing, as commonly taken in the Anscombe-Aumann framework nowadays (1990-2023), is not convincing for the reasons given by the authors. The equating of prior and posterior mixing (reversal of order), while acceptable under Anscombe-Aumann with EU, is not convincing under nonEU and ambiguity, and this is the reason that the Anscombe-Aumann framework, so popular in the modern literature, is not suited for analyzing ambiguity. I prefer Jaffray's justification of independence for prior mixing also under ambiguity but against posterior mixing. (So, referring to p. 760 last sentence of §2.2, a DM can reason in terms of the mixture operation but does not want to.) Once Anscombe-Aumann accepted, then "soit" (let it be as it is) as the French would say. A limitation of the analysis is also that it is still completely hooked up with only one ambiguity attitude: Aversion aversion aversion. The reference to Rubinstein (1988) in the concluding para of the main text (p. 764) is irrelevant (we can call everything a "relation" as much as the similarity relation; it is not a preference relation).

The idea of an incomplete primitive relation to start with and then extensions to completeness is natural. The objective/subjective distinction is nice too, although the criteria for objective and even more for subjective rationality is too permissive and more restrictions are conceivable. For example, could the symmetry argument in the middle of p. 757 not be given an objective status, even if ambiguity? Nice is also that two popular conservative approaches to multiple priors, the Bewley (1986, 2002) unanimity and maxmin, are brought together. So, this is a pretty paper. I do not like Anscombe-Aumann for ambiguity and the focusing on only aversion for ambiguity, but, soit. %}

{% Abstract: "A mode of behavior is rational for a decision maker if she feels comfortable with it once it has been analyzed and explained to her." It is the defintion of rationality in many papers by Gilboa, and is an interesting concept, but I think it should not be called rationality. The paper presents a new preference model and its axiomatization that can be seen independent of whatever interpretation of rationality one has.

The model is decision under risk and expected utility (EU) with one modification: the outcome set X is partitioned into X_1 and X_2. X_1 is extra aversive. Further, $b > 0$ is a constant. There is extra appreciation, b, if the probability of receiving nothing from X_1 is 0. Thus, for a lottery L over X, the value is $EU(L) + b$ if $L(X_1) = 0$ and it is EU(L) if $L(X_1) > 0$. It is sort of Archimedean non-Archimedeanity. The authors also consider the cases where there are more than two categories of outcomes. %}

Gilboa, Itzhak, Stefania Minardi, & Fan Wang (2024) "Rationality and Zero Risk," *Journal of the European Economic Association* 22, 1–33. https://doi.org/10.1093/jeea/jvad071

{% The authors discuss the use of preference axiomatizations of individual choice under uncertainty/risk for descriptive applications in economics. (1) Axioms are more useful for normative applications than for descriptive; (2) are more used to defend a model than to criticize it; (3) are more used in a meta-science manner (to convince other researchers, "rhetorically" where this word is not meant to have negative nuances) than concretely.

The authors paraphrase Tolstoy's saying on happy families, replacing happy by rational, and some other things: "All rational people are rational in the same way, but all irrational ones are irrational in their own way." %}

Gilboa, Itzhak, Andrew Postlewaite, Larry Samuelson, & David Schmeidler (2019) "What Are Axiomatizations Good For?," *Theory and Decision* 86, 339–359. https://doi.org/10.1007/s11238-018-09685-1

{% **ambiguity attitude taken to be rational**: A didactical discussion of expected utility and preference axioms. The authors argue that the sure-thing principle is not convincing and that, hence, multiple priors is better (p. 184 2nd para is very explicit on this point). They also argue against completeness (**completeness criticisms**) but derive no model from it; multiple priors satisfies completeness. They argue that if it is not clear what the state space should be, then case-based decision theory is better. They also argue that case-based decision theory offers insights into how people choose probabilities.

SEU = risk: P. 173 suggests that if Savage's model of decision under uncertainty holds, then this is "reduced to problems of decision under risk." I prefer to let decision under risk refer only to the case of objective probabilities.

P. 174 4th paragraph assumes that objective probabilities are automatically informationally preferable to cases of unknown probabilities. P. 176 middle likewise assumes that a known 60% probability will be preferred to an unknown 60% probability.

P. 177: they cite Drèze (1961) for his work on state dependence; not for his preceding work on maxmin EU.

Pp. 179-180 argues that completeness is unconvincing because we often have no clear preference. (**completeness criticisms**)

P. 181 suggests that choices of utility are entirely subjective and never irrational (as soon as some basic requirements), but choices of subjective probabilities can more easily be irrational. (**paternalism/Humean-view-of-preference**). It is true that for probabilities there is some more a criterion of truth when objective probabilities exist, which has more exact truth status than linear utility for moderate amounts. But this difference is not essential for most situations where subjective probabilities exist.

P. 185 2nd para nicely states that problem of finding appropriate probabilities has simply been replaced in case-based decision theory by the problem of finding appropriate similarity weights, but continues to argue that the introduction of similarity is nevertheless a meaningful step and that sometimes there can be objective bases for similarity weights (but that also can be for probabilities) and give an example of Gilboa, Lieberman, & Schmeidler (2006) where similarity weights have been obtained through optimal fits with historical data.

The paper ends in its last para with bringing up statistics, where sets of probabilities are considered. There is a difference with multiple priors though, being that in multiple priors the sets of probabilities concern the outcome relevant events, whereas in statistics they only concerns signals (this is what observed statistics are). In statistics the outcome-relevant events concern the unknown statistical parameters, but over these no (sets of) probability distributions are imposed. %}

Gilboa, Itzhak, Andrew W. Postlewaite, & David Schmeidler (2008) "Probability and Uncertainty in Economic Modeling," *Journal of Economic Perspectives* 22, 173–188.

{% **ambiguity attitude taken to be rational**

The authors argue against Bayesian expected utility. I, Bayesian, of course disagree. P. 285 writes: "Choosing one probability number in the interval [0,1] would be akin to pretending that we know something that we don't." a criticism often leveled against expected utility. I disagree. A subjective probability is not an expression of knowledge about some fact in the world, unlike objective probability, but it is only language to express an attitude, a decision. If the authors prefer a multiple prior model to capture their attitude, they have to use language to express their attitude, which will involve utility and a set of priors. They then are not claiming to have some magical info, but only express their attitude. If they are allowed to "exactly" specify a set of probabilities why isn't a Bayesian allowed to "exactly" specify a probability? Same story for utility. How can they pretend to "exactly" know utility?

P. 286 writes: "The Bayesian approach is lacking because it is not rich enough to describe one's degree of confidence in one's assessments." I, again, disagree. One's confidence in one's assessment shows up, in Bayesiansm, where it should, and that is in updating. If you throw a biased coin and observe a heads-up, how much this changes your belief in a next heads-up depends on your degree of confidence in your prior belief, including the nr. of observations that your prior belief is based upon.

P.287 Footnote 2 cites Carnap (1952), Lindley (1965), Levi (1980), and Jeffrey (2004) as people agreeing that expected utility is imperfect. I am sure that this is incorrect for Lindley, strongly convinced it is incorrect for Carnap, am sure it is correct for Levi, and don't know about Jeffrey.

P. 287 writes: "Moreover, many believe that there is no mathematical result in the entire corpus of the social sciences that compares to Savage's theorem in terms of elegance and generality, as well as conceptual and mathematical depth." I belong to those many believing it.

P. 289 writes: "But the quest for a single set of rules that will universally define *the* rational choice is misguided." [italics from original] This is a misleading version of Bayesianism. Bayesianism claims that expected utility is necessary for rationality, not sufficient. It therefore does not "define" rationality. The authors later, when writing their own opinions, do properly point out that consistency conditions are not enough for rationality. P. 290 writes: "Savage's axioms are consistency principles ... In isolation, these principles do not put any constraints on one's beliefs. Hence, they are insufficient for a definition of rationality. A definition of rationality that does not impose additional constraints on beliefs beyond Savage's consistency principles would be … " And later, p. 292: "Internal coherence of beliefs is important, but so is external coherence"

P. 289: "When dealing with the definition of morality or of rationality, we take a normative point of view, rather than a descriptive one: we attempt to model the behaviour that people would like to exhibit, rather than the behaviour they actually do exhibit." I disagree with this definition, also written in other papers by the authors. Rational need not be what people want themselves.

P. 291: "We may also feel that all equally poor people should be entitled to the same level of support." I do not understand this example. We may not be able to support all equally poor people simply because of practical constraints, and I see no relevance for the discussion of rational axioms there. %}

Gilboa, Itzhak, Andrew Postlewaite, & David Schmeidler (2009) "Is It always Rational to Satisfy Savage's Axioms?," *Economics and Philosophy* 25, 285–296. https://doi.org/10.1017/S0266267109990241

{% **paternalism/Humean-view-of-preference**: the paper claims that economics has this view, but the paper argues against it.

ambiguity attitude taken to be rational

The abstract claims that economics reduces rationality to (Bayesian) consistency. I think that Bayesian consistency is necessary but surely not sufficient for rationality. Although some economists claim sufficiency, I don't expect that to be any, given that (I think) it is very dumb. The authors argue that the latter is too permissive and that beliefs, for instance, can be irrational, which I agree with. They also argue that Bayesian consistency is also too restrictive because deviations from Bayesianism can be rational, where I disagree.

P. 17 penultimate para claims (as in first tenet on p. 14) that all relevant info, also regarding the choice of subjective probability, should be captured by the (grand) state space. Such a view is also found in papers by Aumann, and in the circular definitions of types of players by Harsanyi. I disagree. Thoughts about the state space, such as about what the right subjective probabilities are, should be at a higher level and should not be captured in the state space (grand or not), to avoid circular definitions. The set describing ALL information will face the Russel paradox, like the set containing all sets (variation: set that contains all sets that do not contain themselves).

P. 18 3rd para writes that Gilboa & Schmeidler (1989), and Schmeidler (1989), were not meant to be descriptive: "While the non-additive Choquet expected utility model and the maxmin expected utility model can be used to resolve Ellsberg's paradox (1961), they were not motivated by the need to describe observed behavior, but rather by the a-priori argument that the Bayesian approach is too restrictive to satisfactorily represent the information one has."

Gilboa, Itzhak, Andrew Postlewaite, & David Schmeidler (2012) "Rationality of Belief or: Why Savage's Axioms are Neither Necessary nor Sufficient for Rationality," *Synthese* 187, 11–31.

{% Argue that economics is more case-based, and psychology is more rule-based. Economists live with models of which they know that they are "wrong" (I would not say wrong, but only approximative of the truth). The authors argue that every theorem, data set, or whatever, in economics is just an extra argument for or against some hypothesis, adding according to its similarity weight.

Section 3.1 suggests that economic papers can be rejected if the proofs of theorems are not intuitive, but I think that the nature of mathematical proofs in appendices is usually ignored. Axioms/conditions should be intuitive, that is true. Section 3.2 claims that axioms are not useful in testing theories ("Moreover, when statistical errors are taken into account, one may argue that it is better to test the theory directly, rather than to separately test several conditions that are jointly equivalent to the theory.") But in many cases it is easier to test axioms and it is not clear how to test a theory directly. %}

{% If Alice prefers bananas to apples and Bob prefers apples to bananas, then (Alice: 2 bananas, Bob: 2 apples) is Pareto optimal. Nothing wrong with it if we make the assumption, common in economics, that de gustibus non est disputandem, which is commonly taken to mean that any utility function is acceptable (the authors write this more or less on p. 1406). However, now assume that Ann thinks P(E) = 1 and Bill thinks that P(not-E) = 1. Then (Ann: 2 if E & nil otherwise, Bill: 2 if not-E & nil otherwise) is Pareto optimal. But now it is due to different beliefs and we feel that then one must be wrong. Therefore, the authors define the Pareto condition as an allocation being so not only by every person's beliefs but also there must exist at least one common belief such that it is optimal for every agent. In the other case, the Pareto condition can only live by at least one wrong belief, which makes it less convincing.

A deep underlying idea of this paper is that uncertainty/probability is different than outcomes in the sense that there can be one true probability and that it is an error to have a different belief.

conservation of influence: p. 1415 defines (f,g) as swapping g for f.

{% **measure of similarity**; **CBDT**

Actual problem p, to be chosen from set D of acts. Preferences over acts depend on memory M. D is fixed, and M is variable. M is set of cases. Cases are triples (p,a,r), with p problem faced in the past, a the act chosen in problem p, and r the outcome resulting.

Pp. 16-17: behaviorist is strict revealed preference.

behavioral, in the terminology of these authors, is based on revealed preference but that use cognitive metaphors.

cognitive: allow for cognitive (which includes emotional in their terminology as they explain) empirical inputs.

P. 19 ℓ. 3: rationality definition requires cognitive inputs.

P. 27: good decision theory should tell a convincing story about the cognitive processes. (**coherentism**)

Pp. 31-32: CBDT if cannot specify all the states.

P. 35 §4.2: with problems, acts, results, similarity weights are taken to depend only on problems.

P. 35: similarity is the main engine of CBDT

P. 36: similarity weights are nonnegative.

Pp. 34-39, §4.2: each case occurs only once.

P. 38: sum is taken only over past circumstances involving the same act as now considered. (Amounts to taking similarity weights 0 for different past acts.)

P. 40: because sum of similarity weights is not constant, level of utility (where it is 0) is important. Also p. 43.

P. 41: 0 utility level serves as kind of aspiration level. If act has utility below, then a completely new and unknown act is preferred. But if act has positive utility, then no completely new and unknown act is chosen anymore.

P. 44: CBDT and EU are complementary.

P. 45: CBDT if structural uncertainty, where we do not know what the state space is.

P. 47: CBDT can incorporate hypothetical cases, such as Jane knowing she would have run into road construction and delay had she taken route B.

P. 51: circumstance-similarity

Pp. 52-53: case-similarity

Pp. 55 ff.: repetitions approach, where each case (p,a,r) can occur any finite number of times in M. Then techniques similar to Wakker (1986, Theory and Decision) can be used to axiomatize a cardinal representation. Ch. 3, pp. 62-, gives it. P. 66 Axiom A2 (combination) is the additivity axiom.

P. 74 discusses average approach (denoted V) where similarity weights are normalized, and which is appropriate if we observe many repeated independent cases. The page gives the Simpson paradox. For a long time I did not understand the argument the authors give for average versus sum, but now I think I do. If infinitely repeated choices, the act with highest average is best. For one single choice now, the info it gives for all future choices is infinitely more important than the preference value it yields for this one time. So, one is only out for finding the best average in repeated choice, and only for the info-part. In one-time choice one may prefer a first act with a somewhat lower positive average but more info, because a second act with higher positive average one may have less info about so, it is plausible that its real utility will be lower than its average up to now.

P. 75 explains that the additive combination axiom A2 (p. 66) is reasonable only if the memories considered are complete, and have no implicit background memory that in fact makes them nondisjoint. The latter is the case in statistics where two disjoint sets of observations give no rejection of H_0, but their combination does. Violations are further discussed on pp. 174-181.

Pp. 93-95 that CBDT is less hypothetical than EU.

Pp. 133, 148 ff. on zero level of utility.

Pp. 158 ff. on sum versus average. %}

Gilboa, Itzhak & David Schmeidler (2001) "*A Theory of Case-Based Decisions.*" Cambridge University Press, Cambridge.

{% **coherentism**: Argue that nonbehavioral, "cognitive," inputs are desirable. Evaluate consumption streams $(x_1,\ldots,x_n)$, with n variable, through:

There exist real numbers $w_1,w_2,\ldots$ and s_{it} $(1 \leq i < t)$ s.t.

$\Sigma_{1\leq t\leq T}\big(w_t(x_t^T - a_t(x^T))\big)$

with $a_t(x^T) = \Sigma_{1\leq i\leq t-1} s_{it} x_i^T$

evaluates the consumption stream $(x_1^T, \ldots, x_T^T)$.

G&S relate the different coordinates to "facts" and not to timepoints. The fixed ordering of the facts would fit well with timepoints also. One can interpret $a_t(x^T)$ as aspiration level at timepoint t.

For each fixed n the representing function is a linear form, and the authors give the classical additivity preference axioms to justify this form for each fixed n. Then they add existence of a neutral outcome x_{n+1} (depending on $x_1 \cdots x_n$) to make the n+1 tuple indifferent to the n-tuple, probably to fix the location constant of each representation. They give many interpretations of the form regarding aspiration, self-deception, social influence (x_2 can describe the income of your neighbor), etc. %}

{% The paper introduces a method ("ORIV") for handling error in measurement that, apparently, is new. It is something like doing a measurement twice and then using each as an instrumental variable for the other. A specialist in econometrics explained the basic idea of this paper to me as follows: "The way I think about this method intuitively is that you look at the correlation between X (psychological concept of interest) and Z (IV, other way of measuring the same psychological concept). Let's say this is 0.5, then it must be the case that there is 50% measurement error since Z and X should measure the same concept (i.e. the correlation should be 1 in theory). What you then do is assuming that there must also be 50% measurement error in the relationship between Z and Y (the outcome). So, effectively you multiply the coefficient of Z on Y by 2 to account for the fact that X and Z are also only 50% correlated." My worry here is that by getting much noise in Z, you can

boast your correlations much.

When the authors reanalyze existing data, and replicate experiments (with N=786 subjects), they invariably find way higher correlations than was done before. For instance, they find high correlations between different measurements of risk aversion. And they do so with Halevy (2007) on violation of RCLA and ambiguity aversion and find an almost perfect correlation. An "uncorrected" correlation of 0.65 is increased into 0.85 using their correction (p. 1857). This is potentially very interesting, shedding new light on many phenomena, and the paper received much interest.

I did not come to understand the authors' method (colleagues told me that p. 1850 is clear), but I feel doubts because I think that violation of RCLA and ambiguity aversion are just different things. Even exact replications of subjective attitude variables half an hour apart have low correlations usually. Could it have to do with joint variances all being maximally ascribed to what gives correlations? Often, econometric techniques take errors of different actions within one individual as independent, an assumption that I dislike. (Clustering helps.)

Two econometrics specialists told me that the orthogonality assumption on p. 1831 ℓ. 14 is very restrictive.

The paper often writes as if most past papers did not reckon with measurement error at all, suggesting that this paper is among the first. For instance, p. 1828 top: "In contrast, we find that many commonly used measures of risk attitudes are highly correlated once measurement error is taken into account." Or p. 1833: "It emphasizes, as we do, the ubiquity of measurement error, and the paucity of concern about it." Or p. 1844: "However, none of the studies on which this conclusion is based account for measurement error." This is misleading. EVERY statistical test and reported p-value is based on an underlying assumption of measurement error, including every t-test and Wilcoxon test etc. The authors probably have in mind only the sophisticated measurement error models with quite precise quantitative assumptions and parametric assumptions about them that are commonly used by econometricians, and they ignore everything else. Sometimes econometricians are narrow on such things. For instance, they often take t-tests just as special case of regressions, not knowing that t-tests need milder assumptions than regular regressions.

suspicion under ambiguity: I did not find a control against suspicion mentioned on pp. 1835-1836.

random incentive system: apparently they paid for all choices (p. 1838 top), which I regret.

p. 1844: Allocations of assets (called "projects") seem to better measure risk attitudes than choice lists. My gut feeling suggests that it is opposite. P. 1845 end of 1st para suggests that in the projects no risk seeking is possible, which makes me worry about it. %}

{% Motivated Bayesian is a broad term to designate the following concept: a person, when gathering info, will be biased in believing more in info that supports morality of the person. So, it is a form of self-deception, similar to the confirmatory bias (cited by the authors) and, in psychology, rationalization and cognitive dissonance. Bayesian here does not refer to expected utility or even much to updating, but is just the general point that people process info properly in a general informal sense. Motivated is not general motivation but the very particular motivation of self-deception to think to be more moral than is real. One challenge for studying this is that self-deception is a subtle concept, not easy to induce or find. One has to induce a sort of split-personality of on the one hand knowing but on the other not. An even challenge is to empirically isolate self-deception from other factors, in particular deception of others. I read a few experiments reviewed in the paper, but disappointedly came to think that none handles these two challenges.

P. 192 last para: Subjects had to allocate a nice (incentivized) and nonnice (nonincentivized) job, one to themselves and the other to a partner. They could just do it, or flip a coin to decide. They described what they did to the experimenter. But it was unverifiable what they had done, e.g. if they had flipped a coin at all, and if they had, what the result had been. Of the subjects who said they had had a coin flip decide, 90% ended up taking the nice job themselves, as much as the noncoin flippers. The authors interpret this finding as self-deception and motivated Bayesianism. But I take it as the opposite: The subjects only want to deceive the experimenter and possibly the partner, and not themselves. Those who claim to have tossed a coin but lie, add immorality by not only taking the nice thing themselves but by also lying. And they know so, and do and cannot deceive themselves. I have the same problem with the experiment on p. 193 bottom (Figures 1 & 2).

Pp. 199-200: Some subjects are told that endurance to stand cold water predicts longevity of life duration. Others are told the opposite. (Entails deception but so, be it.) The former endure more. Alternative explanation: Subjects are seduced to misperceive the causal relation, and in the second group reason: if I do a big effort then I get punished by living shorter. So, I don't do a big effort.

P. 200 2nd para: a winner does not critically investigate own performance. Alternative explanation: because no need, as things are going well anyhow. A loser has to search for changes.

The paper opens with "A growing body of evidence," with "growing literature" in its concluding sentence, opens many sentences with "importantly," repeats its main hypothesis prior to any discussion, mentions "important" implications for economics and policy (p. 191 end of intro), and ends the conclusion with it being desirable to have more future investigations. %}

{% N = 12, so, not many subjects. Incentives: Subjects got a showup fee, but 6 choices were implemented for real, generating an income effect. Nonzero outcomes were either $1 or $2.

Subjects do decisions under risk from description, with probabilities given, and from sampling, where they observe iid repetitions of a random event and have to guess frequencies (**updating under ambiguity with sampling**). The latter is similar to Wu, Delgado, & Maloney (2009) with a big difference though: Now subjects cannot influence the random event, unlike Wu et al. where it is a skill task. The latter study found the opposite of inverse S (**inverse S**; maybe due to disliking small probability of succeeding in task), but this study finds regular inverse S also for the sampling task. Utility was mostly concave, as is usual for gains.

The lotteries considered had only one nonzero outcome, implying that the joint power of utility and probability weighting is unidentifiable. It is identified here in the sense that the authors used the T&K'92 weighting function, which kind of imposes a scaling convention on probability weighting. The authors are apparently unaware of this problem. Note that while power does affect risk aversion, it need not affect the degree of inverse S.

uncertainty amplifies risk: They find this because probability weighting is more pronounced inverse S under sampling (which has some ambiguity) than under given probabilities. %}

{% Real incentives: **random incentive system** (p. 26 penultimate para) & **losses from prior endowment mechanism** (p. 26 1st para)

reflection at individual level for risk: Have data but do not report it.

They test all kinds of versions of PT (they write CPT) to risky choices of subjects, to see which and how many parameters work best. Measure subjects' choices twice, one week apart, with different stimuli, to test stability and predictive power. Take wide variety of gain-, loss-, and mixed prospects. P. 27 describes limitations that they imposed on parameters.

Introduction is on pros and cons of free parameters, explaining well but only didactical because standard; maybe because of journal.

They use power utility when estimating loss aversion. Wakker (2010 §9.6) describes analytical problems for it, unless the same power for gains and for losses. The latter is exactly what the authors do here.

Pp. 23-24 cites studies on stability of risk attitudes over time, pointing out that instability of preference may be caused by instability of some parameters while stability of some others.

Use two indexes of fit. One is percentage of choices predicted right. Other is loglikelihood distance.

concave utility for gains, convex utility for losses: They only consider models where utility for losses is the reflection of that for gains, with the same power (p. 25 1st column penultimate para, also for EU (p. 25 Eq. 8), and with power between 0 and 1 (p. 27 last para).

P. 27 bottom has nice optimization method for data fitting.

Pp. 28-29: In general, increasing the number of parameters of PT led to a better fit which is obvious, although not much better. The increases did not lead to better or worse predictions (latter could very well happen if overfitting). So, the data are not very informative on predictive performance. Some modifications: 2-parameter probability weighting did not improve 1-parameter (2-parameter utility was not considered); EU and EV can be considered to be special cases of PT, with restrictions on parameters, but their fits and predictions were seriously worse (the authors did not incorporate loss aversion in EU although one could argue for it given fixed reference point). EV did better than Gigerenzer's heuristics (p. 29 end of §3). Individual parameters are better than group medians (could have been the other way around if overfitting), but they were better than the T&K'92 parameters (p. 29). Loss aversion ranged between 1.05 and 1.99, quite smaller than the 2.25 of T&K'92, and loss aversion was most volatile.

As regards stability, they found clear and significant correlations between

choices separated by a week, but not very strong.

loss aversion: erroneously thinking it is reflection: p. 30 middle of 2nd para: "prediction, differences between gains and losses seem to be sufficiently represented by having a loss aversion parameter" %}

Goeree, Jacob K. & Charles A. Holt (2001) "Ten Little Treasures of Game Theory and Ten Intuitive Contradictions," *American Economic Review* 91, 1402–1422.

{% Quantal Response Equilibrium (QRE) is explained in my annotations to McKelvey & Palfrey (1995).

It is a highly desirable step forward in game theory that not just expected value, but more general risk attitude models, are used for evaluations of strategies given others' choice probabilities. For the future of prospect theory etc., it is necessary to find applications in other domains such as here in game theory.

The precise working of the models, and the precise estimations of individual risk evaluations from the findings from game theory, are still complex. The only observable from behavior is the choice probabilities. To what extent these can be ascribed to individual evaluation, expected utility, prospect theory, or whatever the considered theory is, or some transformation of such an evaluation, and to what extent they can be ascribed to the noise parameters and other aspects of the strategic situation, depends on the models and parametric families chosen by the experimenters. That the choice probabilities depend on probabilities/utilities only through the EU or prospect theory of a prospect, so that this functional form is separable, is already a heavy assumption. As another example, in the middle of p. 255, the authors write that overbidding by some players will enhance overbidding by the others, in other words, overbidding is a self-reinforcing effect. However, in the analysis of this paper stronger overbidding leads to higher estimates of individual risk aversion. Thus, estimates of individual risk attitudes are affected by strategic aspects of the game. One observable (choice probability) is used to estimate two or more parameters.

Another difference between these games and usual individual decision theories is that these theories consider decisions that are repeated many times, with repeated payoffs, income effects, etc. We must assume that in each repeated game, a strong isolation effect takes place, where the players forget about all other games. In spite of these difficulties, this is a highly intriguing attempt to apply individual risk theories in other domains.

When they do expected utility with power utility as index of risk aversion, they estimate the coefficient of RRA as 0.52 (so, power 0.48), which is similar to other findings in the literature. (**PT falsified**) When they do rank-dependent utility with linear utility, and Prelec's two-parameter family, they find convex and not **inverse S** weighting functions. This puts the ball in the court of the inverse S advocates. To maintain their hypothesis, they have to find other explanations for the strategic behavior of subjects than put forward in this paper. %}

Goeree, Jacob K., Charles A. Holt, & Thomas R. Palfrey (2002) "Quantal Response Equilibrium and Overbidding in Private-Value Auctions," *Journal of Economic Theory* 104, 247–272.

{% **PT falsified**: Find S-shaped rather than **inverse S** shaped probability weighting. P. 105 2nd para reports evidence against the procedure of paying in probabilities.

For the risk aversion assessment in the games as in §4, there is only one nonzero outcome, and then the problem is that a common power of utility and probability weighting is unidentifiable without further assumptions. The lottery-choice data in §5 have more variation in outcomes and there the problem does not arise.

The paper assumes that Nash equilibrium is what should/will happen under EU and no probabilistic choice. Many people, including me, do not find this a plausible assumption. %}

{% I guess it was hypothetical choice (not explicitly stated as far as I saw but it usually concerned future events); the paper only gives verbal reports of results; a detailed report of the experiment was planned but never completed.

ambiguity seeking for unlikely;

For ambiguous events, subjects are asked to give subjective probability judgments, but then also 2nd order probability judgments (**second-order probabilities to model ambiguity**). So, the latter are subjective, and introspective.

Their theory (hypothesis) H1: either ambiguity aversion or ambiguity seeking.

Their theory (hypothesis H2): likelihood insensitivity.

inverse S: Study A (N = 20) considers gain prospects and loss prospects but not mixed. For gains 8 subjects are ambiguity averse throughout, 7 are a(mbiguity-generated) insensitive (then inflection points between 0.05 and 0.45; p. 465 top), and 5 unclassified. For losses 7 are ambiguity seeking, 9 are a-insensitive (then inflection points between 0.05 and 0.65; p. 465 top), and 4 unclassified.

ambiguity seeking for losses: study A supports it.

reflection at individual level for ambiguity: no info is given on it; i.e., how gain-patterns go together with loss patterns.

P. 464, 3rd (last) para, nicely indicates that H2 (likelihood insensitivity) is unaffected by reflection (taking dual weighting function under modern RDU).

Studies B and C (each N = 20) consider mixed prospects have no unambiguous options, to avoid contrast effects (à la Fox & Tversky 1995), but relate ambiguous prospects (with second-order subjective probabilities) probably to their 1st order expectations. Study B and C have in total 10 subjects ambiguity averse, 1 ambiguity seeking, 17 a-insensitive.

Throughout, verbal reports of subjects nicely support a-insensitivity.

More details on the experiments seem to be available in papers "Do Second-Order Probabilities Affect Decisions?" and "Second-Order Probabilities and Risk in Decision Making," but those papers have never been completed. %}

{% **probability elicitation**: This paper provides a very good method. Incentivization works well if it is for guessing a true existing underlying objective probability distribution. If there is no clear such, and it is to measure purely subjective probabilities, then it is not very easy to incentive/score it. Could impose a scoring rule, e.g. the logarithmic one which is convenient for three or more events.

Five sets of 100 balls, numbered 1-10, were created, with different beta distributions of 1,…,10. Subjects could see the result of a 100-fold sample with replacement, quickly within one minute presented to them one by one. Then they had to predict the distribution of a next sample of size 100 with replacement. That is, their subjective probabilities were measured. Two different methods were used: (1) the more common one of asking some statistics such as quantiles and means. (2) A method where 10 bins were given to subjects, clearly on a computer screen, and they had to distribute 100 markers over the 10 bins to reflect the right distribution (the histogram method). §1.1 reviews the literature, citing four or so surveys, and also discussing preceding implementations of the histogram method. It also cites decision from experience (DFE). There haven't been comparative studies yet it seems, and this paper is the first.

The histogram method performed superior to the other methods, with fewer biases and no overconfidence, and greater general accuracy. This is in a way unsurprising because the visual histogram is more natural and clear. An additional advantage is that subjects are then thinking in terms of frequencies rather than probabilities. P. 11 writes: "To get accurate estimates about various statistics of a subjective probability distribution, our findings suggest it may be better to elicit the entire distribution graphically and compute arbitrary statistics, rather than asking about the statistics directly."

There were no real incentives but it was flat payment (p. 4 §2, beginning). Real incentives can easily be implemented here by paying some distance function to the true distribution (as with expectations of proper scoring rules).

The method only clearly works if there is a clearly defined underlying frequency-based true probability distribution. For natural events with no known probabilities it will be harder to implement. How to pay then if no reference to a true distribution? Some scoring rule I guess. Ambiguity theories complicate life

here. One other problem can then be what partition one then takes (with the 10 numbered balls the basic partition was obvious). Studies by Craig Fox suggest that a bias toward uniform distribution will result. %}

Goldstein, Daniel G. & David Rothschild (2014) "Lay Understanding of Probability Distributions," *Judgment and Decision Making* 9, 1–14. https://doi.org/10.1017/S1930297500004940

{% A deep author. **dynamic consistency**; **updating: discussing conditional probability and/or updating** Suppose you'll observe E (or not E) in two days from now. P(H|E) is conditional probability of H given E today. You think that tomorrow P(H|E) need not be the same as today. (Ramsey 1931 also wrote on this.) But, Goldstein argues, the expectation of your tomorrow-P(H|E) should be today's P(H|E). He calls this requirement temporal coherence. Lindley, discussing the paper, argues that P(H|E) tomorrow will differ because of further info received and that that further info should then be expressed by writing an additional conditioning event.

P. 233: "Subject to the conditions of coherence you have complete freedom of choice in evaluating previsions."

P. 232 2nd para: there is not only the info that E happens, but also the "meta-info" that that info was received, which distorts conditioning.

P.242 cites Good (1977) for arguments as to why we should explicitly consider changes in previsions arising from pure thought. %}

Analysis on pp. 242-243 makes strange assumptions about the f and g function. So does p. 25 2nd column.

Experiment 3 shows violation of monotonicity resulting from neglect of zero-

outcome that was studied extensively in several papers by Birnbaum; it's actually dual to Birnbaum's finding; i.e., replacing a zero outcome by a negative outcome increases the valuation of the lottery. Birnbaum explained to me by email that that may be caused because subjects take a different range of outcomes to refer to. G & E ascribe the idea to Slovic (1984, personal communication). Slovic found it but did not publish.

The family if Eqs. 22-24 is the most popular one today (Oct. 2020) together with Prelec's (1998) CI family. However, the family here is a bit better than Prelec's. In his CI family, the two parameters are not very well separated. The α parameter, supposed to capture insensitivity, also somewhat affects elevation. This can be seen from Wakker (2010 Figure 7.2.2). For the figures with $\beta = 1$, the fourth (outer right) figure with $\alpha = 0.35$ has the curve on average lower than the second figure with $\alpha = 1$ (EU). So, with β fixed, lowering α led to some decrease of elevation. In this regard the Goldstein-Einhorn (1987) family is better (Wakker 2010 Figure 7.2.3). %}

{% Say that long-shot effect (overbet on outsiders, underbet on favorites) can be reconciled with risk aversion because love for skewness drives it. Unfortunately, I did not find a definition of risk aversion. Apparently, the authors identify risk aversion with a negative weight of variance in the regression. %}

Golec, Joseph & Maurry Tamarkin (1998) "Bettors Love Skewness, Not Risk, at the Horse Track," *Journal of Political Economy* 106, 205–225.

{% %}

Gollier, Christian (1997) "A Note on Portfolio Dominance," *Review of Economic Studies* 64, 147–150.

{% Economists often use representative agent with average income. If, in reality, there is inequality of income, will average of risk aversion be bigger or smaller than risk aversion of average? Under linear risk tolerance (HARA family including exponential, power) it's the same, under concave absolute risk tolerance the risk aversion is bigger, under convex it is smaller. Some numerical suggestions give a doubling of the equity premium.

decreasing ARA/increasing RRA: P. 182 and §4 criticize increasing-RRA by mentioning empirical economic findings contradicting it. P. 187 says that the relative share of stocks in total wealth increases with the latter. P. 58 seems to also doubt it.

I am not sure here what the role of consumption of basic is, if that should first be subtracted.) %}

Gollier, Christian (2001) "Wealth Inequality and Asset Pricing," *Review of Economic Studies* 68, 181–203.

{% Book assumes expected utility throughout, and studies how uncertainty affects welfare and equilibria. Analogy with **time preference**s is pointed out. There are 26 chapters, each centered around some theoretical finding from the literature, many results on background risks etc. Exercises at the end of the chapters.

§11.2.3 gives a sufficient condition for young people to be more risk averse

. Pp. 11-12, §1.4.2, treats my dynamic discussion of the Allais paradox. HARA utilities play a central role. Ch. 5 is on the equity premium puzzle, which is presented as a central problem for the field. Proposition 11 on p. 83 in §6.1 gives the appealing diffidence theorem of Gollier & Kimball, the application of the separating hyperplane theorem.

Ch. 19 is on the Samuelson-Merton result for saving-portfolio.

source-dependent utility: Ch. 20 gives an elementary treatment of the Kreps & Porteus (1978) model.

§21.4.2, p. 317, gives the Arrow-Lind theorem.

Ch. 23 is nice, on the nontrivial derivation of the representative agents's characteristics from the characteristics of the individual agents. The average behavior need not result from the average of the individual risk parameters. Sometimes, the absolute risk tolerance of the representative agent equals the average absolute risk tolerance of the individual agents, but such a result does not hold for prudence.

Ch. 24 is on the **value of information**, Blackwell theorem etc.

The concluding sentence is: "Far from that I believe that this book calls for another round of theoretical and empirical research."

Epilogue, p 424ff., argues that it is remarkable that there are so few studies into risk aversion (he means utility curvature).

Gollier, Christian (2001) "*The Economics of Risk and Time.*" MIT Press, Cambridge MA.

{% Discounting: P. 150 explains why saving money yields profits: because we expect that future consumption will be better than past consumption. Paper shows that uncertainty about growth rate, plus prudence, reduces the optimal discount factor.

P. 163: French Commissariat au Plan recommends to use 8% discounting, most developed countries do between 5% and 8%. Author suggests 5% for periods between 50 and 100 years, and 1.5% for over 200 years. %}

{% **information aversion**: The paper considers intrinsic value of information. It extensively reviews cases and literature of this phenomenon, and its many implications. %}

Golman, Russell & George F. Loewenstein (2017) "Information Avoidance," *Journal of Economic Literature* 55, 96–135.

{% **information aversion**: The paper presents a psychological theory for it. An information gap is when a person becomes aware of missing relevant information and develops ideas and emotions about it. Information is not only instrumental in getting better outcomes but also has intrinsic utility.

A question can have countably many possible answers, one being correct and the others not. It is much like Savage's state space. A subject faces n questions. $(a_1,\ldots,a_n,x)$ denotes a situation where the answers are $a_1,\ldots,a_n$, and a prize x results. A cognitive state is a probability distribution over such n+1 tuples. The subject is assumed to maximize EU over cognitive states. The authors then formulate seven conditions that imply a particular shape of utility $U(a_1,\ldots,a_n,x)$, a

sort of weighted average attribute-utility, with also attention weights for the questions coming in.

An *information gap* means that an agent does not know the correct answer for sure, and feels that lack. Thinking about an information gap has intrinsic utility. Some are nice and others are not. Subjects can face several questions at the same time.

The authors also consider compound questions, which are like Savagean multistage acts.

In general, thinking about very nice questions brings positive utility. But the authors also discuss the ostrich effect.

A section on p. 157 discusses ambiguity attitudes, which, according to the theory of this paper, may be driven by information gaps. The authors have a separate paper on risk and ambiguity (Golman, Russell, & Gurney (2016), and this section summarizes only. See my annotations there. %}

{% Asked one time preference question to 13-year olds in longitudinal Swedish data set. Find negative relationship between discounting and school performance, health, labour supply, and income. Males and high-ability children gain more from being future oriented. Measured cognitive spatial ability. %}

Golsteyn, Bart H.H., Hans Grönqvist, & Lena Lindahl (2014) "Adolescent Time Preferences Predict Lifetime Outcomes," *Economic Journal* 124, F739–F761.

{% This paper is the introduction to an impressive special issue on how psychologists and economists can learn from each others' measurements of subjective decision attitudes or personality traits.

P. 2 middle is strange on defining versions of validity differently than I think they should be. For instance, different questions measuring into the same underlying construct is convergence validity and not construct validity, and so on.

Pp. 2-3 point out that test-retest reliability, and predictive tests are more common psychometric requirements for personality traits in psychology than for subjective decision attitudes in economics. Then it continues that economists may have fewer anchoring biases because their outcomes (e.g. monetary reward) are more objectively defined.

§3 is on stability of decision attitudes. Economists may sometimes be too easy going in assuming such stability. The third para, that psychologists define stability in a rank-order sense and not in a cardinal or absolute way, was strange to read for me. Then several studies into stability are cited.

To have clearcut language, the authors often omit nuances. Much so. Thus, they often just state plainly that economists assume that preferences are stable over time. In some other places they may add nuances. In general, as they point out, economists can learn from the advanced knowledge of psychologist on classical test theory, for instance, with factor analysis, test-retest reliability, and so on, and psychologists from economists' ways to get less ambiguous measures. %}

{% **inverse S**; published as Gonzalez & Wu (1999, Cognitive Psychology) %}

Gonzalez, Richard (1993) "New Experiments on the Probability Weighting Function," presented at the annual meeting of the Society for Mathematical Psychology, Norman, OK.

{% I often cite this paper because it has a very good discussion of likelihood insensitivity as discriminatory power (**cognitive ability related to likelihood insensitivity (= inverse S))**

PT: data on probability weighting; **inverse S:** Does nonparametric fitting of

PT for 10 subjects, using choice-derived certainty equivalents for 2-outcome lotteries. Finds inverse S for all 10 subjects! They do not explain how they sampled the 10 subjects, but it seems that they took 10 well behaved subjects from a larger pool. Their purpose is to illustrate that their method can give nice measurements at the individual level, and not to do statistics with a representative sample.

P. 133 warns that prospect with only one nonzero outcome do not identify a joint power of utility and probability weighting.

Pp. 136-139, and else, discuss insensitivity, nicely using the expression diminishing sensitivity also for probability weighting w, although they use the cavexity concept that I think is not very good to capture it.

P. 140: "Because the weighting function is constrained at the end points (w(0) 5 0 and w(1) 5 1), an independent separation of curvature and elevation is not possible due to the "pinching" that occurs at the end points."

P. 142 discusses pros and cons of parametric fitting.

Real incentives: **random incentive system**

They tested the lower- and upper SA conditions of Tversky & Wakker (1995) and found them well confirmed.

P. 157 seems to report that there are substantial interactions between the PT parameters on parametric interaction.

The authors claim, in the appendix, an axiomatization of the Goldstein & Einhorn (1987, Eqs. 22-24) weighting family (also ascribed to Lattimore et al. 1992), but this is not correct. P. 163 ℓ. 1 has the problem that they did not get it for all x,y, but only for x=y. A corrected axiomatization is in Nascimento & Tat Ng (2022 JMP). In my annotations there I give detailed explanations of the math. %}

Gonzalez, Richard & George Wu (1999) "On the Shape of the Probability Weighting Function," *Cognitive Psychology* 38, 129–166. https://doi.org/10.1006/cogp.1998.0710

{% **biseparable utility**; **binary prospects identify U and W**

I use the term CPT (1992 cumulative as the authors do and most others, although I prefer the term PT. The paper and I here focus on gains.

SPT instead of OPT: What the authors call OPT is not really 1979 OPT (original prospect theory), but it neither is separable prospect theory. Instead, they do a mix. For two-outcome prospects they do real OPT, which deviates from separable prospect theory (if both outcomes are nonzero, because then it is rank dependence). But for three-outcome prospects they do separable prospect theory, which deviates from real OPT (if all outcomes are nonzero because real OPT does not want the outcome closest to 0 to be weighted; see Wakker 2023). They point this out in footnote 2. I will use the term OPT henceforth as the authors do.

They use two-outcome prospects, where CPT and OPT agree, and which suffice to measure/identify probability weighting. Then they see which better predicts for three-outcome prospects. CPT does bit better although a close call. CPT underestimates, and OPT overestimates, certainty equivalents. The concluding para of the paper favors CPT. I want to add a strong further argument supporting CPT: OPT has been targeted towards two or three outcomes, but goes nowhere for more outcomes, grossly overestimatng their values. Hence, this paper tests the two theories in the domain most favorable to OPT, the only domain where OPT has any chance at all. %}

Gonzalez, Richard & George Wu (2022) "Composition Rules in Original and Cumulative Prospect Theory," *Theory and Decision* 92, 647–675. https://doi.org/10.1007/s11238-022-09873-0

{% Field experiment with 670 small and medium-sized enterprises (SMEs) and their 33,000 employees. Measured risk preference, time preference, and trust. There is only a nonsystematic, short-term effect of previous phishing emails on clicking behavior. Individuals with greater patience, trust, and risk seeking were more likely to click on phishing links but also more likely to benefit from phishing drills. %}

{% The basic idea of this paper is to exploit probability weighting for incentives. If agents overweigh small probabilities, as is the common empirical finding, then giving them a small-probability reward gives a particular degree of incentivization at the lowest expected-value cost. The paper uses rank-dependent utility to derive the point theoretically, and demonstrates that it works in an experiment. In this experiment, the paper uses Abdellaoui's (2000) method to measure probability weighting and utility (**tradeoff method**). P. 613 discusses multistage updating, a delicate issue under nonexpected utility, and the paper assumes reduction of compound lotteries, citing the relevant Machina (1989). Pp. 614-615 give Yaari's definitions of between-subject within-source comparisons of pessimism and insensitivity. The paper finds almost linear utility, as is common when correcting for probability weighting. It finds stronger insensivity and weaker pessimism than in mnay other studies.

P. 639 Result 4: As the author points out, it is likelihood insensitivity that drives the main result. %}

{% Paper considers the measurement of weighting functions for uncertainty. It explains how software developed by the authors and made publically available can be used to best fit data. It does not formulate the context as uncertainty, but as general aggregation, as multiattribute utility. Uncertainty is an important special case though. Then each attribute refers to a state of nature and $(x_1,\ldots,x_n)$ is a prospect yielding x_j if state j obtains. In general multiattribute utility, to define a ranking of the attributes, they must be commensurable, so that values at different attributes can be compared (p. 767). They assume utility identified. P. 771: They take indifference if the functional-difference is closer to 0 than some threshold δ_C. §4 considers all kinds of distance measures to be minimized, usually in utility units. §5 illustrates an application of choosing between students based on their grades.

Several approaches in the paper consider data not only of the kind of choices and indifferences between n-tuples, but also data such as “the weight of attributes 1,2,3 should be at least 0.3.” P. 778 bottom explains that their LP, minimum variance, and minimum distance approaches work when data are only preferences between n-tuples, as mostly considered in decision theory. %}

{% **source-dependent utility**; **game theory for nonexpected utility** & **dynamic consistency**: Dixit & Skeath (1999) suggested that with high stakes more risk averse strategies in a two-outcome game is more plausible, but EU says the heigth of stakes shouldn't matter. This paper shows that giving up **RCLA** and using recursive utility, and not other aspects of nonEU, can resolve the paradox. The authors are in fact using (as they properly reference) the Kreps & Porteus (1978) model. %}

Grant, Simon, Atsushi Kajii, & Ben Polak (2001) " "Third Down with a Yard to Go": Recursive Expected Utility and the Dixit-Skeath Conundrum," *Economics Letters* 73, 275–286.

{% **Harsanyi's aggregation; source-dependent utility**: This paper characterizes the Kreps & Porteus (1978) model, well-known nowadays (2005-2023) for its use in the KMM smooth ambiguity model, and also analyzed by Grant, Kajii, & Polak (2001). However, it does so not for the Anscombe-Aumann model, but for the more general Harsanyi (1955) model, but the latter in an extended sense. De Meyer & Mongin (1995) showed that Harsanyi (19550 is more general than Anscombe-Aumann (1963). To wit, Harsanyi has a set of outcomes X, with generic element x. Can write x as $(x_1,\ldots,x_n)$ with x_j denoting what x means for individual j. If $y = (y_1,\ldots,y_n)$ has $y_j \sim_j x_j$ then we identify x_j and y_j. That way, Harsanyi's X becomes an arbitrary subset of a product set $X_1 \times \cdots \times X_n$. A Harsanyi probability distribution over X thus becomes an Anscombe-Aumann probability distribution over $X_1 \times \cdots \times X_n$. In this way Anscombe & Aumann (1963) becomes a corollary of Harsanyi (1955).

Whereas Harsanyi, implicitly, has 1/n probabilities over being individual i, in which case different subjective (endogenous) weights for different individuals can be interpreted as different welfare weights rather than probabilities, this paper adds an extra structure, making it different (not more or less general than Harsanyi): It additionally assumes probability distributions over the set I of individuals. Thus, the choice set is a product set $\Delta(I) \times \Delta(X)$, where Δ designates set of probability distributions. On p. 1953, beginning of §6, the authors write that Harsanyi worked with $\Delta(I \times X)$, deviating some from the $\Delta(X)$ that I assumed above. I took weights over I in Harsanyi as endogenous and not exogenous. Harsanyi does not write very explicitly about domain, and one can view it in different ways. %}

{% Find mathematical mistakes in Gul & Pesendorfer (2014 Econometrica). The interval utility u(x,y) can be state-dependent and the set of ideal events does not need to be a sigma-algebra, given GP's axioms. Also, μ need not be countably additive. The auhors propose corrected axioms. %}

Grant, Simon, Shuo L. Liu, & Jingni Yang (2024) "A Comment on: Expected Uncertain Utility," *Econometrica* 92, 247–256.

{% **game theory can/cannot be viewed as decision under uncertainty**: the paper models game theory as Savagean decision under uncertainty.

The authors consider general games. They define states of nature that describe all uncertainties, being not only moves by nature but also all moves of players. For a player an information event is one that she can observe and condition strategy choice on. The authors emphatically assume NO randomization device, which I like. This is the main novelty relative to some preceding general modelings of game theory with ambiguity (discussed on p. 669). They only assume general preferences of players over outcomes, which can be state-dependent (Axiom A1 on p. 648). In fact, they only assume preferences over own strategies when the strategy choices of all others are fixed (sounds normal-form like). This fits with the idea that players choose their strategies independently and cannot influence each other, but not with the idea that in a meta-sense players can still influence each other ("if I come to conclude that x is optimal for me then player 2 will come to conclude that y is optimal for him"). Without further info, it also does not (yet) allow for comparisons of different equilibria. Outcomes can be general combinations of strategies.

A difficulty is that the revealed preference approach to observe preferences over own strategies given strategy choices of all others does not work well in games. It involves problematic thought experimennts as in Aumann & Drèze (2008): "imagine that I can only choose between x and y, but my opponents continue to think that I can choose from all my strategies." The authors write that they will not discuss this issue.

The authors derive the existence of an equilibrium (Theorem 1, p. 656), which requires richness, more or less a continuum of states. They assume such Savage-type richness of nonatomicity. As they emphasize, their model does not use randomization and does not need expected utility in any sense and can allow for general ambiguity attitudes (p. 642 end of 1st para). The absence of randomization and absence of commitment to expected utility for risk add to the generality of their approach. They do assume many conditionings on events that are observable to a player and there assume something like Savage's sure-thing principle, or backward induction (p. 650 ℓ. 1). So, it is not a universal sure-thing principle, but still it is a restriction.

It is useful to have a general framework for game theory without commitment to randomization and expected utility, allowing for ambiguity all over the place, and this is the first paper to do so. There is a price to pay of complex richness, general complexity of model, and still a sure-thing principle at some places.

P. 643, end of 2nd para: "It allows us, as well as behooves us, to model equilibrium behavior without the usual technical paraphernalia of convexity or monotonicity of strategies and preferences, and the related praxis that seems to have arisen more from considerations of analytical tractability rather than motivated by, for example, behavioral properties of the underlying preferences." %}

{% Nice generalization of Machina & Schmeidler (1992) by using P4 and a weaker analog of Savage's P2. %}

Grant, Simon, Hatice Özsoy & Ben Polak (2008) "Probabilistic Sophistication and Stochastic Monotonicity in the Savage Framework," *Mathematical Social Sciences* 55, 371–380.

{% They weaken a central axiom in Machina & Schmeidler's (1995) probabilistic sophistication model in the Anscombe-Aumann setup to stochastic monotonicity (independence when one of the prospects is degenerate). %}

Grant, Simon & Ben Polak (2006) "Bayesian Beliefs with Stochastic Monotonicity: An Extension of Machina and Schmeidler," *Journal of Economic Theory* 130, 264–282.

{% Propose a generalization of mean-variance where the combination of mean and variance is linear. The main contribution: It goes for uncertainty/ambiguity rather than for risk. Assume Anscombe-Aumann. The mean is mean Anscombe-Aumann-EU. Instead of variance they take a generalized dispersion measure, satisfying conditions specified below. The measure of dispersion is the subjective EU an agent would be willing to give up to achieve constant EU over the state space. A generalization relaxing constant absolute uncertainty aversion will be in Chambers, Grant, Polak, & Quiggin (2014 JET).

A probability measure π on the state space S is derived subjectively à la Savage (or Anscombe-Aumann). The model is very general and encompasses Siniscalchi's (2009) vector utility, variational, multiplier, and many other models. The authors share with variational a sort of constant absolute uncertainty aversion. They point out that absolute uncertainty aversion need not always be constant, but they just focus on this case. They axiomatize it in general, given a few inequalities specified below. P. 1363 penultimate para (& p. 1367 5th para): In the models assumed to be special cases, they incorporate Choquet expected utility, apparently implicitly assuming Anscombe-Aumann.

P. 1365: the general form is

$$V(f) = E_{\pi}(U \circ f) - \rho(U \circ f))$$

where $E_{\pi}(U \circ f)$ denotes the subjective Anscombe-Aumann EU, and ρ captures dispersion about $E_{\pi}(U \circ f)$, and $\rho(0) = 0$ for acts with constant k-utility level at every state.

P. 1366 lists axioms. A4 is unrestricted solvability and implies unbounded utility. A5 is constant absolute uncertainty aversion:

$$\alpha f + (1-\alpha)x \succcurlyeq \alpha z + (1-\alpha)x \Rightarrow \alpha f + (1-\alpha)y \succcurlyeq \alpha z + (1-\alpha)y$$

for constant acts x and y, and also constant act z. The latter is immaterial, and could have been any act g, as the authors point out p. 1366 bottom. Hence, the axiom is equivalent to weak certainty independence.

P. 1367 para −4 (also p. 1364 2nd para): without further assumptions, the model is too general to, for instance, have π identifiable. Theorem 1 is called too general to be very useful. (P. 1372 3rd para: in general, any π is possible and π is completely unidentifiable.)

They next consider properties called desirable such as uncertainty aversion (A6 p. 1368: convexity, or A6*: preference for complete hedges, or A7 (p. 1368): certainty betweenness, or A.8 (p. 1368): Siniscalchi's complementary independence, and positivity of ρ, properties that rule out likelihood insensitivity (inverse S) and, hence, will not work well empirically. Theorem 2 (p. 1368) gives the equivalent properties of ρ.

P. 1373: π is identifiable if local smoothness. Problem is that this is a mathematical nontestable condition. P. 1374 5th para: Siniscalchi's symmetry makes π identifiable.

P. 1375 considers (2nd order) probabilistic sophistication. 2nd order because we have not only π on S but also the Anscombe-Aumann objective probabilities. %}

{% Generalize Gul & Pesendorfer's (2014; GP14) Expected Uncertain Utility Theory by having probabilistic sophistication rather than expected utility for the ideal events. Call their theory Generalized Uncertainty utility (GUU). Another deviation that I think is good is that they do not commit to the ideal events being endogenous, but allow them to be exogenous, and commit to neither. In these annotations, I criticize GP14 for claiming to accommodate the Allais paradox but not really doing so. This paper escapes from that and can really accommodate the Allais paradox.

event/outcome driven ambiguity model: outcome driven: like GP14, almost entirely outcome driven.

They share with G&P the central role of diffuse events, which I think is highly problematic. A big problem is that the exchangeability of diffuse events (Gul & Pesendorfer Axiom 3) leads to violations of dominance. The Grant, Rich, & Stecher (2022 p. 10) were forced by a referee (not me) to discuss this issue. I disagree with their defensive text. Their point that this violation of monotonicity comes from geometric reasoning and not from measure-theory reasoning is completely irrelevant to me. So, I agree much with their referee. Another problem is that diffuse events are often unobservable and even nonconstructive (Brouwer; see Birkhoff 1967 Theorem 13 and Cohen 2008). Roughly, it means that no explicit formula can describe them. And, further, the extreme total-absence-of-info α-maxmin type behavior towards diffuse events, violating some forms of dominance (p. 10), is not close to any empirical or normative behavior. For example, a diffuse event D can be a joint union of two disjoint diffuse events D1 and D2, all three nonnull, and all gambling-equivalent. The authors defend by calling this argument "geometric" and then saying that they do measure theory and not geometry, but I disagree with this defense. Anyway, this is essential in GP14 and cannot be avoided when generalizing GP14.

P. 2 cites papers that have NonEU jointly for risk and uncertainty, and writes as aim that any risk attitude can be combined with any ambiguity attitude. This has been achieved before in Choquet expected utility and its generalization of (cumulative) prospect theory, for instance in my 2010 book, which, as most of my papers, argues that one better avoid committing to EU for risk (and the

Anscombe-Aumann framework). Tversky & Kahneman (1992) is one of many papers in this stream. This stream is not cited here; oh well. %}

Grant, Simon, Berend Roorda, & Jingni Yang (2021) "Coherent Rich Beliefs, Decomposable Splits, and Dynamically Consistent Choice," Discussion paper, Australian National University, Canberra.

{% This paper generalizes Gul & Pesendorfer's (2014) expected uncertainty model by not requiring expected utility for unambiguous events but allowing Grant, Kajii, & Polak's (2000 JET) decomposabability model there. It is more general than beteweenness.

There is given a collection of balanced outcome sets, comprising ambiguity about what the outcome is. (**ambiguous outcomes vs. ambiguous probabilities**; **event/outcome driven ambiguity model: outcome driven**) In Savagean framework, agent assigns to each act the minimal map from states to balanced outcome-sets that contains the act. Certainty equivalent is such that, taking that as "balancing value," gives EBUU value 0. It is a special case of implicit utility, satisfying betweenness.

Atttitude to nonambiguous acts (where balanced sets are singletons) gives risk attitude, and what comes to it is ambiguity attitude. Decomposable events E satisfy Grant, Kajii, & Polak's (2000 JET) decomposabability for all acts f,g: [$f_E g \succ g$ and $g_E f \succ f$] $\Rightarrow$ $f \succ g$. An act is decomposable if it is measurable w.r.t. the decomposable events. Decomposable events are taken as unambiguous. The authors define diffuse acts similarly as Gul & Pesendorfer (2014, 2015). Those acts are maximally ambiguous and imply extreme behavior.

The authors conclude by pointing out that they have introduced an ambiguity model thataccommodates betweenness for risky decisions. I add here that Chew & Sagi (2008) is another ambiguity model doing so. I have always taken as the "real" definition of betweenness, also covering uncertainty/ambiguity, that expected utility holds within every indifference class. The authors do not consider this concept and I conjecture that their model does not satisfy it, whereas Chew & Sagi's model does. %}

{% **principle of complete ignorance**: & **ordering of subsets**: This paper considers rankings of finite subsets of some "motherset," that is a connected topological space so that it is infinite and even a continuum. They consider all finite sets of size n, for each natural n, so, all finite subsets. They interpret sets as choice objects, let me say prospects, as resulting from decision making under complete ignorance. You know that you get one element from the finite set, but you know nothing more. In a preceding paper they axiomatized maximization of average utility. For what they axiomatize in this paper, first note that sets can be reinterpreted as probability distributions assigning the same probability 1/n to each of the n elements of an n-element set. This way the domain becomes all simple equal probability distributions with the restriction that each outcome can appear only once. Thus we, for instance, do NOT get all simple rational-probability distributions. Anyway, here they characterize a generalization of rank-dependent utility (RDU), where for every fixed n all n-outcome sets are evaluated by an RDU functional, but the weights for different n are completely unrelated. The end of the paper gives some restrictions. In this, they use the **tradeoff method**. This case has the popular α maxmin models, taking a convex combination of minimal and maximal utility, as a special case, and average utility as another. %}

Greco, Gabriele (1982) "Sulla Rappresentazione di Funzionali Mediante Integrali," *Rend. Sem. Mat. Univ. Padova* 66, 21–42.

{% They propose a generalization of the Choquet integral that can be interpreted as having **state-dependent utility** or as having outcome-dependent weighting function. They cite Green & Jullien (1988) and Segal (1989) for a similar functional for decision under risk. They do not know Chew & Wakker (1996) who, more generally, consider such functionals also for a state space and who consider connected topological spaces (in their appendix) generalizing the reals, and allow for nonlinear, continuous, utility functions. This paper concerns the special case of the Chew & Wakker (1989) functional for the reals and with utility the identity.

This paper takes the functional as primitive when axiomatizing its form, whereas Chew & Wakker (1996) did it with the represented preference relation as

primitive. Chew & Wakker also point out that 1992-prospect theory is a special case, but, unlike this paper (§9), do not note that the Sugeno integral is also a special case.

P. 15 ℓ. –3 correctly points out that the functional in itself is too general to be very useful. They also analyze the Möbius transform (§8.1), and bipolar generalizations.

I next show briefly how the characterization provided in this paper in Theorem 1 is related to Theorem B1 of Chew & Wakker (1993). Their main characterizing condition, cardinal tail independence (p. 9) implies ordinal independence of Chew & Wakker (Remark A1). The other axioms in Theorem B1 of Chew & Wakker (1993) are implied readily, mainly by the assumed existence of the functional. Thus, this Theorem B1 implies the existence of the functional of Chew & Wakker, and all that remains to be proved is that their utility function is the identity, which follows from cardinal tail independence. %}

{% No new experiment; seems that they don't fit data at the individual level, only at group level. %}

Green, Leonard, Joel Myerson (1993) "Alternative Frameworks for the Analysis of Self-Control," *Behavior and Philosophy* 21, 37–47.

{% Survey of intertemporal choice together with risky choice. They consider only one nonzero outcome and mostly take linear utility. Then risk attitude is entirely driven by probability weighting, which the authors also call discounting. They consider exponential functions exp(-bx), hyperbolic functions A/(1+kx), and what they call hyperbola-like $A/(a+kx)^s$. In intertemporal context they take time t for x, and in risky choice they take odds ratio p/(1-p) for x (then the hyperbola-like family is the same as the one used by Goldstein & Einhorn (1987). Why odds ratio would be the analog for time is not clear to me, even if it does cover the same range. So, different behavior of utility for one than for the other (a finding presented in several places) is not clear to interpret, the more so as transaction costs work differently for one than for the other. The authors find that both for intertemporal choice and for risky choice the hyperbola perform better than exponential, and the extra parameter s improves the fit. From no more than this usefulness of extra parameter s for time as for risk the authors again and again derive the far-fetched conclusion that the mechanisms for time are the same as for risk, making this the main message of their paper.

They say they find support for inverse S but this is little surprise if only functions are fit that are inverse S.

P. 774 claims that hyperbola-like functions fit well at individual level for ALL individuals. P. 774: When they find that the extra parameter s is worthwhile both for children and for elderly people (**relation age-risk attitude**) this is what they conclude: "These findings demonstrate that the hyperbola-like discounting function (Equation 3) is extremely general in that it describes temporal discounting in individuals from childhood to old age." Variation in payoff (p. 781, top of 2nd column) amounts to tests of constant relative risk aversion.

loss aversion: erroneously thinking it is reflection: p. 768 3rd para thinks that loss aversion generates different predictions for losses than for gains, not realizing that loss aversion is only about exchanges between gains and losses.

real incentives/hypothetical choice, for time preferences: they have several references on it on p. 775. %}

{% The authors seem to think that all violations of EU are due to misunderstanding utility.

risky utility u = strength of preference v (or other riskless cardinal utility, often called value); Subjects did direct quantitative judgments of utility. Next they did welfare evaluations, and risky decisions (sure vs. two-outcome gamble) where outcomes were money and where outcomes were their own utility assessments. For utility outcomes, risk aversion remained though less pronounced than for monetary outcomes. For welfare, similar aversion to equity. The result is plausible if risky utility = direct assessment and there is extra risk aversion because of nonEU, say probability transformation. However, the authors never consider the possibility that the subjects may deviate from EU (and additively-separable utilitarianism). Instead, they argue that all deviations are caused by misunderstandings of the concept of utility.

P. 245 4th para, about subjects facing outcomes in terms of their own direct assessments of utility, and nicely and appropriately suggesting that the subjects just treat these as monetary outcomes:

"In making such esoteric judgments, do they take the pains necessary to exclude whatever momentarily inappropriate intuitions they have developed over a lifetime of reasoning about the goods of everyday life?"

P. 246 first half gives informal version of the aggregation argument. %}

Greene, Joshua & Jonathan Baron (2001) "Intuitions about Declining Marginal Utility," *Journal of Behavioral Decision Making* 14, 243–255.

{% **survey on nonEU**: Well on EU that is. Gives nice survey of empirical risk studies up to that point, especially regarding relations with demographic variables.

questionnaire for measuring risk aversion: Uses it. No significant correlation between risk attitude measurements and general insurance questions. Maybe because former are for mixed prospects, and latter for losses. %}

Greene, Mark R. (1963) "Attitudes toward Risk and a Theory of Insurance Consumption," *Journal of Insurance* 30, 165–182.

{% **foundations of statistics**: Discusses p-values. The paper does not bring new insights but does an exceptionally thorough job. Especially impressive is that it has 100 or so references on the topic. I kept track of such references all my life and the keyword "Foundations of Statistics" gives about 120 references at this moment of writing (01Nov2016).

The paper many times repeats that p-values and the like are only valid if all assumptions made are valid, which I do not find very informative. Only point to note is that p-value is probability conditional on H_0 being true.

P. 338 2nd column 1st para: "Many problems arise however because this statistical model often incorporates unrealistic or at best unjustified assumptions. This is true even for so-called "non-parametric" methods, which (like other methods) depend on assumptions of random sampling or randomization."

P. 338 2nd column 2nd para points out a problem of classical methods that is avoided under the likelihood principle: "There is also a serious problem of defining the scope of a model, in that it should allow not only for a good representation of the observed data but also of hypothetical alternative data that might have been observed."

P. 338 2nd column 2nd para "many decisions surrounding analysis choices have been made after the data were collected—as is invariably the case [33]."

P. 339 1st column 3rd para "In conventional statistical methods, however, "probability" refers not to hypotheses, but to quantities that are hypothetical frequencies of data patterns under an assumed statistical model. These methods are thus called frequentist methods, and the hypothetical frequencies they predict are called "frequency probabilities." "

P. 343 the 16th common misinterpretation of P value comparisons and predictions:

"16. When the same hypothesis is tested in two different populations and the resulting P values are on opposite sides of 0.05, the results are conflicting.

No!" So, if one test rejects a null hypothesis H_0, and another does not, then this is not inconsistent because accepting H_0 does not mean much.

P. 343 the 17th common misinterpretation of P value comparisons and predictions: "17. When the same hypothesis is tested in two different populations and the same P values are obtained, the results are in agreement. No! Again, tests are sensitive to many differences between populations that are irrelevant to whether their results are in agreement. Two different studies may even exhibit identical P values for testing the same hypothesis yet also exhibit clearly different observed associations. For example, suppose randomized experiment A observed a mean difference between treatment groups of 3.00 with standard error 1.00, while B observed a mean difference of 12.00 with standard error 4.00. Then the standard normal test would produce P = 0.003 in both; yet the test of the hypothesis of no difference in effect across studies gives P = 0.03, reflecting the large difference (12.00 - 3.00 = 9.00) between the mean differences."

P. 347 penultimate para sings the usual song of statistical analyses. %}

Greenland, Sander, Stephen J. Senn, Kenneth J. Rothman, John B. Carlin, Charles Poole, Steven N. Goodman, & Douglas G. Altman (2016) "Statistical Tests, P Values, Confidence Intervals, and Power: A Guide to Misinterpretations," *European Journal of Epidemiology* 31, 337–350. https://doi.org/10.1007/s10654-016-0149-3

{% Pp. 36-37: "The term "uncertainty" is meant here to encompass both "Knightian uncertainty," in which the probability distribution of outcomes is unknown, and "risk," in which uncertainty of outcomes is delimited by a known probability distribution. In practice, one is never quite sure what type of uncertainty one is dealing with in real time, and it may be best to think of a continuum ranging from well-defined risks to the truly unknown."

P. 37: "In essence, the risk-management approach to monetary policymaking is an application of Bayesian decision-making."

P. 37: "Given our inevitably incomplete knowledge about key structural aspects of an ever-changing economy and the sometimes asymmetric costs or benefits of particular outcomes, a central bank needs to consider not only the most likely future path for the economy, but also the distribution of possible outcomes about that path. The decision-makers then need to reach a judgment about the probabilities, costs, and benefits of the various possible outcomes under alternative choices for policy."

P. 37: "The product of a low-probability event and a potentially severe outcome was judged a more serious threat to economic performance than the higher inflation that might ensue in a more probable scenario."

P. 38 suggests ambiguity aversion: "When confronted with uncertainty, especially Knightian uncertainty, humans beings invariably attempt to disengage from medium- to long-term commitments in favor of safety and liquidity."

P. 38: "In pursuing a risk-management approach to policy, we must confront the fact that only a limited number of risks can be quantified with any confidence."

{P. 38: "…how … the economy might respond to a monetary policy initiative may need to be drawn from evidence about past behavior during a period only roughly comparable to the current situation."

P. 39, that subjective info cannot be ignored: "Yet, there is information in those bits and pieces. For example, while we have been unable to readily construct a variable that captures the apparent increased degree of flexibility in the United States or the global economy, there has been too much circumstantial evidence of this critically important trend to ignore its existence."

P. 39: "Thus, both econometric and qualitative models need to be continually tested."

P. 40: "In fact, uncertainty characterized virtually every meeting, and as the transcripts show, our ability to anticipate was limited." %}

{% Assume that E is an outcome-relevant event, and s a signal. For odds, under Bayesianism,

$P(E|s)/P(E^cs) = P(s|E)/P(s|E^c) \times P(E)/P(E^c)$.

This paper considers a generalization,

$P(E|s)/P(E^cs) = \alpha + \left(P(s|E)/P(s|E^c)\right)^\beta \times \left(P(E)/P(E^c)\right)^\gamma$

Bayesianism has $\alpha = 0$, $\beta = 1$, $\gamma = 1$. If $\beta=2$, it is as if the signal is received twice (independently, having unaltered odds). Assume $\alpha=0$ and the signal uninformative $\left(P(s|E)/P(s|E^c) = 1\right)$. Then still for $\gamma \neq 1$ the person changes probability, making it more extreme if $\gamma>1$ and more towards 0.5 if $\gamma<1$. %}

{% **updating: testing Bayes' formula**: Descriptively examine Bayesian updating. Distinguish between strength of evidence, which is what probability it would generate if there were no other evidence (or if its "weight" were infinite), and weight of evidence which is how much this evidence will weigh relative to other (say, prior) evidence. For example, if we make a number of observations strength is the observed relative frequency, and the number of observations is the weight. The authors conjecture that subjects are not sufficiently sensitive to the weight dimension, and treat weights as all the same, "average," which means underestimating large weights and overestimating small weights. Verify it in a number of experiments. It explains patterns of both over- and under-confidence found in the literature. %}

{% This paper shows that subjects have a preference for skewness (always taken to be positive skewness), citing preceding literature finding this too. The paper only considers gains. It presents choices between prospects that have the same expected value and variance (taken as riskiness), but differ in skewnes. If subjects positively evaluate skewness, they are of course willing to take some extra risk so as to get extra skewness, as this paper shows empirically. Importantly, §4.5, p.

213, shows that preference for skewness is indistinguishable from the overweighting of small probabilities. Thus, preference for skewness amounts to the same as inverse S probability weighting. Prudence amounts to the same. Unfortunately, the authors only cite 1979 prospect theory for it, and not the many more recent papers showing it. The keywords "**inverse S**" and "**risk seeking for small-probability gains**" in this annotated biblioography give many papers on it. %}

{% **intuitive versus analytical decisions**; Mechanical Prediction means based on quantitative (statistical, computer, etc.) analyses, and clinical means direct intuitive judgments by specialists (unfortunate term, originated from medical domain and now has become generally accepted). This meta-analysis finds that in most cases the mechanical predictions did better.

I agree that mechanical does better than commonly thought, and deserves more attention. The work done in decision theory can be considered to be one big attempt at promoting quantitative analyses. Still, mechanical will not be preferable in most cases.

Concerning a different but more interesting question, when can mechanical analysis contribute something at all to other such as clinical analyses, I guess that it can in 1 out of 10,000 cases. 1 out of 10,000 is so much that it is worth dedicating one's life to. So, how come about the finding of this meta-analysis? I think that it was subject to a selection bias. Published studies concern those rare and interesting cases where mechanical can do something. The obvious point that mecanical mostly doesn't work is too trivial to be published. %}

{% **three-doors problem** ; **updating: discussing conditional probability and/or updating**: Many papers have discussed the issue that conditioning on an observed event can only be done under a ceteris paribus assumption, entailing that the observation does not carry other information, and does not affect anything conditional upon the event. This paper provides mathematical conditions and formulas stating when exactly Bayes formula for conditioning holds and when not, referring to some other recent papers, and many statistical papers, on similar issues. The mathematics by itself is not particularly hard, but is illuminating by bringing in the right concepts. The three-doors problem provides a good illustration of when a naïve version of Bayes formula need not hold. No one will, after reading this paper, ever again fall victim to forgetting the ceteris paribus condition of Bayes' formula. The precise mathematical statements work better than vague philosophical discussions.

Nice concept: The *naïve* [state] space contains only the states that determine the consequences resulting from acts. There are also observations, which do not directly affect consequences of acts, but only indirectly through their influence/information about the naïve state space. To condition upon information often more than just the naïve state space is required. We also need to know the probabilities of the "sophisticated" state space, which describes both the naïve states and (part of) the observations; i.e., what Shafer called the protocol. In the three-doors problem, you also need to know what the jailor does when he has a choice which of the other two prisoners to indicate, before you can calculate posterior probabilities. The sophisticated space should also describe those things. %}

{% benedenstaande achterkant voorblad artikel Gudder geschreven

I spent several hours (spread out over years, starting from Gudder's paper) on finding out if not the axiom M5, cancellation, was implied by the others, M1–M4 and M6. It almost is, but not completely. I did observe a possible weakening of M5 in the presence of the other axioms. It can be derived (took me some hours) from Axioms M1–M4 and M6 that [ApC = BpC for some 0 < p < 1] implies [ApC = BpC for all 0 < p < 1]. So, then only for p = 1 we may have inequality. Hence, Axiom M5 may be weakened to: if ApC = BpC for all 0 < p < 1, then A=B. Examples violating this condition, but satisfying M1–M4 and M6, can be constructed.

An open question to me is if in the axioms, in the presence of the full force of M5, the "three-dimensional" associativity can be weakened to the "two-dimensional" associativity as has been used by von Neumann & Morgenstern and others. %}

{% **linear utility for small stakes**: This is how they justify, in §2, why they use a hypothetical question with a large amount. In this, they correctly specify that they assume expected utility.

decreasing ARA/increasing RRA: this is what they find.

Use household survey data of 8,135 subjects of 1995 Bank of Italy Survey of Household Income and Wealth (SHIW). Risk attitude is measured through the following question, presented "unprepared":

"We would like to ask you a hypothetical question that you should answer as if the situation were a real one. You are offered the opportunity of acquiring a security permitting you, with the same probability, either to gain 10 million lire or to lose all the capital invested. What is the most that you would be prepared to pay for this security?" Here 10 million lire is about $5000. I am afraid that the question leaves many ambiguities. The authors have in mind that it designate a 50-50 prospect. Problem 1. However, one thing unclear is whether not also other outcomes might occur. In practice that will always be the case, so that it is very likely that subjects will assume that there could be other outcomes.

Problem 2. A second difficulty is the vagueness in "with the same probability."

In practice, people never have probabilities given for securities, so, the subjects won't know what probability is being referred to, and will have a hard time picking up that these probabilities are the same.

Problem 3. A third difficulty is that the subjects don't know what guarantee they have that their money will be treated in a fair way. If you invest in stocks you may lose all money, but you will read in the paper that that was the "fair" outcome that the bank had to offer you. If you just give money to a stranger under the terms that maybe the stranger will not return the money, and you don't know the rules of the game, you just will not do it because you don't trust the stranger.

The data, indeed, are bad. Of the 8,135, more than half, 4,677 subjects, were either not willing to pay any positive amount for the security. 3,091 wanted to pay only 0 for it, and 1,586 said they did not know. Only 3,458 were willing to pay a positive amount. The authors argue that it is due to the “complexity” of the question and that it is good to get rid of those who don’t understand, but I think that the security is way more unfavorable than the authors take it. It is also unfortunate that the subjects dropped are not randomly misunderstanding, but comprise the most risk averse and ambiguity averse among the subjects.

Despite the above problems, the data set is so very nice that it is still interesting to analyze the relation between the answers given and demographic variables etc., among the 3,458 that did want to pay a positive amount.

In this group, the young take less risk than the old. (**relation age-risk attitude**) %}

Guiso, Luigi & Monica Paiella (2008) “Risk Aversion, Wealth and Background Risk,” *Journal of the European Economic Association* 6, 1109–1150. https://doi.org/10.1162/JEEA.2008.6.6.1109

{% Idea of the model: To prepare, first consider traditional EU for $(p_1{:}x_1,\ldots,p_n{:}x_n)$, with $x_1 \geq \cdots \geq x_n$. Then CE (certainty equivalent) satisfies, with $x_k \geq CE \geq x_{k+1}$,

$$SUM_{i\leq k}p_i\big(U(x_i)–U(CE)\big) = SUM_{j>k}p_j\big(U(CE)–U(x_j)\big).$$

This paper considers a generalization of EU where there exists a $\beta > -1$ such that the CE satisfies

$\mathrm{SUM}_{i \le k} p_i(U(x_i) - U(CE)) = (1+\beta)\mathrm{SUM}_{j>k} p_j(U(CE) - U(x_j))$ (*)

That is, the disappointing outcomes (worse than the lottery, so, than its CE) are reweighted by a factor $1+\beta$. $\beta > 0$ is in the spirit of loss aversion. In his equation on top of p. 673, the weights are $\alpha/(1+(1-\alpha)\beta)$ and $(1+\beta)(1-\alpha)/(1+(1-\alpha)\beta)$, so, the bad outcomes are indeed overweighted by $(1+\beta)$ relative to the good outcomes, confirming my Eq. (*). Eq. (*) is easiest to understand and analyze the model, I think.

P. 670 above Def. 1 for once and for all imposes that big sure money amounts are preferred to small ones, which will imply that utility is strictly increasing. Stochastic dominance can readily be inferred from Eq. (*) above, where by transitivity it suffices to consider only improvements that do not cross the u(CE) level: If one outcome is increased then, both if $\mathrm{SUM}_{i \le k} p_i(U(x_i) - U(CE))$ was increased and if $\mathrm{SUM}_{j>k} p_j(U(CE) - U(x_j))$ was decreased, to maintain the equality, the CE value has to increase too. Thus, we get classical weak stochastic dominance (increasing any monetary outcome weakly improves the prospect).

biseparable utility: p. 677 points out that for two-outcome lotteries this theory is a special case of rank-dependent utility, with probability weighting function (I write p for probability where Gul writes α)

$p \to p/(1 + (1-p)\beta)$.

If the probability of the worst outcome is $1-p$, then its weight is $(1-p)(1+\beta)/(1 + (1-p)\beta)$. In other words, we at first leave the good-outcome probability p unaffected but give the bad-outcome probability $1-p$ and extra weight factor $1+\beta$. Then we normalize. This means that the Wakker & Deneffe (1996) **tradeoff method** also measures utility for Gul's disappointment aversion theory. Pity I did not know this before Sept. '98, so could not mention it in the 96-paper. Disappointment aversion is a betweenness model, having linear indifference sets and EU within each indifference set, and satisfying quasi-convexity and quasi-concavity w.r.t. probability mixing. (It is not a special case or Chew's (1983) weighted utility.) I guess that Gul did not know these models when inventing his theory, but with his creativity just automatically invented the best and nicest model that can be. %}

{% This paper, which received a lot of attention, is typically an ivory tower paper by economists who never did applied work. The reasoning of the authors is simple: for everything they argue that that could also be done using only revealed preference and, in fact, could be done better using only revealed preference. (**ubiquity fallacy**)

Endnote 3 explains why the authors avoid the term behavioral economics. They focus on the issue of using choiceless inputs in economics, departing from the revealed preference paradigm. However, they then unfortunately mostly focus on one small subset of choiceless inputs: Neuro-economics inputs, and often seem to take the latter as fully capturing the former. (P. 9 middle calls "psychology and economics," their term for behavioral economics, a pedecessor of neuroeconomics!?). This is because they react much to a Camerer, Loewenstein, & Prelec (2005) paper that greatly overstates the role and potential of neuro-economics.

They take a very strict and I think overly dogmatic revealed-preference viewpoint. (The famous Becker & Murphy 1977 is another example of a paper with such overly dogmatic viewpoints.) Again and again they argue that economics can ignore choiceless inputs, because, as they argue, those are defined to be outside of economics. But it cannot be denied that sometimes choiceless inputs can better predict consumer choices or, say, patient preferences, than choice-based inputs. The authors never take issue with this point, leaving me puzzled. The real reason why the ordinalists in the 1930s chose to go this way is that it gives unambiguous clear definitions, as a pro, with the con of losing inputs and info. The tradeoff between this pro and con cannot be judged on methodological arguments, or in an ivory tower. It came from over half a century of experience, showing that the con of losing inputs and info is too big. Such arguments are not found in this paper. To understand such points, it is better to have worked in a hospital for a year (one can never explain doctors that they should ignore info they read from the faces of patients, also for economic decisions on which money to spend on which treatment …) than to have proved theorems in an ivory tower. ☺

Typical is p. 2 3rd para, on subjective states and hedonic utility being legitimate topics of study. "This may be true …" So, about the whole field of psychology, they don't say that it is legitimate, but only that it may be legitimate. %}

ABBREVIATIONS:

GP: Gul & Pesendorfer

GP14: Gul & Pesendorfer (2014), being this Econometrica paper

GP15: Gul & Pesendorfer (2015), being the JET paper

In short, both papers have deep maths, but their requirement that all ideal events and their probabilities be measured, needed to define inner and outer measures, and their requirement that diffuse events exist that involve unrealistic extreme decision attitudes (violating monotonicity; see Grant, Rich, & Stecher 2022 p. 10), make it impossible to use these theories in applications.

GP14: This paper is close to Jaffray (1989) (see below), only cited on p. 20. Would have been more appropriate to cite Jaffray in the intro. Thus, on p. 13 end of first para the authors claim a subjective foundation of Dempster-Shafer belief functions, not crediting priority of Jaffray.

SUMMARY PART 1. This paper (GP14) considers a Savage framework with acts mapping state space Ω to outcome space $X = [\ell,m] \subset \mathbb{R}$. The paper considers all maps from Ω to X, and imposes no measure-theory restrictions here. (Non-measurable sets will be crucially used.) A sub-σ-algebra of events (called *ideal*), and acts measurable w.r.t. them, satisfy all of Savage's axioms and has SEU, with utility v and subjective probability measure μ. It is atomless and countably additive, so that it has the full richness of the continuum with ample space for nonconstructive concepts, and those will be heavily used through diffuse events for instance. Anyway, GP do not want to commit to taking the ideal events being risky with known probabilities. (GP15 p. 469 calls them least uncertain.) These events are characterized by satisfying the sure-thing principle, thus allowing for conditioning, also for their complement. All such events are ideal. (In general, the collection of events with SEU maximization need not be intersection-closed. In this respect this paper is restricted, but it is OK that one doesn't always maximize generality.)

For all non-ideal events, the inner and outer measure are taken w.r.t. μ. For each act f, a tightest ideal lower bound $[f]_1$ and a tightest ideal upper bound $[f]_2$ exist with the pair $([f]_1,[f]_2)$ called the *envelope*.

GP14 P. 5 Theorem 1 gives the representation of their e*xpected uncertain theory* (*EUT*)

$$\int u([f]_1,[f]_2)d\mu$$

where the bivariate u is *interval utility*: $u(x,y) = \alpha_{x,y}v(x) + (1-\alpha_{x,y})v(y)$ with $0 \le \alpha_{x,y} \le 1$ (always $x \le y$) and $\alpha_{x,y}$ depends on x and y but, as appears from notation, does not depend on f or on events otherwise. u is continuous and monotonic and μ is countably additive (with sigma-algebra complete). GP interpret μ as uncertainty perception and ($\alpha_{x,y}$,v) as uncertainty attitude. GP15 p. 470 interprets v as "risk attitude for ideal events," but the authors use the term risk very differently than I do (I discuss this point at GP15).

As for axioms, the usual weak ordering and monotonicity in outcomes (Savage's P3) are imposed, and pointwise convergence continuity, giving countable additivity of μ and also continuity of u. For ideal events we also have Savage's P2 (sure-thing principle), P4 (more likely than) and P6 (tight and fine), giving SEU there. For nonideal events, complete absence of info à la Jaffray (1989) and others is imposed through Axiom 3 (called interchangeability of diffuse events by GP15), with weak monotonicity and the symmetry that necessitates violation of strong monotonicity (betting on D_1 is equally good as on $D_3 \cup D_4$ but then also as good as on $D_1 \cup D_2$). It implies that only the infimum and supremum outcomes matter there, leading to the interval utility. Diffuse events are maximally nonideal, with inner measure 0 and outer measure 1, nonnested with every nonnull ideal event. Axiom 3, the only nonEU axiom, is only imposed on diffuse events, implying it for all nonideal events through the other axioms.

SUMMARY PART 2. Then the paper gives several comparative results in §3 (pp. 8 ff) and later. I find the following text on p. 8 misleading. The authors claim that EUU achieves separation between attitude and perception, but in reality their result only compares attitude *assuming the same perception*. The authors suggest that they can handle different perceptions but this is just by equating them across agents, which involves not-directly-observable theoretical constructs. It is like me claiming that I can compare agents with different utility functions of outcomes by simply replacing outcomes by their utility values. Here is the text:

"Lemma 3, below, shows how the EUU model achieves separation between uncertainty perception and attitude. Consider two EUU agents with identical priors. How these agents rank acts depends only on their uncertainty attitudes (i.e., interval utilities). When the two agents have different priors μ, μ-bar, we can still isolate the uncertainty attitude by *controlling for the uncertainty they perceive* ($\lambda_\mu = \lambda_{\mu bar}$). Lemma 3 establishes that two agents have the same uncertainty attitude if and only if one's interval utility is a positive affine transformation of the other's interval utility." [italics added]

They provide the following results:

(1) Agent 2 is *more cautious than* agent 1 if, for the same interval lottery

(probability distribution over outcome intervals) the former has lower certainty equivalents than the latter, which holds iff v_2 is more concave than v_1 and each uncertain interval [x,y] has a lower certainty equivalent for agent 2 than for agent 1. (Theorem 2, p. 9) This condition suggests to allow for different μ's, but I disagree (see above).
(2) Agent 1 is *more uncertainty averse* than agent 2 if she compares interval lotteries less favorably to noninterval (μ) lotteries. It is equivalent to being more cautious but having the same v (up to level and unit). (Corollary 1, p. 10)
(3) There is also a comparison of one event being more uncertain than another, which happens iff its probability interval is a superset of the other's. (Theorem 3 p. 10) Corollary 2 in §4 relates it to a greater gap between belief and plausibility of Dempster-Shafer belief functions.

Theorem 5 (p. 14) considers α independent of x and y and shows that the EUU model then becomes a special case of CEU/RDU and α maxmin. Then it is tractable. But it is the topic of GP15, called HEU, and, more there.

§5, p. 14, turns to Ellsberg, so, source dependence (they only consider source preference). It considers urns with finitely many balls and several possible compositions (so, several possible relative frequencies—my term). An event is experimentally unambiguous if it has the same relative frequency for each composition. Here is the only interpretation of ambiguity in GP14. It gives a lambda system, but not a sigma algebra of experimentally unambiguous events, and they can be different from ideal events. A *finite source* is a collection of experimentally unambiguous events if any pair of them with the same relative frequency is exchangeable. So, it is like a finite exchangeable partition. It is a special case of "local" probabilistic sophistication. P. 17, 2nd displayed eq., states that the relative frequency then is the betting preference, but I think that that should be a possibly nonlinear transformation (depending on the source) of that relative frequency. The paper then defines as Ellsberg experiment a source preference for the experimentally unambiguous events over corresponding other events. P. 21 (Conclusion) and throughout say that ideal events are perfectly quantifiable and diffuse events are completely unquantifiable.
==================================

EVALUATION

GP14, and especially its followup GP15, model ambiguity (they mostly write about uncertainty, which is more correct but less fashionable) similarly to the source method, which I most like to work with. In this sense it is the model in the literature by others than my friends/co-authors that is closest to my interests and opinions. For instance, it also puts source dependence (introduced by Tversky but discovered independently by Ergin & Gul 2009) central, and does not focus on uncertainty aversion but explicitly allows for insensitivity. (GP15 p. 467 2nd para lists these views, and on p. 473 uses the expression "uncertainty loving at poor odds" to capture insensitivity).

On many details I have different interpretations (see later). The violation of monotonicity, mentioned below GP14 Axiom 3, is a very serious problem. I think it should have been discussed more rather than almost being put under the cover. Further, the use of nonconstructive mathematical tools such as the continuum hypothesis used to show the existence of many diffuse events (e.g., needed in Lemma 1 on p. 5), used in the only nonEU Axiom 3, is very unsatisfactory for an empirical theory (but can be fixed—see below). Especially for someone like me coming from the Holland, the country of Brouwer. The assumed preference conditions for nonideal (e.g., diffuse) events are also too extreme and unrealistic both empirically and normatively (in a way similar to α maxmin (p. 7), but more extremely). They, for instance, rule out expected utility maximization, which is necessarily violated in this model. (They have countable additivity and atomlessness of μ on the ideal events, which means that the ideal events cannot comprise all events (Banach & Kuratowski 1929; Ulam 1930).) As regards this deviation from EU, it is also impossible to have it gradually. Lemma 2, that every lottery over outcome intervals is present in the domain, also crucially depends on the assumed continuum hypothesis, unfortunately.

Another difference is that my papers are explicitly descriptive and seek much to link with data. GP14 are not explicit on it, but, as mostly in theoretical papers on ambiguity, do not try much to link to data, only Ellsberg and a Machina paradox. Yet, GP do better than almost any other theoretical paper in this regard in GP15 p. 467 2nd para, where they well seek to accommodate the main empirical findings. Jaffray in his related model clearly wanted to be normative, but few will follow his extreme aversion to using subjective inputs to model uncertainty (only utility of outcomes can be subjective for him).

The axioms of Theorem 1 (on the general theory) are admirably efficient, staying close to Savage's with the variations easy to understand. The handling of nonideal events through sups and infs is rigid but in return tractable. The rigidity concerns that we don't use any likelihood info other than what can be captured through the additive (even in SEU) probability μ. The whole work transpires great creativity.

Unfortunately, the comparative axioms involve theoretical constructs such as μ and are not directly observable from preferences. Thus, GP give mathematical theorems that can serve in derived-measurement analyses where one can use utility and so on as inputs, but they cannot qualify as good (preference-foundation) decision-theory results. Papers co-authored by Gul often have this problem.

=================================

ABSENCE OF MEASURE THEORY, AND NONCONSTRUCTIVE INPUTS (E.G. FOR DIFFUSE EVENTS)

It is common in probability theory to impose measure-theory structure, with (sigma)-algebras of events and measurability restrictions, because, without those, weird events and random variables (acts) exist. For instance, it is impossible to have a countably additive atomless probability measure on a power set (Banach & Kuratowski 1929; Ulam 1930).

Savage (1954) did not impose measure-theory restrictions, but did so only for didactical reasons, as he explained on pp. 40-43, §3.4. Everything in his analysis remains unaltered if he had imposed measure theory, and then the probability measure could have been countably additive.

With GP things are less good. They do not impose measure theory either, but for their analysis as written it is crucial that they do not have it. Axiom 3, the only nonEU axiom, is imposed only on diffuse events. To prove that diffuse events exist, GP use the absence of measure theory and the aforementioned "weird" events. They need the mathematically controversial continuum hypothesis for it. (Shown in Lemma 1, p. 5, with footnote 5 mentioning the continuum hypothesis.) I find it unsatisfactory to use such nonconstructive mathematical technicalities to suggest empirical implications. For example, GP assume the agent to bet on events that no mathematician knows how to construct, that some mathematicians think do not exist, and that other mathematicians can prove to exist only if they assume the controversial continuum hypothesis.

Axiom 3: complete absence of info

P. 3 $\ell\ell$. −9/−6 tries to defend, but this text (reproduced next) does not make any sense to me: "Note that Savage's theory allows for a similar possibility for infinite collections of sets. Diffuse sets are limiting events that play a similar role in EUU theory as arbitrarily unlikely events do in Savage's theory. They allow us to calibrate the uncertainty of events." I do not know what "arbitrarily unlikely" events would be in Savage's model. Null events won't do. There is no event for Savage that has the status "arbitrarily unlikely" similarly as any one diffuse event has the status of arbitrarily unmeasurable. Sequences of events decreasing to null are something different. I also do not understand "possibility for infinite collections of sets," or why these events could be used to calibrate the uncertainty of events. Maybe GP refer to finite additivity of P in Savage, where countable partitions of S consisting of only null events can exist, but this is something different. It seems that GP want to suggest that diffuse events are no more artificial than events used in Savage's model, but there is no analogy here. Their axiom 3, and the violation of strict dominance mentioned in the lines below, is unsatisfactory both normatively and descriptively. Grant, Rich, & Stecher (2022 p. 10) were forced by a referee (not me) to discuss this issue. I disagree with their defensive text, and agree much with their referee.

I conjecture that the non-measurability problem is not crucial, and does not affect the essence of the theory. That it could have been avoided by imposing measure theory, and imposing Axiom 3 on nonideal events in a modified manner and also for nondiffuse events. The existence of all warranted diffuse events can be imposed as an extra axiom. For instance, the state space could have been taken as a product space where the first-stage events satisfy the Savage axioms and the second-stage events (that occur conditional on the first-stage events) are diffuse, as I learned from Jaffray. It is a kind of Aumann-Anscombe model, where conditioning on the first-stage events is plausible because they are ideal. The violation of monotonicity then remains as a serious problem.

==================================

FURTHER COMMENTS

The set of ideal events, where we have EU maximization, is taken endogenously given, with an event ideal iff it satisfies the sure-thing principle. This makes the axioms referring to them less observable, referring to endogenous objects as inputs. But, because the ideal events are readily identified through the sure-thing principle, this is not very bad and is acceptable. Irrespective of observability, for studying ambiguity I prefer to assume unambiguity exogenously given rather than endogenously, and, then, if one wants to assume EU somewhere (for empirical purposes this is better not done at all), then do it on the exogenously unambiguous events. The ideal events are the ones with minimal, not at all, vagueness, so, they are the ones maximal regarding sensitivity.

The set of ideal events is intersection-closed, leading to them being a sigma-algebra, because of Gorman's (1968) theorem.

GP claim that they can accommodate not only Ellsberg but also Allais, and put this central. But I disagree (see below). GP14 cite the 2013 working paper version of GP15 for elaboration and I will discuss the point more at GP15.

event/outcome driven ambiguity model: almost entirely outcome driven, through the bivariate function u with parameter $\sigma^{x,y}$. GP15 let $\sigma^{x,y}$ be independent of the outcomes x and y, taking out all outcome dependence, and then only a bit of event-dependent utility remains, although not much and their model is close to expected utility.

§3, p. 8 ff. gives comparative results, all of the Yaari type where either all the components not compared have to be assumed identical by mere assumption (ideal would be by directly observable preference condition), or these theoretical constructs are used as inputs in the axioms, which is what GP usually do, and which is undesirable in decision-theory theorems.

P. 10 first definition: Gul often violates the rule of the game of axiomatizations of only using preference conditions, but uses theoretical constructs such as utility in his conditions. Here again. Theorem 3 is of course mathematically correct but it is not a preference axiomatization.

§5 (p. 14 ff.) discusses the separation of uncertainty perception (μ) and attitude (u), mentioned before on p. 2.

P. 17 uses the term and concept of source introduced by Tversky, imposing probabilistic sophistication as with the uniform sources of Wakker (2008 New Palgrave) and Abdellaoui et al. (2011). However, they only cite Epstein & Zhang (2001) here. I disagree with this reference because Epstein equated probabilistic sophistication with unambiguity (criticized by Wakker 2008) and did not have the general concept of source (similarly as Ellsberg 1961 had a special case but not the general concept). This general concept was introduced by Tversky in the early 1990s, with Heath & Tversky (1991) and Tversky & Kahneman (1992) already mentioning the concept and Tversky & Fox (1995) and Tversky & Wakker (1995) developing it.

P. 17 last displayed Eq. shows that here the authors are completely focused on ambiguity aversion, as most researchers in the field, defining only that as Ellsberg paradox. No more consideration of ambiguity seeking or insensitivity, which becomes relevant if |a| and |b| there are small.

===============================

DETAILED DISCUSSION OF OVERLAP WITH JAFFRAY (1989)

The remainder of my annotations for GP14 compares with Jaffray (1989 *Operations Research Letters*). This paper is an intriguing variation of Jaffray's model of decision under uncertainty. A detailed explanation of Jaffray's ideas is in Wakker (2011, Theory and Decision). In short, Jaffray adopted a philosophy of complete absence of information, applying to events that I, following GP, call diffuse here. Consider a partition of the state space S into diffuse events $\{D_1, \ldots, D_n\}$. Such D_j's are exchangeable (interchanging outcomes of two does not affect preference). But even no statement of D_1 being less likely (in gambling on sense) than $D_2 \cup \cdots \cup D_n$, or, for that matter, than $D_1 \cup \cdots \cup D_{n-1}$, is accepted. Thus, with 100_D0 meaning that 100 results under event D and nothing otherwise, the problematic indifference

$$100_{D_1}0 \sim 100_{D_1 \cup \cdots \cup D_{n-1}}0$$

follows (Wakker 2011 Figure 4.1). (Cohen & Jaffray (1980) take another route by giving up completeness, but we maintain completeness here.) This violation of strong monotonicity is the price to pay for avoiding any subjective commitment about uncertainty. GP treat their diffuse events the same way, mainly through Axiom 3. Under weak monotonicity, it follows that an act conditional on the above uncertain partition is completely characterized by its inf. outcome and its sup. outcome.

Continuing on Jaffray's model, he also assumes unambiguous events (similar to the ideal events of GP except that Jaffray's events are objective and exogenous) that have objective probabilities. He allows for conditioning on unambiguous events (Wakker 2011 p. 18 ℓ. 1). Jaffray's model considers acts conditioned on unambiguous events $E_1,\ldots,E_n$ that have probabilities $p_1,\ldots,p_n$, resulting in a probability distribution $(p_1:(m_1,M_1),\ldots, p_n:(m_n,M_n))$ and utility $p_1U(m_1,M_1) + \cdots + p_nU(m_n,M_n)$. Jaffray gave a preference foundation based on an independence axiom imposed on what amounts to probabilistic mixtures of the above kinds of general acts.

GP generalize Jaffray's model by not assuming the objective probabilities $p_1,\ldots,p_n$ of unambiguous (ideal) events given beforehand, but deriving the probabilities p_j subjectively from the Savage axioms. They specify this relation with Jaffray's model on p. 20: "Hence, EUU theory and Jaffray's model stand roughly in the same relationship as Savage's theory and von Neumann-Morgenstern theory."

The job of GP14's generalization of Jaffray is less trivial than may seem from the above. Several problems to be solved are solved cleverly, leading to tractable modeling. Thus, the separation between ideal and nonideal events is obtained endogenously, through the sure-thing principle (allowing conditioning) in their definition of ideal. Mostly by imposing pointwise continuity (Axiom 6, p. 4; they don't use this term) they ensure at the same time that the probability measure will be countably additive, and that an algebra of ideal events can be extended to a sigma-algebra (and that u is continuous). And, the sigma algebra need not be all subsets, avoiding the problems demonstrated by Banach & Kuratowski (1929) and Ulam (1930). GP need not commit to a product structure of ideal/diffuse or these being given a priori, because the ideal/diffuse separation follows naturally from the axioms. I expect that Jaffray would have been delighted to see this work. For one, it revives his ideas, in a refined version. What deviates from his views is that Jaffray really only wanted objective probabilities, and not any subjectivity in beliefs such as with the subjective Savage probabilities of GP. %}

==================================

SUMMARY

This paper follows up on GP14. In my annotations there, Summary Part 1 was written also for this GP15 paper and I assume it read henceforth. Several other issues discussed for GP14 also pertain to GP15, but will not be repeated here. One is: that their model violates dominance, through their Axiom 3 of interchangeability of diffuse events (even if one is a superset of the other).

event/outcome driven ambiguity model: event driven: Relative to GP14, this GP15 paper reinforces axiom 4, Savage's (1954) more likely than axiom P4, from the ideal events to all events. This axiom is the dividing line between event-based ambiguity theories and utility-based or more general ambiguity theories. GP14 was mostly utility based but, by adding full-force P4 here, it becomes utility/outcome independent so only event-dependent or, one might even argue, everything-independent, being constant (for a given agent). Now that $\alpha_{x,y}$ becomes independent of x and y, the generality of the model is greatly and conveniently reduced making it tractable. In fact, given SEU on the ideal events (see below), all deviations from SEU are captured by only one number, α. This achieves an incredibly high level of parsimony and efficiency, reminiscent of Gul's (1992) disappointment aversion model (also one number α only to deviate from expected utility), mathematically brilliant. But at the same time it is too rigid to connect with empirical reality and this model will never work in applications, neither empirically nor normatively. It is an ivory-tower theory. Bleichrodt, Grant, & Yang (2023) claim to have measured this theory empirically, but this is not correct. See my annotations there.

The authors assume a source (sub-sigma algebra satisfying local probabilistic sophistication) of ideal events, that are least uncertain. For these they assume SEU, axiomatized à la Savage but with pointwise monotonicity, so, countable additivity, which makes it more convenient and efficient. The also assume completeness of the subjective probability measure μ (all subsets of null sets are contained). In their overall model, an event is ideal if and only if it, and its complement, satisfy the sure-thing principle. It is very natural, and in agreement with most papers in ambiguity theory today (2022), to assume that the ideal events are what I call risky, meaning they have exogenously determined objective probabilities. GP emphasize that they do NOT assume so and that they can be different. I think that there is little interest in this generalization because usually SEU is violated the least for risky events.

GP assume further sources beyond the ideal events, being groups of events with local probabilistic sophistication. There, GP take the inner and outer measure. The event's weight then is an α/1−α convex mixture of the inner and outer measure, and RDU holds for that source. Here α depends on the agent but not on the events or acts, and is an index of pessimism or ambiguity aversion or "universal" source-independent source dispreference. The resulting basic model of *Hurwicz expected utility* (*HEU*) is

$$W(f) = \alpha \overset{min}{\pi\in\Pi_\mu}\int v\circ f d\pi + (1-\alpha) \overset{max}{\pi\in\Pi_\mu}\int v\circ f d\pi\ . \qquad (*)$$

It is a special case of α maxmin. It is also a special case of CEU/RDU, being where the nonadditive weighting function is a convex combination of an inner and outer measure derived from a countably additive and complete μ on a sub-sigma-algebra. GP show that the weighting functions resulting this way are always a power series with positive weights that sum to 1. They show, remarkably (but extremely weird!), that for every power series there exists a source with that power serious as weighting function. Here, they heavily use the axiom of choice (i.e., continuum hypothesis), implying that there exist all kinds of the most weird nonmeasurable subsets of a continuum. These things are nonconstructive objects, meaning, roughly, that we have no formulas or even words to describe them, making them, in my words, very nonimplementable and empirically irrelevant. The power series if taken in full generality involve infinitely many parameters which is not so nice, and the parameters have no clear interpretation which is also not so nice. In fact, it is all determined, given EU on the ideal events, by one parameter that is only one number: α. It is extremely weird that for every source attitude (weighting function), no matter how weird, there exists a source of events for which the agent has this attitude.

Given μ, inner and outer measures are uniquely determined and in this sense do not add extra parameters, so, in this sense, do not reduce tractability. But they may be hard to calculate and in this sense they do reduce tractability.

The model is a special case of Jaffray & Philippe (1997), who considered CEU/RDU with weighting functions that are convex combinations of convex weighting functions and their duals. This paper is the special case where an additive μ with SEU is available and the convex weighting function comes from extensions/inner measure of that additive μ.

Because nonadditive event-weighting functions of CEU/RDU (and also CPT/PT) are too general, Abdellaoui et al. (2011) introduced the source method, in which the weighting function is a transformation of an additive probability in subcollections of events called uniform sources. The weighting functions are called source functions by Abdellaoui et al. (2011). (GP use the term source utility for the whole preference functional defined relative to the source.) A source function depends on the source, accommodating Ellsberg. GP here go the same way, using the term source instead of uniform source, and also putting such sources and their transformation functions central. So, they are the special case of the source method where the source function is a convex combination of an inner and outer measure, $\alpha\gamma + (1-\alpha)\gamma'$ (γ' is the dual of γ). γ is convex (mentioned on p. 476 two lines below Proposition 6). Thus, within a source GP15 have an RDU representation with as weighting function an $\alpha/1-\alpha$ mixture of a convex weighting function and its dual. (Stated again in Proposition 6.)

§4 starts comparative results that, as with GP14, use theoretical constructs as inputs. Thus, while mathematically true, they cannot be considered preference axiomatizations, which limits their usefulness in decision theory. Typical is for instance that they define risk aversion as aversion to mean-preserving spreads, but those concern the *subjective* probabilities.

P. 472 Proposition 3 gives more uncertainty aversion of one agent over another iff bigger α, related to more favorably comparing bets on ideal events to bets on other events. As stated on p. 470 in the middle, just once in the flow of the text and not displayed, they assume the same μ for throughout. Although they do not say it very explicitly, this is assumed to be the same μ for all agents.

P. 472 Proposition 4 gives more uncertainty of one source over another iff the source function (I prefer this term for the probability weighting function to the vague term source of GP) pointwise dominates (which I would take as source preference). It involves a quasi-preference-condition, called source preference by GP, that for two events from the two sources with the same a-neutral probability (again, my term), always the one from the preferred source is preferred for betting on, next related to being “more uncertain.” Proposition 5 will show that a more uncertain source can be preferred at low likelihoods, à la insensitivity, if for the uncertainty aversion α we heve $\alpha < 1$.

P. 475 §5 continues on sources. Here the general HEU model, which is CEU/RDU for uncertainty, becomes like Quiggin’s RDU with a source-dependent probability transformation that I already referred to above as source function (my term). Proposition 6 states it explicitly, where the source function now is an $\alpha/1-\alpha$ convex combination of a convex function γ and its dual. Proposition 7 states that bigger aversion to mean-preserving spreads iff v more concave and α bigger. For this, it assumes the same γ. Mean-preserving spreads involve subjective probabilities here and, hence, are also not directly observable, again, reducing the interest of this result.

The top of p. 471 shows that insensitivity can be accommodated.

Proposition 8 shows that the functional is concave in source-function units iff $\alpha = 1$ and v is concave.

==================================

COMMENT ON USE OF TERM RISK

GP take the term risk attitude in an uncommon manner. μ and the implied π and so on are uncertainty perception, which could have potentially been source- and not person dependent (as assumed in many other papers) were it not that they are subjective. (α,v) is uncertainty attitude, apparently person-dependent but source-independent. But now risk attitude is to capture it all (p. 468 3rd para), and also μ. Whereas for me uncertainty is the encompassing term capturing risk and ambiguity, for GP risk is the encompassing term. Risk attitude is taken source dependent (in conclusion called context-dependent). There is a discussion of this in the para on pp. 467-468:

“Allais-style experiments confront subjects with lotteries; that is, acts that depend on a roulette wheel, on the draws of a card from a deck, or on some other objective randomization device. …

In a subjective model such as ours, *the randomization devices in Allais-style experiments are a source like any other*; randomization devices *need not yield the least uncertain or most preferred source* nor do *all randomization devices necessarily yield the same source*. Indeed, Heath and Tversky (1991) provide experimental evidence showing that agents may not favor sources based on randomization devices. … In addition, the experimental literature has found that measured risk attitudes vary with the experimental technique used to measure those attitudes. Thus, subjects differentiate among seemingly objective sources." [italics added here]

I have a different opinion on the first italicized text because, in practice, randomization devices, exogenously determined, ARE a special source. I make a big distinction between subjective probabilities and objective ones (they are limiting cases of subjective ones). Objective probabilities are usually, surely by me, taken as ambiguity-neutrality calibration point.

I have a different opinion on the relevance of the second italicized part. Most researchers can think of only one thing as regards ambiguity, and that is ambiguity aversion. They often equate ambiguity with ambiguity aversion. GP are broader in several places, understanding that there is systematic **ambiguity seeking** and insensitivity (my term) in an absolute sense. But they don't yet come to a full comparative treatment of it. Given that GP take α, reflecting ambiguity/uncertainty aversion, source independent, they will not be very open to source-dependent ambiguity aversion.

As for the third italicized part, this is true, although the Dave et al. (2010) reference given by GP is not relevant here (they are indeed about different elicitation methods but that is irrelevant here), the keyword "violation of risk/objective probability = one source" in this bibliography gives references showing it. However, this dependence is too weak to incorporate, and for tractability reasons I favor taking risk as one source, and assume one risk attitude (following Tversky's preference here) (modulo utility for different kinds of outcomes). Risks with unusual emotions (e.g., due to complexity) give deviations but are to be taken as exceptions. Risk is less rich than ambiguity. One further point: ambiguity = uncertainty - risk, but this can no more be defined well if risk is not one thing.

Speaking of source-dependent risk attitude may work easiest when first presenting to uninitiated audiences. But this terminology cannot survive. Not so much risk attitudes, but rather ambiguity attitudes, are a rich domain and are source dependent. Kilka & Weber (2001) used the same unfortunate terminology of source-dependent risk attitude. It is so confusing that I usually avoid citing K&W, even though it otherwise has many great ideas. Chew, Li, Chark, & Zhong (2008) used the same unfortunate terminology.

==================================

COMMENT ON ACCOMMODATING ALLAIS OR NOT

GP15, and also GP14, claim that they can accommodate not only Ellsberg but also Allais, and put this central, but I disagree with the Allais claim for two reasons listed below. Like most other papers on ambiguity, GP do assume EU, only, not necessarily for objective probabilities but for what they call ideal events, which in their analysis can be “less uncertain” than objective probabilities.

(1) For the ideal events, GP cannot accommodate the Allais paradox. Thus, if the Allais paradox is taken as a general certainty effect for all events (this is how I prefer to take it; it speaks to uncertainty as much as to risk), then GP cannot accommodate it.

(2) The generalization that ideal events need not be risky (in my terminology) events but can be different, is of very little interest, both normatively and descriptively. If they are different, objective known probabilities would be more uncertain than some subjective probabilities, which is very implausible. Also, the common finding is that EU is more violated for unknown probabilities than for known (see the keyword **uncertainty amplifies risk**). Fox & Tversky (1995) and Tversky & Fox (1995) found source preference for football/basketball events over risky events among football/basketball fans, but this is not the most relevant component here. Ideal events are optimal regarding sensitivit/perception, and Fox & Tversky (1995) and Tversky & Fox (1995) find *higher sensitivity*, so better understanding, for the risky events than for the football/basketball events.

At the background here is that GP seem to dislike using exogenous concepts such as objective probabilities, which they share with Epstein (1999) but not with me.

p. 466 1st para writes that GP accommodates Ellsberg, Allais, and source preference. As for general aim, this is another aim that GP share with the source method and CPT/PT, making the approaches close. My 2010 book writes on p. 2, penultimate para: “At this moment of writing, 30 years after its invention, prospect theory is still the only theory that can deliver the full spectrum of what is required for decision under uncertainty, with a natural integration of risk and ambiguity." In many places in my book and papers, and in many applications of the source method, it is emphasized that there is no commitment to EU for risk (or unambiguous events). Wakker (2010 §11.6) discusses the different roles that the Allais and Ellsberg paradox have in uncertainty. I by the way disagree that GP15 can accommodate the Allais paradox. For their ideal events they need full EU.

==================================

FURTHER COMMENTS

biseparable utility: satisfied.

event/outcome driven ambiguity model: event driven: Relative to GP14, the parameter α is independent of outcomes here in GP15, so that the theory is no more outcome driven. It is in fact close to expected utility, with only a bit of event dependence.

The authors use the outdated and inefficient terms rank-dependent EXPECTED utility and RDEU instead of RDU.

P. 466's functional formula (Eq. * in my annotations above): I do not understand how it is defined if f is not measurable with respect to π. Given that this paper does not impose measurability (Borel or Lebesgue or anything), so, considers all subsets of Ω and all f (and that is even crucial for its results), that no sigma-additive π can be defined on all subsets of Ω (Banach & Kuratowski (1929) and Ulam 1930), this will surely happen.

Note that, with expected utility available on a Savage-type rich domain as is the case here, RDU can easily be axiomatized, for completely general outcomes, by cumulative dominance (Sarin & Wakker 1992).

P. 466 Footnote 7: only if two FIXED prizes!

P. 466-467 para is confusing to me, because it seems to have in mind a group of agents rather than one. Their 2020 paper may clarify.

The paper defines sources as countably additive probabilities on complete sigma-algebras where "local" probabilistic sophistication holds, which the source method calls uniform source. One difference is that GP take sources entirely endogenous, whereas the source method takes a source as exogenous (like commodity), and only uniformity is endogenous.

Given that α and v are assumed source-independent, source-dependent utility is related to the source functions of the source method.

P. 468 last 4 lines discuss the source method: "Abdellaoui et al. (2011) study source specific lottery preferences and estimate source-specific RDEU utility functions. Our model exhibits related source utilities and, in addition, *provides a utility function for arbitrary multi-source acts*." [italics added here]

The italicized claim, suggesting difference with Abdellaoui et al. (2011), is not correct. GP have the general HEU theory that compares all acts. This justifies their italicized claim. In some subcases they have (uniform) sources, with a convenient special structure. Entirely the same way, Abdellaoui et al. (2011) **have the general CPT/PT that compares all acts.** In some subcases they have (uniform) sources, with a convenient special structure. Because of the bold sentence, Abdellaoui et al. (2011) as much satisfy the aforementioned italicized claim of GP. GP missed that Abdellaoui et al. (2011) is a special case of CPT/PT, or of RDU/CEU if one prefers. GP repeat this omission in footnote 22 p. 477.

P. 467 2nd para lists major empirical findings and, to my joy, and unlike most theoretical papers, seeks to link with them. P. 473 will use the expression "uncertainty loving at poor odds" to capture insensitivity.

P. 468 just above §1.1: It is strange that risk attitude is context/source dependent but uncertainty attitude is not.

P. 469: "A prior is a countably additive, complete, and non-atomic probability measure on some σ-algebra of subsets of Ω."

P. 469: "The σ-algebra $\mathcal{E}_\mu$ consists of the events the decision maker perceives to be least uncertain."

P. 470 middle, in the flow of the text, states an assumption crucial for all results to follow: "For the remainder of this paper, we fix μ, the agent's uncertainty perception, and let $W=(\alpha, v)$ denote an HEU." As stated before, I regret that the authors use the theoretical construct μ in this assumption and, hence, in all following results.

P. 471 ℓ. 5 gives a sort of preference condition excluded by probabilistic sophistication within a source, i.e., excluded by uniformity of the source. Unfortunately, contrary to what I automatically thought it must be until August 2018, it is not excluding source preference within a source, which exclusion would lead to Wakker's (2008) uniform sources. Instead, it involves two different preference relations, a maximally pessimistic ($\alpha = 1$) and a maximally optimistic ($\alpha = 0$) one, and gives a condition involving these two different hypothetical agents, which cannot serve as a good observable preference condition.

P. 471: Unfortunately, the authors use the term power series in an unconventional manner. Usually, it means a polynomial where the coefficients can be any real number. But the authors do it only for coefficients from [0,1] summing to 1, meaning convex combinations (of powers). There is a Weierstrass theorem saying that each continuous function on a compact interval (e.g., [0,1]!) can be written as a power series (in the traditional meaning), in which case the claim of the authors would be vacuously true and uninformative, if traditional terminology. The weights adding to 1 follows from normalization $\gamma(1) = 1$. Nonnegativity of the weights implies convexity of γ. Unfortunately, the authors do not discuss if their power series is more restrictive than general convexity, so, if their condition is vacuous or not. Well, it is not vacuous, and is more restrictive than convexity. For example, $1.1 \times t^2 - 0.1 \times t^3$ is strictly increasing and convex and continuous, but is no power series in the authors' sense. I do not find power-series a convenient family. First, it has infinitely many parameters (if not restricted to be derived from μ by only the parameter α.) Second, the parameters have no clear interpretation—at least, no such is given. This result is a mathematical fact but I do not see empirical interest.

P. 472 Proposition 2: Every γ (prior) is a power series. And, every power series occurs for some prior on some sigma-algebra. This does not illustrate attitudinal richness for the agents, because here the model in fact is extremely parsimonious and nonrich where, given EU and μ on the ideal events, only one number α determines the whole nonEU attitude. Instead, it illustrates the mathematical richness of nonmeasurable (nonconstructive!) events. The idea that every attitude would appear for every agent is weird I think. So, for every agent every situation of ambiguity perception would exist!? This is hard to imagine if ambiguity perception is subjective. Mathematically, it follows from the authors not having imposed measure theory restrictions, so that weird and nonconstructive things exist. This needs the continuum hypothesis, making it nonconstructive and empirically unsatisfactory.

P. 472: for the comparative results that follow in §4 and further, the restriction of same μ, stated before (p. 470), is restrictive (and is formulated using theoretical constructs).

P. 472 Proposition 4 gives more uncertainty of one source over another iff the source function (I prefer this term for the probability weighting function to the vague term source of GP) pointwise dominates. So, this is what I would take as source preference (implicitly assuming same insensitivity). GP have a quasi-preference-condition, (informally?) called source preference by them, that for two events from the two sources with the same a-neutral probability (again, my term), always the one from the preferred source is preferred for betting on. Here the requirement of same a-neutral probability involves a theoretical construct. They use this as input in a definition of “more uncertain” that is a bit complex and at any rate not easily observable, involving existence and for all quantifiers over different HEU models, so, not one agent.

[Absence of real comprehension of insensitivity] Proposition 4 shows that they equate more uncertainty with what I would call source preference. It shows that here they only think of ambiguity aversion and not of ambiguity seeking, and that they ignore insensitivity here. Although the authors show awareness of insensitivity in several places and play lipservice to it, they did not really digest the concept. They mostly think only one-dimensional, aversion/seeking. Thus, they define as ideal (unambiguous) events simply those events that have maximal source preference. So, the only thing about ambiguity is that it brings extra aversion. Of the one dimension aversion/seeking, they yet lose half, being ambiguity seeking.

P. 473 last para: as a nostalgic typo, the authors here still twice use the term issue, which Ergin & Gul (2009) used instead of source.

P. 476 Proposition 7 can be derived from Chew, Karni, & Safra (1987). More aversion to mean-preserving spreads iff utility v is more concave and probability weighting is more convex. Given that the authors have fixed the theoretical construct γ there, more convex probability weighting is equivalent to α being bigger.

Bleichrodt, Grant, & Yang (2022) claim to have empirically measured HEU. However, as I explain in my annotations there, HEU is totally and completely unobservable. As brilliant as HEU is mathematically, so ivory tower and disconnected it is from reality. %}

Gul, Faruk & Wolfgang Pesendorfer (2015) "Hurwicz Expected Utility and Subjective Sources," *Journal of Economic Theory* 159, 465–488. https://doi.org/10.1016/j.jet.2015.05.007

{% **Ambiguity = amb.av = source.pref, ignoring insensitivity**

SHORT SUMMARY: They have a sub-sigma algebra $\mathcal{E}$ of unambiguous events endowed with an additive probability measure μ, $(\mu,\mathcal{E})$. Then they have (ν,Σ), where Σ is the overall sigma algebra. ν is a belief function capturing ambiguity. All of this is belief/info, objectively given, and independent of the agent. It is the same for all agents. The agents take for each ambiguous events an inner measure with added δ times the belief function ν. Here $0 < \delta < 1$ is a subjective discount measure. The small δ, the more ambiguity aversion. This is attitude, not belief, subjective, and agent-dependent stimuli-independent.

The rest of these annotations provide more detailed comments.

DETAILED COMMENTS.

Unfortunately, the authors do not number definitions, making it harder for others to cite them.

P. 4 specifies that they have single-stage, and not two-stage as in Anscombe-Aumann.

Unambiguous events are often taken as risky events (e.g. by me although not necessarily by these authors), which has an objective status. Objective means something like all clever people agreeing on it. This paper does seek to get objectivity in, and to formalize this, similarly as Gilboa et al. (2010 ECMA) did. There is a group of decision makers (DMs). For events A,B, $A \succcurlyeq_j B$ means the usual thing: Agent j prefers betting on A to betting on B. We write $A \succcurlyeq B$ if all DMs agree. Then this preference is objective and taken as unambiguous. It is, obviously, incomplete. It is called qualitative uncertainty assessment (QUA). It is meant to work for all ambiguity attitudes, which are all assumed present in the population. (Given that they take ambiguity of info objectively available, we can just calculate what preferences result from ambiguity attitudes and, accordingly, assuming that available is not restrictive.) For any individual j and any ambiguous event, whether $A \succcurlyeq_j B$ depends on the agent's ambiguity attitude.

The ambiguous info is assumed to be objectively available. The quantitative model of this info/belief, a capacity π on the events that will be a Dempster-Shafer belief function, is as follows. There is, first, a *risk measure* $(\mu,\mathcal{E})$. Here $\mathcal{E}$ is a subsigma-algebra of unabiguous events, and μ is an atomless probability measure (countably additive). For these, $\pi = \mu$. Second, there is an *ambiguity measure* (ν,Σ). Here Σ is the overall sigma-algebra (of which E was a sub-sigma-algebra). And ν is a probability measure, but not on the state space assigning probabilities to elements of Σ, but on Σ assigning probabilities to subsets of Σ. It is the Möbius inverse of the belief function ν. Because of ambiguity, ν is sort of discounted by a factor $0 < \delta < 1$, and only $\eta = \delta\nu$ is used. So, $\eta(\Omega) = \delta$. Note that this is a purely pessimistic ambiguity attitude. They satisfy some regularity (p. 5 bottom point (ii)). Then

$$\pi(A) = \max_{E \subset A, E \in \mathcal{E}}\big(\mu(E) + \eta(A \backslash E)\big)$$

Roughly, not precisely, they first take the largest unambiguous subset E, and its μ measure, and of the rest take the ν measure. (This would hold if μ and ν in a way were orthogonal, as in the example below.) This is close to taking inner measure. π is indeed a belief function.

Their Example 1:

EXAMPLE 1: $\Omega = [0,1] \times [0,1]$. First coordinate is unambiguous with $\mu = \lambda$ (Lebesgue measure), second coordinate has $\nu = \lambda$. If δ were 1 we'd have the product measure, but it is different and $\delta = 0.5$. Take

$A = [0,1/3) \times [0,1] \cup [1/3,2/3] \times [0,3/4]$.

$\pi(A) = \mu\big([0,1/3) \times [0,1]\big) + \eta\big([1/3,2/3] \times [0,3/4]\big) = 1/3 + 0.5 \times 1/3 \times 3/4 = 1/3 + 1/8$.

We can sandwich any ambiguous event A by an interval $[E^1, E^2]$ with E^1 and E^2 unambiguous and closets with $E^1 \preccurlyeq A \preccurlyeq E^2$, called a tight window. It gives a probability interval $[\pi(A), \overline{\pi}(B)]$ with the upper and lower probability, as usual for belief functions. They take this as a measure of ambiguity.

π represents $\succcurlyeq$, the unambiguous ordering of events, with $A \succcurlyeq B$ iff $\pi(A) \geq \pi(B)$

and $\overline{\pi}(A) \geq \overline{\pi}(B)$. Next the authors give a preference axiomatization for π. To this effect, they first consider only two fixed outcomes, i.e., only a qualitative ordering of events. To get probabilistic sophistication on the unambiguous events, they use an unambiguity axiom as in Epstein & Zhang (2001), which calls E unambiguous if, kind of, E^c is separable w.r.t. more-likely-than. (Their double expected utility model of §5.1 gives complete separability so that an Aumann-Anscombe model results, with first lottery events and then horse events.) Wakker (2008) mentions drawbacks of this condition. For instance, in any Anscombe-Aumannn framework with exactly two horses, both ambiguous, this definition, in the corresponding one-stage state space, implies that the two horses are unambiguous, and this is undesirable. Further, it does not work well for general (betweenness-type) ambiguity, but only for Savage-P4-type ambiguity, as the online appendix of Wakker (2008) shows. As for structural richness, they use Savage-type, efficiently so that it also incorporates the ambiguous events.

They use matching probabilities, which they call risk equivalent, one for each probability interval, specifying the ambiguity attitude of an agent. They assume that this is the same for all events with the same probability interval through their range dependence axiom (p. 9).

Proposition 3 separates ambiguity perception, captured by the probability intervals and being objective, and ambiguity attitude, captured by the matching probabilities. For every individual agent, the ambiguity preferences uniquely determine ambiguity perception and $\succcurlyeq$.

P. 15 1st sentence of §5 incorrectly writes that Machina & Schmeidler (1992) introduced probabilistic sophistication. This concept had been standardly known long before. See, for instance, Cohen, Jaffray, & Said (1987, p. 1).

The authors give a weak and strong version of more ambiguity averse than. The weak one has systematic more dispreference for ambiguous relative to unambiguous. The strong one is more restrictive (more incomplete) and has systematic more preference for more ambiguous versus less ambiguous (the latter tighter upper and lower probabilities). They have a quantitative representation for it, capturing more overweighting of the bad probability, but it uses derivatives which is not very tractable. It is extended to general acts in §5.2.

They extend the qualitative ordering theory to general decision theories for many-outcome acts in three ways. In the first, they assume EU for risk. The second is a generalization of (special versions of!) Choquet expected utility with a clear separation of QUA (belief), risk attitude, and ambiguity attitude. The third is most general. The authors suggest almost complete generality there, but I do not agree with that. Their Epstein-Zhang definition of unambiguous does not work for betweenness-type ambiguity (Wakker 2008 online appendix) but only for Savage-P4-type ambiguity.

Pp. 18-19, end of paper, argue that common definitions of ambiguity in the literature require EU for risk and can be conflated by deviations from EU under risk. This paper brings separations for those also if nonEU for risk. However, they have EU-type for the least uncertain events, the ideal events, which in practice almost always have to incorporate the risky events. Being closer to ambiguity neutrality for some ambiguous events than for risky events is implausible. %}

Gul, Faruk & Wolfgang Pesendorfer (2020) "Calibrated Uncertainty," *Journal of Economic Theory* 188, 105016.

{% **updating: nonadditive measures**: The authors start from a static CEU model of decision under uncertainty model with Dempster-Shafer belief functions. That is, these are extremely pessimistic. And, they are a special case of maxmin EU. Then they consider updating. Whereas much literature is sloppy in implicitly assume backward induction for instance, the authors carefully discuss this point and make clear that and how they assume backward induction with dynamic consistency and consequentialism, but violating independence of order of resolution of uncertainty (like RCLA for risk), that is, the law of iterated expectation. After updating, the model is no more CEU/RDU. But it still is maxmin EU, beccause the updating is like the Epstein-Schneider (2003) rectangular updating, called the reduced family by Sarin & Wakker (1998, JRU), although it is more general (p. 4 §1.1).

P. 2 Figure 1 has the nice Raiffa-type problem where hedging against ambiguity or not just depends on the order of resolution of updating/conditioning.

Their Theorem 3 is a reverse to Sarin & Wakker (1998 Theorem 2): a maxmin evaluation can be *approximated* by a general compound evaluation.

The conclusion (p. 17) points out that, whereas most of the paper takes the

order of resolution of uncertainty as given, things could be reversed and the preference model satisfied could be used to reveal the order of resolution of uncertainty as endogenous. %}

{% **second-order probabilities to model ambiguity; updating under ambiguity with sampling**;

Redo a Dutt et al. (2014) study with some modifications. Dutt et al. generate ambiguity through second-order probabilities. But in the DFE treatment they let subjects sample only the outcome with no knowledge of the 2nd order process, so that subjects in fact sample a fifty-fifty 1st order process. This paper lets subjects sample from the 2nd order distribution; i.e., lets them sample what the 1st order composition is. Thus, the subjects experience the 2nd order distribution. The subjects know it is one of three, one dichotomous (1st order p is 0 or 1), one normal, and one uniform. Experience reduces ambiguity aversion relative to description. I agree that this paper better brings out the 2nd order distribution. But a problem is that for all 2nd order distributions, the 1st order distribution is 1/2. If subjects understand this, then they know that it does not matter what the 2nd order distribution is. Both Dutt et al. and this paper, in the experienced ambiguity treatment, renew the procedure each time so that the previous observations don't inform about the actual process faced next.

It is natural that the 50% of subject for whom sampling from ambiguous happened to come out favorably, prefer ambiguous (as reported in last sentence of abstract), and the other 50% disprefer ambiguous. %}

{% This paper studies source dependence with comparisons between persons and (though less so) also between sources. It uses the source method, defined below. It considers only gains. Biseparable utility is assumed. That is, the binary act $x_E y$ (giving x if event E and y otherwise), for x ≥ y, is evaluated by

$$x_E y \to W(E)U(x) + \big(1 - W(E)\big)U(y). \qquad (1)$$

This model includes source theory, i.e., local probabilistic sophistication, with

$$W(A) = w_{\mathcal{A}}P(A) \qquad (2)$$

where $\mathcal{A}$ is a source (say, subalgebra of events), A an event in $\mathcal{A}$, P an additive probability measure on $\mathcal{A}$, and $w_{\mathcal{A}}$ a probability transformation function that, importantly, depends on the source $\mathcal{A}$. P is called a-neutral and $w_{\mathcal{A}}$ is the source function. This paper considers comparative results using formulas

$$w_{\mathcal{A}} = w_{\mathcal{C}} \circ \varphi \qquad (3)$$

where φ is called the pmatcher from $\mathcal{A}$ to $\mathcal{C}$, depending on $\mathcal{A}$ and $\mathcal{C}$, a dependency not expressed in notation here. I add here that this formula primarily serves within-subject between-source comparisons, as shown theoretically by Baillon, Bleichrodt, Li, & Wakker (2021). For simplicity, it is convenient to assume that $\mathcal{C}$ is a more established source than $\mathcal{A}$ (e.g.,$\mathcal{C}$ is risk with known probabilities) and the pmatcher specifies for every a-neutral probability q of an event in $\mathcal{A}$ the gambling-equivalent a-neutral probability p of an event in $\mathcal{C}$. (It is convenient to assume here that the latter is better understood and is kind of used for calibration.) Thus, if $P(A) = q$ for event A from $\mathcal{A}$, and we want to "calibrate" how much this is liked, then φ tells us, because, with $\varphi(q) = p$, the event C from $\mathcal{C}$ that is gambling-equivalent to A ($x_C 0 \sim x_A 0$ for $x > 0$) has $P(C) = p$. φ gives between-source within-person comparisons. For instance, if $\varphi(p) \le p$ for all p, then events from $\mathcal{A}$ are disliked and there is source preference for $\mathcal{C}$ over $\mathcal{A}$. φ in itself gives no absolute results. If $\mathcal{C}$ is risk (known probabilities), then φ gives matching probabilities and ambiguity attitude, in my interpretation of ambiguity, as shown already by Dimmock, Kouwenberg, & Wakker (2016).

Note that φ in Eq. (1) is to the right of $w_{\mathcal{C}}$, and not to the left as one would see in Pratt-Arrow types of utility transformations. May I use this occasion to qualify this point as a deep insight? It was axiomatically justified by Baillon, Bleichrodt, Li, & Wakker (2023), with a simple version appearing in Wakker (2004 Psychological Review) and it underlied Dimmock, Kouwenberg, & Wakker (2016). The authors of this 2024 paper chose this writing based on intuition, and have me impressed by that.

One can manipulate uncertainty attitudes by bringing in φ. An insensitive φ increases source insensitivity, with source preference likewise. Baillon, Bleichrodt, Li, & Wakker (2023) derive this point axiomatically, for within-subject comparisons (so that fixed utility function cancels, making much life easier).

One can directly measure φ by finding indifferences

$$x_A0 \sim x_C0 \qquad (4)$$

and then, with $P(A) = q$, $P(C) = p$, we gave $\varphi(q) = p$. One can also do it indirectly using transitivity and then using certainty equivalents CE to get $CE(x_A0) = CE(x_C0)$, or using matching probabilities MP to get MP(A) = MP(C). The authors do not use Eq. (4), but use the two indirect methods, presenting them as two separate methods.

The authors do the measurements in three experiments, and do parametric fittings of φ. They take $1–2\varphi(0.5)$ as index of pessimism (anti-index of elevation) and used the derivtive φ' in their index of insensitivity: $1 - \varphi'(0.5)$. The unit of the first index, $1–2\varphi(0.5)$, is probability. It is the probability premium one wants extra to gamble on $\mathcal{A}$ rather than on $\mathcal{C}$. The unit of $\varphi'(0.5)$ is change in weight per probability unit. It shows that to achieve a particular change of weight, one needs $\varphi'(0.5)$ more units of probabilities of $\mathcal{A}$ than of $\mathcal{C}$. The latter holds only in the middle of the probability interval, and near the boundaries it is opposite. What precisely is that middle needs formalization of an insensitivity region, provided by Baillon, Bleichrodt, Li, & Wakker (2023), but this point is complex and better left unformalized in informal papers.

In all three experiments, the authors find source preference for a familiar source $\mathcal{C}$ (home temperature) over an unfamiliar one (foreign temperature), which is natural. In two of the three they find more sensitivity for the familiar source, which is natural. In one they find less sensitivity, which is surprising. They find much individual heterogeneity.

P. 394 reanalyzes the data of Abdellaoui et al. (2011 AER), and nicely shows that the pmatcher φ can be directly obtained without doing any utility estimation. (By using certainty equivalents and transitivity.)

Regarding novelty:

CONTRIBUTION 1 [not in this paper; done before]: Several papers measured W in Eq. 1 and also source functions $w_{\mathcal{A}}$ (and $w_{\mathcal{C}}$) in Eq. 2 before. Several papers also measured single-number indexes (not entire φ) of source attitudes regarding preference and sensitivity, and compared those across subjects and sources. The latter was often done only if $\mathcal{C}$ was risk (known probability), in which case φ captures ambiguity attitude (in my interpretation), but not always (Li, Müller, Wakker, & Wang 2018). In these manners uncertainty attitudes have been measured before, and also comparisons across sources and individuals. Hence, the authors do not have Contribution 1.

CONTRIBUTION 2 [novelty of this paper]: No empirical study went for the general φ in Eq. 3 before, let be if $\mathcal{A}$ and $\mathcal{C}$ can be general uncertainty with no need to have risk involved.

It will not be surprising that I, fan of the source method, am enthusiastic about this paper. It is the first to empirically measure φ of Eq. 3 which, unsurprisingly, I find important. It provides important new empirical insights into uncertainty attitudes. It does not need the assumptions of the Anscombe-Aumann (AA) framework, which are problematic surely in an empirical sense. And, it handles the important insensitivity component well. Again unsurprisingly, I think the paper deserves many follow-ups.

================================

With all these new concepts and components still to be established, there are different interpretations possible that are yet to be settled. In the rest of these annotations, I list three points where my interpretations diverge from the authors'.

POINT 1. I prefer different indexes for source preference and insensitivity than the ones used by the authors, who use $1-2\varphi(0.5)$ and the derivate of φ in $1-\varphi'(0.5)$. Unsurprisingly, I prefer the indexes of Baillon, Bleichrodt, Li, & Wakker (2021). The rest of this point (1) gives details.

DETAILS OF POINT 1: The authors' indexes concern local behavior of φ at $p = 0.5$, whereas it should capture global properties of φ. The total area under the curve φ would be better for source preference, and $(\varphi(0.95)-\varphi(0.05))/0.90$, even while clearly ad hoc, would be better for sensitivity. Unsurprisingly, I prefer yet more the indexes of Baillon, Huang, Selim, & Wakker (2018), which received firm theoretical justifications in Baillon, Bleichrodt, Li, & Wakker (2021). The parameters of the Goldstein-Einhorn family (more than of Prelec) are also preferable. The authors point out that for the parametric families considered their parameters $1–2\varphi(0.5)$ and $1–\varphi'(0.5)$ correspond one-to-one with global properties (p. 400 3rd para). But, as said, global is what is relevant, so better to go for that. Problem is that for other weighting functions, other parametric families of empirical parameter-free measurements, there may be ad hoc local peculiarities at $p = 0.5$ that confound, especially because $p = 0.5$ (fifty-fifty) is known to have many psychological peculiarities.

POINT 2. The authors overstate their novelty claims, ignoring the above Contribution 1.

DETAILS OF POINT 2. Here are six citations ignoring Contribution 1:

P. 379 (abstract): "*there is currently no definition* of source dependence that allows for comparisons across individuals and sources" [italics added]

P. 380: "*there is currently no way* to interpret differences in attitudes across sources in terms of source dependence" [italics added]

P. 381: "Methods … measure ambiguity premia in terms of money and willingness to bet, which do not have the same values for individuals with different risk attitudes. [Other] Approaches … define source dependence as differences in weights that are not easily interpretable. Therefore, *these approaches preclude the direct comparison* of source dependence across individuals or (pairs of) sources." [italics added]

P. 387, §2.3.1: "This case illustrates that differences in the parameters of ambiguity functions *cannot be compared* across individuals with different probability weighting functions for risk. The reason is that ambiguity functions are measured on the scale of known probabilities (willingness to bet), and this scale is different for two individuals who weigh risk differently." [italics added]

P. 388, §2.3.2: "This example illustrates that differences in source function parameters *cannot be compared* across pairs of sources, even within an individual, since differences in source functions correspond to differences in "weight," which have different values depending on the sensitivity toward the sources being considered." [italics added]

P. 408: "While existing methods can capture attitudes toward specific sources, *there is currently* *no sound way* to convert differences in ambiguity attitudes across sources into source dependence." [italics added]

Other approaches did compare source dependence across individuals and sources through single-number indexes, and also indirectly through ambiguity comparisons (e.g., more ambiguity aversion for source $\mathcal{A}$ than $\mathcal{C}$ is equivalent to source preference for $\mathcal{C}$ over $\mathcal{A}$). The authors can exclude Contribution 2 from other studies, but they go too far in excluding Contribution 1 from other studies.

Scenario 1 in §2.3.1, p. 387, shows that two persons with the same uncertainty attitude towards a source can have different ambiguity attitudes. This is a trivial consequence of uncertainty attitude being ambiguity attitude PLUS risk attitude. Unfortunately, the authors misinterpret: "This case illustrates that differences in the parameters of ambiguity functions *cannot be compared* across individuals with different probability weighting functions for risk. The reason is that ambiguity functions are measured on the scale of known probabilities (willingness to bet), and this scale is different for two individuals who weigh risk differently." [italics added] It is true that *ambiguity parameters* cannot just be compared across individuals to *compare uncertainty attitudes*. But, trivially and contrary to the authors' claim, *ambiguity parameters* can be compared across individuals *to compare ambiguity attitudes*.

Scenario 2 in §2.3.2 on p. 388 is similar. Details: It shows that probability units can be different than weight units because of different weighting functions. The authors misinterpret, again: "This example illustrates that differences in source function parameters *cannot be compared across pairs of sources*, even within an individual, since differences in source functions correspond to differences in "weight," which have different values depending on the sensitivity toward the sources being considered." [italics added] It is true that *weights* cannot just be compared across sources *to compare probabilities*. But, trivially and contrary to the authors' claim, *weights* can be compared across sources *to compare weights*.

Scenario 3 on p. 288, §2.3.3 shows similarly that an increase of 0.2 in a pessimism parameter can have different effects on source premiums in different parts of the domain if the effects are nonlinear, with a misinterpretatio similar as above.

POINT 3. I use the term ambiguity in a broad sense, capturing all differences between an uncertain source and a (standard) risky source. The authors mostly use the term ambiguity in a narrow sense, where it captures the difference between unknown and known probabilities with the big ceteris paribus assumption added that there is no other relevant difference. This explains why I claim that φ captures ambiguity (+ risk attitude) whereas the authors claim that φ does not do so and even sometimes that φ is "independent" of ambiguity attitude. DETAILS OF POINT 3. My term ambiguity can capture competence, betrayal aversion, and many other emotions and cognitions. I do not like the narrow sense of ambiguity because it is practically unobservable. In particular, the Ellsberg urns do not measure it at all: they measure the difference between natural uncertainty and weird uncertainty with weird secrets kept for no good reason that one can think of. The literature has as yet mostly been inconsistent. If work to be done, taking the narrow definition and claming that with one Ellsberg experiment all of "the" (as if one thing) ambiguity attitude is captured. If reward to be claimed, taking the broad definition: almost all our decisions involve unknown probabilities, i.e. ambiguity, and, hence, with the little Ellsberg experiment all these decisions can be predicted.

The authors here do take the broad, and not narrow, meaning of ambiguity on p. 384 below Eq. 5, when they write: "Comparing w_S to w characterizes the *ambiguity attitude* toward a given source S. The difference between source functions w_A and w_B of two distinct sources A and B characterizes source dependence, i.e., the fact that *ambiguity attitudes* differ across sources." [italics added] But the rest of the paper adopts the narrow sense, when claiming that source preference is different than ambiguity and even that pmatchers are independent of ambiguity. %}

{% The author expresses an extreme econometric viewpoint in preface 2nd para:

"The method of econometric research aims, essentially, at a conjunction of economic theory and actual measurements, using the theory and technique of statistical inference as a bridge pier. But the bridge itself was never completely built. So far, the common procedure has been, first to construct an economic theory involving exact functional relationships, then to compare this theory with some actual measurements, and, finally, "to judge" whether the correspondence is "good" or "bad."

Tools of statistical inference have been introduced, in some degree, to support such judgments, e.g., the calculation of a few standard errors and multiple-correlation coefficients. The application of such simple "statistics" has been considered legitimate, while, at the same time, the adoption of definite probability models has been deemed a crime in economic research, a violation of the very nature of economic data. That is to say, it has been considered legitimate to use some of the tools developed in statistical theory without accepting the very foundation upon which statistical theory is built. For no tool developed in the theory of statistics has any meaning-except, perhaps, for descriptive purposes-without being referred to some stochastic scheme." %}

Haavelmo, Trygve (1944) "The Probability Approach in Econometrics," *Econometrica* 12, supplement, July 1944, pp. iii-vi+1-115.

{% Presidential address, meeting of Econometric Society, Philadelphia, Dec. 29 1957; P. 351: "econometrics is something that should be done, rather than talked about."P. 354 warns against first using deterministic models and only then bringing in randomnessw/error (usually my preferred approach):

"Sometimes the introduction of reasonable random elements into an originally "exact" theory changes the observational implications of a model very profoundly. This is one reason why one might well doubt whether the kind of "division of labor" between pure theory and econometrics, which we have been relying on, is practical and fruitful. It has become almost too easy to start with hard-boiled and oversimplified "exact" theories, supply them with a few random elements, and come out with models capable of producing realistic-looking data. At the same time the introduction of random elements in the theories has made it possible to account for seemingly rather puzzling phenomena"

The author pleads for the use of subjective probability. "are realities in the minds of people" and "ways and means can and will be found to obtain actual measurements of such data."

P. 357: "I think most of us feel that if we could use explicitly such variables as, e.g., what people think prices or incomes are going to be, or variables expressing what people think the effects of their actions are going to be, we would be able to establish relations that could be more accurate and have more explanatory value. But because the statistics on such variables are not very far developed, we do not take the formulation of theories in terms of these variables seriously enough. It is my belief that if we can develop more explicit and a priori convincing economic models in terms of these variables, which are realities in the minds of people even if

they are not in the current statistical yearbooks, then ways and means can and will eventually be found to obtain actual measurements of such data." %}

Haberlandt, Karl (1994) "*Cognitive Psychology*." Allyn and Bacon, Boston. (2nd edn. 1980, Krieger, New York.)

{% This paper investigates if a status quo, or an expectation just prior to it, serves as reference point.

In the first ("indirect") experiment, a choice list determines the CE (= certainty equivalent) of (0.5: CHF10, 0.5: 0). Payment is in Switzerland CHF. This determines the risk aversion of N = 121 subjects, with the random incentive system used to implement real incentives. This is done for a control treatment and for two experimental treatments. This first receive a sure prior endowment of CHF4, the second receive (0.5: CHF4, 0.5: CHF8), and the third receive (0.75: CHF4, 0.25: CHF12). The two experimental groups have expected prior endowment CHF6. The prior endowments were carried out prior to the choice lists, that is, the lotteries of the two experimental groups were carried out before

the aforementioned measurement of risk aversion. For the subjects who received CHF4 as prior endowment in the control groups, we can see if they take that 4 as reference point so, behave as in the control group, or if they take the CHF6 expectation as reference point and behave differently. It turns out that they, for both experimental groups, are somewhat less risk averse than the control group. (The evidence for group 1 is not so strong, p = 0.04 one-sided.) The two experimental groups are mutually similar. Had they taken the expected CHF6 as their reference point, then the prospect would have been perceived as mixed leading to greater, and not smaller, risk aversion for the experimental groups. So, other things must be going on. %}

{% d**ynamic consistency**

Discussed in Paris on March 8, 1999.

Dynamic consistency condition definition seems to comprise **RCLA**, and is restricted to fixed counterfactual strategies.

Uses a "generalized conditional dominance condition": "If, given every element of a partition, I prefer replacing f by g only given that one element of the partition, then I prefer replacing f by g in total. Given dynamic consistency (which is defined in this paper to imply reduction of events), the condition is weaker than forgone-event independence but is "in that spirit." The condition was introduced independently by Grant, Simon, Atsushi Kajii, & Ben Polak (1999) "Decomposable Choice under Uncertainty," %}

Halevy, Yoram (1998) "Trade between Rational Agents as a Result of Asymmetric Information," .

{% Considers an experiment with four urns with each 10 balls of two colors, red and black.

Urn 1 is fifty-fifty;

Urn 2 is unknown composition

suspicion under ambiguity: as it should, subjects can choose the color on which to gamble, so, no suspicion.

Urn 3 is two-stage, first stage randomly chooses one of the 11 compositions of the urn and then stage two carries out the drawing of the ball from that composition. (**second-order probabilities to model ambiguity**)

Urn 4 is also two-stage, but chooses randomly only a 0-10 or 10-0 composition. So, urn 4 is quite like urn 1.

The author compares the explanation of ambiguity aversion through violations of probabilistic sophistication (Epstein 1999) with the one of Segal that assumes that for the ambiguous urn 2 the subjects subjectively assume a two-stage uncertainty with the first stage uncertainty about the composition of the urn, coupled with violations of **RCLA.** He makes the plausible but debatable assumption that probabilistic sophistication assumes no violation of RCLA. The two theories then differ regarding predictions about urn 3:

The probabilistic-sophistication explanation says urns 1, 3, 4 all have known probabilities and will be treated alike, with only urn 2 valued lower.

The RCLA-violation-explanation says that urns 2 and 3 will be treated similarly, and will be valued lower than urn 1.

The data find the latter prediction, with urns 2 and 3 valued lower than urn 1. At group average level urns 2 and 3 are treated alike, but I guess there remain many differences at the individual level. The author distinguishes two subgroups with different attitudes.

Urn 4 also seems to be treated like urns 2 and 3. Subjects may simply have a general dislike of complex urns. %}

Halevy, Yoram (2007) "Ellsberg Revisited: An Experimental Study," *Econometrica* 75, 503–536.

{% Assumes consumption stream (c_0,c_1, …). Assumes that for each timepoint there is an r probability of death ("implicit risk"), to be modeled as the 0 consumption outcome from there on, so that the probability of consumption of c_t (and then all preceding consumptions) is $(1-r)^t$. In some formal results (Theorem 1) conditions are assumed over all values of r. Risk is processed using nonEU. Each consumption c_t is assumed nonnegative; i.e., it is at least as good as death (stated on p. 1152 2nd para ℓ. 2).

The representation is of the form $\mathrm{SUM}_t g\big((1-r)^t\big)\beta^t u(c_t)$ where u is utility (with the scaling $u(0) = 0$), β is intertemporal discount rate, and g is a probability weighting function. Thus, constant discounting results iff g is linear (EU, discount rate being $(1-r)\beta$), diminishing impatience corresponds with convex g and increasing impatience corresponds with concave g. In this way the immediacy effect of intertemporal choice becomes the certainty effect of decision under risk. This analogy has been alluded to many times in the literature but this paper gives a formal model capturing it.

The author uses "diminishing impatience" for the immediacy effect and otherwise uses the expression strongly diminishing impatience. I next discuss separability issues, resulting from emails with the author in March 09.

(Saito (2011) will show that there is a confusion of these concepts and that in Theorem 1 there (p. 1150) diminishing impatience (in Halevy's terminology) does not imply common ratio, but instead is equivalent to the certainty effect, and it is strong diminishing impatience (in Halevy's terminology) that is equivalent to the common ratio effect.)

OBSERVATION 1. The SUM representation above can be obtained by first aggregating risks at each timepoint, and only then aggregating over time. At each timepoint t, the probability of consuming c_t is $(1-r)^t$ and the probability of consuming 0 is $1 - (1-r)^t$. The RDU value at time t is $g((1-r)^t u(c_t))$. Next these RDU values are aggregated over time, discounted by β, giving the above SUM.

OBSERVATION 2. The SUM representation above can also be obtained by first aggregating over time, i.e., by considering all consumption paths and their probabilities, and then calculating RDU. This is explained in §4, in particular Theorem 2, p. 1154. This is the author's interpretation in the paper.

The two observations displayed here imply that we have weak separability of timepoints (even strong, additive) and also weak separability of the risky events. It is well known, by applications of Gorman's (1968) theorem, that this implies strong complete additive separability of time and risk. So, a puzzle for the readers maybe, how can we then still have nonEU? The answer is that we are considering a restricted, comonotonic, domain. For two uncertain events always the one with the longest life duration has the best outcomes. The events always have the same ranking position and we look at RDU within one comonotonic set. Thus, even the sure-thing principle holds for uncertainty, and replacing a common outcome on an uncertain event by another one will not affect preference. The model very efficiently combines aggregation conveniences of classical expected utility and discounted utility models (making the model tractable) with empirical features of nonexpected utility. %}

Halevy, Yoram (2008) "Strotz Meets Allais: Diminishing Impatience and the Certainty Effect," *American Economic Review* 98, 1145–1162.

{% **DC = stationarity**: This paper carefully distinguishes the three concepts and tests them separately, in particular, employing the longitudinal data required for testing time consistency (also known as dynamic consistency). It is very similar to Casari & Dragone (2015), but the two studies were done independently and do not cite each other.

The paper uses the common term time consistency for what could be called decision-time independence (the calendar time of consumption remains fixed, but the calendar time of decision-taking is changed; it is a between-preference-relations conditon if we take preference relations at different times as different preference relations), the common term stationarity for what could be called consumption-time independence (the calendar time of decison remains fixed, but the calendar time of consumption is changed; it is the only within-preference-relation conditon), and the term time invariance for what could be called age independence (the whole decision situation, with both time of decision and time of consumption) shifted in time. Time invariance means that we can use stopwatch time. Although the terms by themselves do not describe the concepts, and could from this perspective be interchanges, they have several advantages:

- they have all been used before in the sense used here;

- they are short;

- time consistency can be argued to be normative, so, the strong term consistency works well;

- time invariance is not normative but is empirically plausible as ceteris paribus; causes of violation can be taken as distortions; here the immediacy effect does not imply violations; the neutral term variance fits well with this role.

The definitions are in §3, p. 341.

P. 341 Proposition 4 states that every two conditions implies the third. I once jokingly said that this result is a corollary of transitivity of the identity relation. This claim is clearest in Fact 5: Stationarity holds iff $x_2 = x_1$; time invariance iff $x_{21} = x_1$, and time consistency iff $x_{21} = x_2$. One can also do it by each condition requiring that choices in two of three choice situations are the same.

As argued above, violations of time invariance are a bit like violations of ceteris paribus. This paper finds that mostly time invariance is violated. It may be because the late timepoints in the experiment were close to the end of the term, or because students had then gotten used to the experiment, or built up confidence seeing that experiment did pay in early times.

P. 342 following Proof of Proposition 4 points out that much of the literature has taken time invariance implicitly. This annotated bibliography has a keyword **DC = stationarity**: for studies that made this confusion, and studies that did not. %}

Halevy, Yoram (2015) "Time Consistency: Stationarity and Time Invariance," *Econometrica* 83, 335–352.

{% **biseparable utility violated**; Considered a combination of the models of Seo (2009) and Ergin & Gul (2009). Use a domain similar to Seo (2009), with a state space and then objective probabilities both before and after the states. Their domain is actually smaller, with compound lotteries and Savage acts. Thus, they can use the prior probabilities to calibrate subjective probabilities over the state space with matching probabilities as Seo did, and they need not invoke the second-order acts of KMM. They generalize Seo's model by not assuming expected utility within each stage, but only probabilistic sophistication, similar to Ergin & Gul (2009. Their model is supported empirically by evidence from Halevy (2007). %}

Halevy, Yoram, Massimiliano Amarante, & Emre Ozdenoren (2008) "Uncertainty and Compound Lotteries: Calibration," working paper, University of British Columbia.

{% **biseparable utility violated**; Consider unknown urn of Ellsberg as second-order probability distribution. In repeated choice, if the compositions of the various unknown urns are positively correlated, then aversion to mean-preserving spreads will imply aversion to repeated choices + repeated payments on the unknown urn versus the known (would be opposite if the urns are negatively correlated). In single-choice situations people may have been conditioned to act as if repeated. Thus, ambiguity aversion could be generated by aversion to mean-preserving spreads. %}

Halevy, Yoram & Vincent Feltkamp (2005) "A Bayesian Approach to Uncertainty Aversion," *Review of Economic Studies* 72, 449–466.

{% This paper provides a general preference axiomatization for two-stage probabilistic sophistication where RCLA is abondoned. For this, it is a sort of analog of what Machina & Schmeidler (1992) is for probabilistic sophistication. However, the two-stage model is way more complex and less nice, unavoidably, with, for instance, no uniqueness. Further, it needs the extra assumption of objective two-stage lotteries available in the preference domain.

We assume a Savage framework of decision under uncertainty, with acts mapping states to outcomes. For simplicity, assume only finitely many states $s_1,\ldots,s_n$. However, we add objective probability distributions to the preference domain. This also happens in the Anscombe-Aumann framework, but that is more complex by assuming more than one stage. We assume only one stage.

To prepare, I first consider probabilistic sophistication à la Machina & Schmeidler (1992). It holds if and only if there exists an objective probability vector $(p_1,\ldots,p_n)$ such that every act $(s_1{:}x_1,\ldots,s_n,x_n)$ is indifferent to the objective lottery $(p_1{:}x_1,\ldots,p_n,x_n)$. So, the agent does not distinguish between objective and subjective probabilities. One might take this as a Version-1 preference axiomatization, be it trivial and ugly because of the “there exists” clause. We can do better because for each uncertain event s_j we can readily calibrate the objective matching probability (gambling-equivalent) p_j and that is s_j’s subjective probability p_j. So, here we used only two outcomes. Subjective probabilities are readily observable this way and can be used as input in preference axioms, making the above axiom nicer, giving a nicer Version-2 preference axiomatization. Sarin & Wakker (1997) did a similar thing for subjective expected utility instead of probabilistic sophistication, which I consider to be better than Anscombe & Aumann’s (1963) axiomatization of subjective expected utillity.

This paper does something related for two-stage probabilistic sophistication where RCLA is abandoned. Now the preference domain consists of Savage acts and objective two-stage lotteries. We can obtain, trivially and ugly, a Version-1 axiomatization by simply assuming an isomorphic, preference-equivalent, objective two-stage framework. (Details: we consider all first-stage probability distributions $(p_1,\ldots,p_n)$, and then a second-stage distribution over them. Then each act $(s_1{:}x_1,\ldots,s_n{:}x_n)$ is equivalent to the objective two-stage lottery where each $(p_1,\ldots,p_n)$ is replaced by $(p_1{:}x_1,\ldots,p_n{:}x_n)$.) A problem here is that, even with a continuum of outcomes, I guess that the objective two-stage framework may not be unique. Anyway, this paper goes for a Version-2 axiomatization, by first, in Axiom 6, doing calibration using only two outcomes, and then extending to general acts in Axiom 7. But Axiom 6 seems to be somewhere between the above

Version 1/Version 2 by involving a more heavy “there exists” clause, and probably there is no uniqueness. %}

{% **updating: nonadditive measures**; Paper distinguishes between belief functions as "generalized probability," which reflects belief of a person that he is willing to act upon (which may be subjective in my terminology although Joe in a discussion with me in Jan. 2002 never wanted to commit to this term), and that we are born with and keep up updating, and as "evidence," which is a piece of (in my terms, objective) information that need not reflect anybody's belief. For example, evidence may be sample size + relative frequencies in a data set. Paper has the nice interpretation that evidence is to be taken as an updating function mapping prior beliefs to posterior beliefs (claimed as possibly new on p. 290). Two pieces of evidence can be combined as through Dempster/Shafer's formula, a belief can be updated through evidence. The writings of Shafer, Dempster, Smets, do not always fit very clearly/completely in one or other category. P. 289 points out that combining beliefs, as with combining experts, requires subjective judgment of importance weights of the experts.

Second part of paper, starting in §4 on p. 288, assumes the special model as in statistics, where there are hypotheses with nonprobabilized uncertainty and then, conditional on each hypothesis, probabilized uncertainty about the observations. It imposes that evidence, to be proper, should map each Bayesian prior probability towards a posterior Bayesian probability. This then implies that evidence should be like a normalized likelihood function; i.e., as an additive probability (e.g., Theorem 4.6, p. 301). And this is a conclusion of the paper, that evidence is best represented as (Bayesian, additive) probability.

P. 303 gives refs to papers showing that under some axioms à la Cox, evidence must be represented by likelihood. %}

{% About half of 1075 (p. 126 bottom) farmers were asked hypothetical questions about willingness to pay or accept for risky gains and losses. Assuming EU, their utility functions were derived. Their utility curvature was related to their kind of business, whether more or less risky, and to other characteristics. Farmers with weak loss aversion (utility steep for losses and shallow for gains) engaged in risky activities such as cash crops en fat-stock feeding. Farmers with strong loss aversion engaged in safe activities such as general farming. Qualitative relations are reported, but no statistics. The authors use an unclear terminology of high and low marginal utility where high for gains probably means more convex, so, more risk seeking, and high for losses means the opposite.

risky utility u = transform of strength of preference v: they clearly and repeatedly favor this view, e.g. footnote 4 p. 119.

Pp. 122-123 lists the vNM axioms without independence, but with a nice point 4 that is like the DUR assumption 2.1.2 of my book (only generated probability distribution over outcomes matters) or like no-framing.

P. 123 penultimate para explains that direct matching would be too complex for subjects, so, they derived from choices. They did like choice lists, but I think not all choices related to one choice list in a row or on one page, but randomly intermingled, and only as binary choices. P. 124 text explains that they took

midpoints between switches of preferences as indifference point. Not very clear to me what exactly their stimuli were in Table 1.

P. 124 note a at the table writes that they only use small probabilities so as to avoid distorting effects of what we nowadays (2013) call probability weighting.

PE doesn't do well: p. 124 note c at table says that variations in outcomes are easier to understand than variations in probability.

P. 131 ℓ. 9 reporst a 26 times higher marginal utility for losses than for gains but it is not clear. %}

{% **dynamic consistency**: **favors abandoning time consistency, so, favors sophisticated choice,** because he considered precommitment only viable if an

extraneous device is available to implement it (p. 162/163). P. 162 defines sophisticated and myopic choice; also defines precommitment (called resolute choice by McClennen) but, similar to me, thinks that that is not really an available option. Hammond says that if it is indeed available, then it should be added as a new decision option, a new branch in the tree. (To which McClennen would probably reply that precommitment is in the head and needs no additional decision option, and Machina would reply that tastes themselves have changed and thus generate what seems to be precommitment.)

Hammond takes paths (called "branches") as primitives. n = x(t) means that node n occurs at timepoint t in the path x. In a decision node, all paths emanating from it are simply in the choice set. The one actually happening from there on is the one most preferred by the choice function, but not necessarily in a preference sense and a myopic person will therefore end up with addiction. For any subset of paths, one considers the choice between them by simply snipping off all other paths and otherwise leave the tree as is. Then from that one sees what choice is revealed. Preference between two paths x and y in a node n is then inferred by deleting !all! other paths, and then see what is chosen.

Such procedures do not seem to be useful if there are interactions between paths in the sense that the preference between x and y can be affected by another path z, such as happening in game theory when other actors also choose. It is also problematic for DUU and nonEU when there is nonseparability (e.g., my paper "counterfactual").

Coherence: choice function over paths in some fixed node satisfies some revealed preference conditions to agree with a (weak) ordering.

Consistency: choices at different timepoints reveal the same preferences between paths; it is, basically (6.2 suggests, but I am not 100% sure), the thing violated by myopic choice.

Endogeneously changing tastes describe changes due to previous decisions (so, violations of DC (dynamic consistency), e.g., previous decisions of chance). Exogeneously changing tastes describe changes due to the progression of time (say, factors not in the tree; so, violations of stationarity). Seems that first may rather be violation of history-independence and second of stationarity???

The paper shows that in trees where **sophisticated choice** is coherent, it agrees with myopic choice. In other words, whenever myopic choice leads to

irrationality, then sophisticated choice is not coherent.

There may be a point in the last lines of the conclusion. Sophisticated choice may seem like some sort of resolution of changing taste, but it still is incoherent, so the basic irrationality still remains. %}

{% Considers combinations P*Q of prospects P and Q, interpreted as receiving both of them where they are played independently. Assumes that if P~Q, then P*C ~ Q*C. Under EU, it is implied by constant absolute risk aversion but need not hold in general, similarly as with Samuelson's colleague-paradox. The author doesn't seem to be aware of this. He points out that P*Q can be nonequivalent to P´*Q even though P ~P´ if P´ is more risky than P, under EU. Taking his operation too seriously, he does not conclude from it that his operation is no good, but instead that EU must be no good and that we should reckon with riskiness beyond EU (p. 181 middle sentence). §2 discusses reference dependence, but lowest para of p. 183 confuses money and utility. P. 184 compares level of U(m,x) with level of U(m´,x´), where m is reference point and x is money, in direct manners. However, the common thinking is that preferences can only compare alternatives under one same reference point. Hence, U(m,x) is a ratio scale that is completely independent of U(m´,x´), and comparisons of their levels is not meaningful. We can compare their degree of concavity yes, but their level no. %}

{% **probability elicitation**: applied to experimental economics.

They measure matching probabilities of events using BDM (Becker-DeGroot-Marschak), but in a particular way. To "control for belief," and to focus entirely on the (un)clarity of the mechanism, they take matching probabilities of events with known probability, such as the event of winning from a bag A with 10 chips, 2 of which are winning. Let us focus on the latter event. In the "declarative" design (direct matching in fact) they present subjects with an alternative bag B, with an unknown composition of winning chips, which has 1, …, or 9 winning chips, each with probability 1/9 of being the true bag. So, this B is an Ellsberg-type bag with an unknown number of winning chips, generated using second-order probabilities (**second-order probabilities to model ambiguity**). The subjects perceive ambiguity (or second-order probability) at this stage, but will like the unknown bag more because the known one has only two winning chips.

Then the subjects have to submit a number X. If the number of winning chips ≥ X, so, the unknown bag B is more favorable, then the draw will be from B, and otherwise from A. Given that they depict the unknown bag with a question mark, some subjects may have misunderstood and may have erroneously thought that they are supposed to guess the right number of winning chips. Another misunderstanding may be that subjects first make up their mind that they like bag B more, and then think that they always get their preferred bag B if they submit 0, thus encouraging them to submit 0. The design encourages the subjects not to perceive the possible decision situations in isolation, as desirable for BDM (Becker-DeGroot-Marschak), but as an integrated meta-lottery.

Once the subjects understand the decision task properly, they understand that it is a trivial decision task (a test of stochastic dominance). In a lecture in Atlanta Oct. 2010, the first author explained that in the experiment subjects were encouraged to follow their "gut-feeling," so as to make it seem less trivial probably.

The design reminds me some of that of Bohnet et al. (2008 American Economic Review) which, when properly understood, was only the elicitation of a PE probability, but the BDM mechanism was implemented, not through an ambiguous bag, but through the percentage of subjects in an experiment that deceived in a trust game, arousing trust- and indignification emotions with subjects who do not see through the BDM mechanism.

They use a "declarative" and "clock" implementation of BDM, and find that clock is more accurate.

The authors are enthusiastic, expressing it at the end of their abstract: "Our findings hold practical value to anyone interested in eliciting beliefs from representative populations, a goal of increasing importance when conducting large-scale surveys or field experiments." %}

Hao, Li & Daniel Houser (2012) "Belief Elicitation in the Presence of Naïve Respondents: An Experimental Study," *Journal of Risk and Uncertainty* 44, 149–160.

{% Distinguish between strategic uncertainty (market entry game) and what they call state uncertainty, and what might also be called nature uncertainty. Migrants are more likely to enter competition, but have no different risk or ambiguity attitude. It is nice that for using price lists they cite Fox & Tversky (1995) rather than Holt & Laury (2002) (p. 132). They do cite the latter elsewhere. For risk aversion, they measure one CE of a fifty-fifty lottery, and for ambiguity of an ambiguous-two-color urn but, as far as I could see, no control for suspicion (**suspicion under ambiguity**). %}

Hao, Li, Daniel Houser, Lei Mao, & Marie Claire Villeval (2016) "Migrations, Risks, and Uncertainty: A Field Experiment in China," *Journal of Economic Behavior and Organization* 131, 126–140.

{% Takes a general functional representing uncertainty attitude. Uses local derivatives to define probabilities (state-contingent prices) and, thus, SEU/SEV. Decomposes local uncertainty premium as sum of risk premium and ambiguity premium. Is in spirit of Machina (1982). In version that I saw, EU was assumed for risk, so that al of nonEU was taken as ambiguity, in main text. The end suggested generalizations to nonEU risk attitude.

Typical of the spirit of these days (2021) is that the author starts from the Anscombe-Aumann framework, as if the only thing conceivable, and then almost apologetically moves to a Savagean framework. %}

Hara, Chiaki (2021) "Comparative Ambiguity Aversion for Smooth Utility Functions," working paper.

{%Introduces an index of ambiguity aversion and ambiguity premiums. It is a local index near constant acts, involving generalized second derivatives that also work for maxmin expected utility (maxmin EU) and rank-dependent utility. It is second order, which is opposed to first-order. There is a central role for the Peano form of the remainer, being the functional after subtracting the best second-order approximation. The paper throughout assumes the Anscombe-Aumann framework and thus, for instance, assumes expected utility for risk. The index captures the first-order impact of the size of prizes on matching probabilities. As far as I can understand, this means that for biseparable utility with linear utility the index is 0?? %}

Hara, Chiaki (2023) "Measure of Ambiguity Aversion," working paper.

{% Under EU with homogeneous beliefs but heterogeneous utility ("risk aversion"), if all consumers have convex absolute risk aversion then so has representative agent. %}

{% %}

Hara, Kazuhiro (2016) "Characterization of Stationary Preferences in a Continuous Time Framework," *Journal of Mathematical Economics* 63, 34–43.

{% Analyze all logical impications of subsets of the vNM EU axioms. They take as nice starting point a characterization of all preference relations that satisfy vNM independence and nothing else. They assume in this that the outcome set is a separable metric space. Then the characterization is that there is a collection of sets of continuous utility functions such that x R y (lottery x is preferred to lottery y) if and only if for every set in the collection there is one utility function whose EU accommodates the preference. So, within each set there is a "there exists" quantification, but across sets there is a "for all" quantification. The first can deliver all required richness, the second all required restrictions. This paper is the linear analog of Nishimura & Ok (2016). With linearity added the results are nicer. There is no clear uniqueness result for the sets to be chosen. As with N&O, because there is much richness in the sets to be chosen, one can always choose the utility functions continuous. The authors call their representation coalitional minmax. %}

Hara, Kazuhiro, Efe A. Ok, Gil Riella (2019) "Coalitional Expected Multi-Utility Theory," *Econometrica* 87, 933–980.

{% **PT falsified**: this paper falsifies any other classical economic theory as well, with its extensive risk seeking, especially for gains.

Choices between one nonzero outcome prospects, and the sure outcome that was always the expectation of the prospect. Did it for children, young adults, and adults, ages 5-8, 9-13, 14-20, and 21-64. Did it for probabilities 0.02, 0.10, 0.80, and 0.98. Find in everything the almost exact opposite of the fourfold pattern predicted by prospect theory: People seem to underweight small probabilities and overweight high probabilities, both for gains and for losses, yielding the exact opposite of the fourfold pattern. As people are older they are closer to expected value maximization (**relation age-risk attitude**). People are closer to expected value maximization for gains than for losses. People are more risk averse for gains than for losses.

Real incentives: **random incentive system** where one choice is played for real. Implementation of losses: through **prior endowment mechanism** to ensure no real loss.

P. 59: people who violated monotonicity tended to be more risk averse.

P. 60 bottom: Strange is that the majority choices, 56%, were risk seeking, and were so mostly for gains. Maybe the design generated a strong joy of gambling? This is evidence against prospect theory, but against any other current theory as well.

linear utility for small stakes: they make this assumption for pragmatic reasons.

The authors conjecture (p. 72 penultimate paragraph) that their deviating findings may be due to their stimuli of risky versus riskless choices, claiming that this is different to almost all prior work. This is not so, Tversky & Kahneman (1992) and many others also considered such choices (not doing WTP but choice). %}

Harbaugh, William T., Kate Krause, & Lise Vesterlund (2002) "Risk Attitudes of Children and Adults: Choices over Small and Large Probability Gains and Losses," *Experimental Economics* 5, 53–84.
https://doi.org/10.1023/A:1016316725855

{% **equate risk aversion with concave utility under nonEU**: p. 597: Unfortunately, they use the term risk neutral for linear utility, also under PT, even though with linear utility there then can still be large deviations from risk neutrality because of probability weighting. They mention that only few studies have tested the fourfold pattern using choices. The following search keywords in this bibliography can give related references:

concave utility for gains, convex utility for losses;

risk averse for gains, risk seeking for losses

PT falsified

risk seeking for small-probability gains

P. 598 last para explains why their 2002 study is so unique.

losses from prior endowment mechanism: Subjects received $22 in beginning, well, it was put on a table in front of them and apparently not yet put in their pocket. They might have to pay back from that.

random incentive system: Each subject was paid twice, so, there is income effect. When they played their first choice they did not yet know a second would come (p. 601 ℓ. 6), so, this can be taken as without the income effect (but then with a minor deception) (**deception when implementing real incentives**). Second time they were, again, endowed with $22.

Although pricing tasks confirm 4-fold pattern, I find it hard to interpret the stimuli and results. Subjects had to pay their WTP to get a gain prospect, so that losses could be involved and it was not really a gain prospect. The authors point this out in footnote 8 (p. 599) and discuss it more in §5, but nevertheless analyze what they call gain prospects as if gain prospects. Further complication is that, with prior endowment put on table before them, it is not clear to me if subjects integrated or not, took it as house money or not, and so on.

P. 602 writes that loss aversion can explain that for losses the WTP in absolute value was usually found to be larger than for gains. If subjects took the prospects as the authors analyze and describe them (gain-prospects and loss-prospects) then there would be no mixed prospects and loss aversion had no role to play. (**loss aversion: erroneously thinking it is reflection**)

Pp. 602-603 finds relations at individual level between gain- and loss-attitudes, different than Cohen, Jaffray, & Said (1987) who found no relation.

In the choice task where subjects chose between prospects and their expected values, but were endowed with $22, not given but put on the table before them. They found mostly nonsignificant deviation from EV, and the deviations all suggested to go opposite to the 4-fold pattern. I find it hard to assess the effect of the prior endowment mechanism though. Much of this evidence does not only go against PT, but against any theory we know.

In some places the authors put forward the dual self theories when discussing their results. %}

{% Use hypothetical choice, defended on basis of large outcomes and losses, something that I agree with.

Find that fixed-cost for delay, both for gains and losses, and independent of outcome-magnitude, explains much, and for instance explains a bias, confirmed empirically, to *prefer* immediate losses to future losses, whereas classical theories predict the opposite. %}
Hardisty, David J., Kirstin C. Appelt, & Elke U. Weber (2013) "Good or Bad, We Want It now: Fixed-cost Present Bias for Gains and Losses Explains Magnitude Asymmetries in Intertemporal Choice," *Journal of Behavioral Decision Making* 26, 348–361.

{% The authors show that subjects prefer an uncertain future payment less than an immediate uncertain or a future certain payment, thus confirming risk aversion and impatience.

For losses, people disprefer risky losses, which might contradict risk seeking as predicted by prospect theory were it not that the delay can have led to the dislike. I did not study the paper enough to see how the authors correct for this. For example, I did not understand in the abstract: "While holding the expected value of payouts constant, participants preferred immediate gains and losses if the future was uncertain, and preferred future gains and losses if the present was uncertain." %}
Hardisty, David J. & Jeffrey Pfeffer (2017) "Intertemporal Uncertainty Avoidance: When the Future Is Uncertain, People Prefer the Present, and When the Present Is Uncertain, People Prefer the Future," *Management Science* 63, 519–527.
https://doi.org/10.1287/mnsc.2015.2349

{% Study intertemporal choice, for money, health, and environment, with delays of 0, 1, or 10 years. Use hypothetical choice which I think is best for such intertemporal studies.

For money they assume linear utility, and for health and environment they take number of days (or weeks) of exposure to some gain or loss as unit of which utility is taken linearly just as money when calculating discounting. They find that discounting is similar for money, health, and environment (maybe for gain health some more discounting and for loss health some less), so that this aspect of outcomes does not matter much. But sign of outcome ("valence") matters much, with gains discounted way stronger than losses.

P. 330 column 1 makes the strange claim that the dominant "rational-economic" assumption is that risk attitude should be independent of the outcome. However, I think that no economist will think that utility should be the same for money, wine, life years, and the exponential of money. The authors add a clause "after adjusting for differences in the marginal value of outcomes in different domains" but it is unclear what that marginal value is other than utility, and adjusting for utility gives expected value, so risk neutrality if I understand right. Maybe they think of probability weighting with this claimed to be the same across domains?

To fit data, they use hyperbolic discounting 1/(1+kt) with k the discount parameter. They find strong discounting for gains, with $250 today equivalent to $337.50 next year, and weak for losses, with losing $250 today equivalent to losing $265 next year (pp. 332). Correlations between gains and losses were weak. %}

Hardisty, David J. & Elke U. Weber (2009) "Discounting Future Green: Money versus the Environment," *Journal of Experimental Psychology* 138, 329–340.

{% **bisection > matching**: They measure discounting using matching, choice list (they call it fixed-sequence choice titration), and bisection (they call it dynamic "staircase"). Compare and discuss them. Matching better fits hyperbolic discounting. Choice list better predict real choices. The authors are negative on bisection.

End of §1.1, p. 3: The authors study discounting for periods taking up to 50 years. They use hypothetical choice. They properly motivate this, and I agree:

"Studying the discounting of complex outcome sets on long timescales can be logistically difficult in the lab, if the goal is to make choices consequential: tracking down past participants in order to send them their "future" payoffs is hard enough one year after a study, but doing so in 50 years may well be impossible. Truly consequential designs are even trickier when studying losses, since they require researchers to demand long-since endowed money from participants who may not even remember having participated in the study. Fortunately, hypothetical delay-discounting questions presented in a laboratory setting do appear to correlate with real-world measures of impulsivity such as smoking, overeating, and debt repayment (Chabris et al., 2008; Meier & Sprenger, 2012; Reimers et al., 2009), suggesting that even hypothetical outcomes are worth studying."

As do Ariely, Loewenstein, & Prelec (2001), they use the nice term "coherent arbitrariness" for coherent choices that are coherent biases rather than coherent genuine preference. It is what Loomes, Starmer, & Sugden (2003 EJ) call the shaping hypothesis. Methods that can elicit more inconsistencies/noise can be good. The authors use the nice term "ability to detect inattentive participants" for it.

coherentism: although the authors do not really get into that, the term coherent arbitrariness nicely indicates disagreement with coherentism. %}

Hardisty, David J., Katherine F. Thompson, David H. Krantz, & Elke U. Weber (2013) "How to Measure Time Preferences: An Experimental Comparison of Three Methods," *Judgment and Decision Making* 8, 236–249.

{% All comments below refer to 2nd edn.

Watch out that these authors use the term convex to designate only midpoint convexity. I will use the term in the usual way below.

Section 2.20, the definition of average, reminds me of Blackwell's theorem, but I will not try to check out the link now.

Ch. 3: P. 65 Eq. 3.1.1 writes the quawi-linear functional (CE of EU under risk) but does not do much with it. P. 158, Theorem 215, will characterize it. The Ch. considers probability-contingent prospects (q_1:x_1,…,q_n:x_n) with all q_j's positive and summing to 1 and the x_j's real-valued. They take the prospects as abstract mathematical objects and never refer to probabilities or anything. I could not find out from the text if they assume n variable or fixed. Most theorems and proofs seem to hold for both, as long as n is fixed at at least 2. What they call means are what DUR calls certainty equivalents under expected utility with possibly nonlinear utility U. Theorem 82 shows that the CE (certainty equivalent) is uniquely determined if U is continuous and strictly monotonic. Theorem 83 shows that CEs (certainty equivalents) determine U uniquely up to level and unit and sign of unit. P. 67 bottom states that we can always take U strictly increasing. (For just CEs it does not matter if we take U or –U).

Theorem 84 shows that CE is homogenous, which is equivalent to constant relative risk aversion (CRRA), if and only if U is of the log-power family! This precedes Pfanzagl (1959) and others.

Theorem 85, and also Theorem 92, show the Pratt-Arrow-Yaari result that, undet EU, U has lower certainty equivalents than EU under V iff U is a concave transformation of V. Theorem 243 extends this to nonsimple distributions.

Section 3.5-3.8 give results on convex functions that are useful in decision theory (midpoint convexity and the like).

Section 3.15 compares sums instead of averages, and Section 3.17 compares sets (I am not sure but maybe this book lets set refer to n-tuples, i.e., they are sequences instead of sets).

Section 3.16 has all kinds of results on concavity of higher derivatives, which might be related to prudence.

Observation 88 in §3.7 (p. 73 in 2nd edn.) gives a beautiful result on convexity (full-force, and not just midpoint convexity) for continuous functions: they are convex as soon as for each pair of arguments there exists an argument in between them for which the function is below the chord. Beautiful proof:

"Suppose that PQ is a chord, and R a point on the chord below the curve. Then there is a last point S on PR and a first point T on RQ in which the curve meets the chord: S may be P and T may be Q. The chord ST lies entirely below the curve, contradicting the hypothesis."
http://personal.eur.nl/Wakker/refs//pdf/hardy_et_al((1934)_obs.88.pdf
An illustration and further explanation is here:
http://personal.eur.nl/Wakker/refs//pdf/hardy_et_al((1934)_obs.88.pdf.

Observation 111, §3.18 (p. 91) shows that on any open interval, midpoint convexity plus boundedness on some nondegenerate subinterval imply continuity and full convexity on the whole open interval. They refer to Jessen (1931) and M. Riesz (1927) for this result.

P. 158, Theorem 215 gives the von Neumann-Morgenstern EU axiomatization if certainty equivalents exist!! The domain is the set of all simple prospects over ℝ, as explained in §6.19. The necessary and sufficient conditions for EU with a

continuous strictly increasing utility U are:

[1] CE(x) = x;

[2] Strict stochastic dominance;

[3] CE(F) = CE(F*) $\Rightarrow$ CE(tF+(1-t)G) = CE(tF*+(1-t)G) for all 0 < t < 1.

Condition [3], called quasi-linearity on p. 161, is nothing other than the celebrated independence condition. Footnote a then cites three references, by Nagumo, Kolmogoroff, and … de Finetti(1931) “Sul Concetto di Media”! They then say that they follow de Finetti’s proof. Note how continuity of CE, and the vNM Archimedean axiom, all follow from the conditions, mostly CE existence. P. 161 last two lines state uniqueness up to level and unit.

Theorem 216: velocity averaged by time is less than velocity averaged by distance.

Theorem 236 (p. 168): defines comonotonicity, called similarly ordered there.

Theorem 249 and 250 shows that second-order stochastic dominance is necessary and sufficient for preferability under every concave utility function. This can be seen as follows: Take a = 0, b = 1, and let f be the generalized inverse of the distribution function F of a prospect that I will denote F, and let g be the generalized inverse of the distribution function G of a prospect that I will denote G. Then the integral from 0 to 1 of f is EV(F), and the integral from 0 to 1 of psi(f) is the EU of F under utility function psi. The inequality of integrals written in the beginning means that F is preferred to G under every convex utility. The necessary and sufficient condition is that F and G have the same expected value and every above truncation of the two at level y has higher expectation under F than under G. A discrete analog is in Theorem 108. That theorem compares n-fold sums. We can as well take averages and then have equal-probability lotteries, which captures all rational-probability lotteries. Then the majorization amounts to 2^{nd} stochastic dominance, I guess, but did not try to check more. %}

{% I comment on the version of May 11, 2011.

This paper criticizes the statistical tests in the main text of

Abdellaoui, Baillon, Placido, & Wakker (2011) "The Rich Domain of Uncertainty: Source Functions and Their Experimental Implementation," *American Economic Review* 101, 695–723.

As one of the authors criticized, my role is someone involved rather than outsider commenting.

I mostly use t-tests or Wilcoxon to test (in)equalities. Leaving aside for now my Bayesian sympathies, I like those tests in that they can be used between-subjects, as I usually do, without making any assumption about probabilistic error distributions within-subjects-between-stimuli. In particular, they do not assume those to be statistically independent. They only assume between-subject statistical independence, which I find more convincing.

Many econometric analyses do add assumptions about probabilistic error distributions within-subjects-between-stimuli, and often that they are independent. There are pros and cons, with different preferences in different fields. However, Harrison only knows the latter econometric approach, says that one must specify within-subject errors, does not know that one can do without in t-tests and Wilcoxon, and claims that our tests are wrong for not doing what he knows. My cv on my homepage shows that I have a degree in mathematics with statistics as one specialization, and that until 1995 most of my teaching was in statistics, to mathematical, psychological, and medical students. I should know about t-tests! Harrison is effectively claiming that vitually every t-test used in the literature is wrong. He erroneously thinks that variables that, in his terminology, are estimates, cannot be submitted to t-tests. In regressions as commonly used in econometrics, unlike in t-tests, it is often required that the independent variables have no errors. (See Gillard (2010) for a survey.) Maybe this is confusing Harrison. An alternative source of confusion may be that econometric analyses often impose error assumptions (often normality) on basic measurements, and then for derived concepts one has to investigate how the assumed errors propagate, and one cannot just impose normal distributions on derived concepts. But we do not do anything of this kind.

Details: Abstract and many places; The criticism that we do not worry about sampling errors is because Harrison does not understand that we can avoid assumptions about within-subject errors.

P. 1 footnote 1: We do use calculations within subjects, getting indexes and parameters of utility and so on, sometimes based on minimizing squared distances. These are mathematical calculations and recodings of data. We do not assume any probabilistic theory and, in return, not any statistical claim is associated with these within-subject calculations. The results of such calculations can be submitted to (between-subject) t-tests or Wilcoxon tests. Not any speculation on within-subject errors needs to be made for that. (Errors there will contribute to variance of the t-statistic, but this variance is handled properly.) Harrison confuses recodings of data with estimations-endowed-with-statistical-claims.

A didactical example to clarify the difference between calculation/recoding and statistical estimation: Imagine that one wants to investigate whether the relative density (weight per volume unit) of men is bigger than that of women. One measures the body weight and also body volume of every person in a representative sample. And then, one does mathematical calculation and recoding and not statistical estimation by calculating the ratio of weight per volume for every person. Then one uses a t-test to compare those ratios. Glenn's view is that this is wrong, that our ratio taking was a statistical estimation, that we have not specified the errors involved in this process, and so on. Will he want to forbid to ever use a t-test to test relative density? Maybe he adds a reference to the statistical principle that estimations should be based on more than two observations (our weight-per-volume was calculated using only two observations, weight and volume), and that doing it by only two observations is too unreliable? Would he then want to forbid worldwide that someone ever calculates relative densities of any human being? Anyway, he is just confusing general calculations/recodings with statistical estimations.

P. 4 2nd para: The random incentive system assumes isolation, which is one implication of independence (and a dynamic principle). Independence (+ dynamic) is sufficient, but not necessary, for validity of the random incentive system. Harrison misunderstands this point. Bardsley et al. (2010) explain the point well.

P. 4 footnote 6: This specification, rather than the main text, is required. Comparisons across different sources are not to be done directly through utility values (which are from different scales) but through certainty equivalents.

P. 6 & Table 1 do within-subject statistical tests for every subject. Unlike with us, errors within-subject-between-stimuli are assumed independent here. Our design was not made for this purpose, and the choices per subject are too few to get statistical conclusions this way. (Another problem is that statistical conclusions are inflated because the choices of one individual are not really independent according to my preferred views.) Table 1 indeed shows no statistical power. Harrison blames our design for it rather than his unfortunate test.

Pp. 6-7 criticizes the semi-parametric fitting introduced by Abdellaoui (who has a degree in economnetrics). The method first does parametric fitting to obtain a power utility function. Then, in the second stage, it uses that to estimate the things that interest us most: The event weighting functions. And the latter then is non-parametric. This two-stage way emphasizes that for the weighting function not any parametric assumption is made. For this reason, the first-stage estimates of w(0.5) are not used in the second stage (another thing criticized by Harrison on p. 7). In addition, Abdellaoui uses this method to stay close to techniques in decision analysis. The procedure here is within-subject, with not any probabilistic assumption or statistical conclusion made at that stage. Again Harrison confuses calculations with statistical estimations by criticizing our absence of statistical assumptions/conclusions. The whole rest of the paper is confusing calculations and estimations, and between- and within-subject errors. %}

Harrison, Glenn W. (2011) “The Rich Domain of Uncertainty: Comment,” working paper. Incorporated in

Harrison, Glenn W. (2019) “The Methodologies of Behavioral Econometrics.” *In*

Michiru Nagatsu and Attilia Ruzzene (eds.) *Philosophy and Interdisciplinary Social Science: A Dialogue*, 107–138, Bloomsbury, London.

{% Glenn expresses his characteristic opinions in his characteristic style:

"In general the book confounds scholarship with advocacy in a way that is now all too common in behavioral economics."

"I am tired of reading scholarly work in this vein, and feeling the need to constantly check the record against what is alleged."

That Glenn only knows econometric methods of doing statistics, and thinks that all else unknown to him must be wrong, appears for instance from the following text and its context:

"in general we need both theoretical and econometric assumptions to identify and estimate the latent construct"

Here is how he cites his "friend" Rabin (2000):

"The folk theorem on calibration of risk preferences for "small stakes," originally stated by Hansson (1988) and popularized by others" %}

Harrison, Glenn W. (2015) Book Review of: Daniel Friedman, Mark R. Isaac, James Duncan, & Sunder Shyam (2014) "Risky Curves: On the Empirical Failure of Expected Utility, Routlege, New York," *Journal of Economic Psychology* 48, 121–125.

{% Given that this paper criticizes Abdellaoui, Baillon, Placido, & Wakker (AER 2011), I read it from a defensive perspective. The paper is full with negative claims on behavioral economics, typical of Glenn. P. 108 writes: "Section 4.6 considers empirical evidence for the notion of "source dependence," the hypothesis that risk preferences depend on the source of risk, and shows why we must not confuse point estimates with data." This is on my aforementioned paper.

P. 108 last para ℓ. 2 has a remarkable confusion: "nominal (e.g., integer-valued)"

The paper throughout mostly gives self-references. For instance, p. 112, §4.2.1, writes: "There are now many published statements of the structural models of risk preferences underlying EUT and RDU models, starting with Harrison and Rutström (2008, §2)."

§4.3.1, on measuring time pref., is typical of the author. Andersen, Harrison, Lau, & Rutstrom (2008, Econometrica), Andersen et al. (2008) henceforth, proposed to measure discounting as follows: First estimate the utility function from RISKY choices assuming EU. Then use that function in the discounted utility (DU) model to estimate discounting. In my annotations to that paper I criticized all these steps. One of the many strange points: If measuring utility, why use risk preferences and not intertemporal preferences??? The present §4.3.1 repeats the approach of Andersen et al. (2008). But, very strangely, it assumes that this is the only way possible, and that there can be no other way. Here are sentences showing this frame of mind: "The idea of joint estimation, again, is that one jointly estimates preferences from one structural model in order to correctly identify and estimate preferences of another structural model. The need for joint estimation comes from theory." (p. 115)

"In many settings in experimental economics we want to elicit some preference from a set of choices that also depend on risk attitudes. An example due to Andersen et al. (2008) is the elicitation of individual discount rates. In this case it is the concavity of the utility function, U″, that is important, and under EUT that is synonymous with risk attitudes. Thus the risk aversion task is just a (convenient) vehicle to infer utility over deterministic outcomes. One methodological implication is that we *should* combine a risk elicitation task with a time preference elicitation task, and use them jointly to infer discount rates over utility." (p. 115; italics added here) It is puzzling why the author does not want to elicit utility directly from intertemporal preference, which can well be done also if discounting is only subjective. Another thing the author does now know is that one can estimate discount rates without knowing or assuming anything about utility, e.g. in Attema, Bleichrodt, Gao, Huang, & Wakker (2016 AER). Section 4.3.2, on estimating subjective probabilities, similarly claims that one has to measure utility for it. The author does not know that one can measure subjective probabilities without knowing or assuming anything about utility.

P. 120, §4.4, claims that one can use probability weighting for losses to capture loss aversion, not realizing that by normalization the total decision weight assignable to losses is always 1. Eq. 9.3.2 in Wakker (2010 p. 254) shows this point, with always total decision weight 1 for losses.

P. 122 cites an incorrect claim by Nilsson et al. (2008):

"It is likely that these results are caused by a peculiarity of CPT, that is, its ability to account for loss aversion in multiple ways. The most obvious way for CPT to account for loss aversion is by parameter λ (after all, the purpose of λ is to measure loss aversion). A second way, however, is to decrease the marginal utility at a faster pace for gains than for losses. This occurs when α is

smaller than β. Based on this reasoning, we hypothesized that the parameter estimation routines compensate for the underestimation of λ by assigning lower values to α than to β; in this way, CPT accounts for the existing loss aversion indirectly in a manner that we had not anticipated.”
Utility curvature cannot substitute for loss averion in general. Most one can say is that for particular sets of stimuli, limited and of particular kinds, utility curvature (and also probability weighting) can substitute for loss aversion only within that set.

§4.6, p. 127, aims to criticize Abdellaoui, Baillon, Placido, & Wakker (AER 2011). The title, “Point Estimates Are Not Data: A Case Study of Source Dependence” hints at what the author has in mind. The sentence:
“Unfortunately, their conclusions are an artefact of estimation procedures that do not worry about sampling errors.30 These procedures are now often used in behavioral economics”
also refers to it. I embarked on reading this paper hoping to get here a publically available text that I could then react to. Unfortunately and to my disappointment, the rest of the section does not give a justification of these criticisms, so that they are not available in public. The text refers to an online appendix that I could not find on the author’s website or elsewhere. But it will be what the working paper Harrison (2011) wrote, and what I criticize in my annotations to that working paper. %}

https://doi.org/10.1007/s10683-021-09738-3

{% **equate risk aversion with concave utility under nonEU**: They explicitly state, somewhere in the middle, that risk aversion, risk seeking, and so on, refers only to utility curvature, also under prospect theory. Confusing, because then we do not know how to refer to what is traditionally called risk aversion (preference of EV, involving both utility, probability weighting, and loss aversion)! Unfortunately, the paper, whereas mentioning original 1979 prospect theory, the separable-weighting generalization often used (though not really prospect theory), and the new 1992 version, but leaves it completely unspecified which of these versions is used in the analysis, for instance, by not giving the formula.

PT falsified: they confirm the violations of inverse S found by Humphrey, & Arjen Verschoor (2004).

They measure probability weighting but use the RIS, something strongly criticized by Harrison & Swarthout (2014). %}

Harrison, Glenn W., Steven J. Humphrey, & Arjen Verschoor (2010) "Choice under Uncertainty: Evidence from Ethiopia, India and Uganda," *Economic Journal* 120, 80–104.

{% **decreasing ARA/increasing RRA**: This is a comment on Holt & Laury (2002, American Economic Review) "Risk Aversion and Incentive Effects." It shows empirically that there is an order effect for the high-real payment treatment, which always followed after the low-real payment treatment. They did it now (for 10 times higher payments, not 20 times) both with and without the order effect, and without the order effect the increase in risk aversion versus the low-payment group was reduced by about a factor two. This order effect may be due to loss aversion (see my comments on the Holt & Laury paper). This study confirms the order effect empirically. On the positive side, it shows that half of the high-low-real-payment difference effect of Holt & Laury is not due to the order effect and is genuine.

Confirm Holt & Laury (2002) on the following: women more risk averse than men for low payment but not for high payment (**gender differences in risk attitudes**). %}

Harrison, Glenn W., Eric Johnson, Melayne M. McInnes, & E. Elisabet Rutström (2005) "Risk Aversion and Incentive Effects: Comment," *American Economic Review* 95, 897–901.

{% **decreasing ARA/increasing RRA**: find increasing RRA.

Point out that empirical studies of the common ratio effect etc. can gain power if conditioning on degree of risk aversion. The first pages mention that in existing studies there can always exist as yet unknown confounding factors, which of course holds for every statistical study. Also point out that subjects may be almost indifferent between al kinds of choices, so that these do not give much information, and estimating their risk aversion helps us detect such almost-indifferences.

They use questions similar as in Holt & Laury (American Economic Review 2002), estimate CRRA parameter from it, and use that as index of risk aversion to condition on. %}

{% This paper considers the Rabin (2000) paradox, but, unfortunately, has many weaknesses.

Rabin (2000) puts loss aversion forward as the main factor to explain his paradox in the last para of his main text (pp. 1288-1289). This involves reference dependence, the main ingredient of prospect theory, the theory sharing the 2002 Economics Nobel prize with its 1979 introductory paper the 2nd most cited in economics. Reference dependence indeed is the main factor explaining Rabin's paradox. Then how is it possible to write a paper on this topic while never even mentioning reference dependence or loss aversion? Yet this is what this paper does. It also does not cite Kahneman or Tversky.

Although the authors informally use terms utility of final wealth versus utility of income to refer to the aforementioned difference, they do not formalize it, so that they cannot analyze the case properly. Their writing w+x suggests that wealth goes into outcomes (changes-with-respect-to-reference-point) and leaves ambiguous the essence, where w should go into the reference point rather than into the outcome. They should have used a notation such as x_w, denoting the reference point w differently than the outcome x, so that the readers can know. They also do not make this difference explicit in their experiment. The experiment, thus, seems to test constant absolute risk aversion, finding decreasing absolute risk aversion. This has been found in dozens of studies before, and is generally assumed. See the keyword **decreasing ARA/increasing RRA** in this bibliography for many references. It is implied by the common parametrizations of prospect theory, with power utility.

There is another problem. Rabin did not claim that *all* choices are invariant under wealth changes. He only claimed it for the preference $110_{0.5}(-100) \prec 0$. The authors consider 28 different lottery pairs in their Table 1 (p. 27), and not Rabin's pair. So, they tested a different phenomenon and then for different stimuli. (And for a third problem: the largest wealth change is about $120, which is not enough to be very relevant.)

The animosity between experimental economists and behavioral economists that was strong until about 2010, and that is described by Svorenčíkj (2016), but still is very present in this paper, contributing to the confusions and non-objectivity in this paper. (**Prospect theory not cited**) This explains not only why Kahneman & Tversky are not cited, and why the 2017 Nobel prize winner Thaler is insulted in footnote 6, but also that, whenever Rabin is cited, one can recognize an implicit negative suggestion. Below, italics are always added by me, and the first two cases are debatable but fit the picture, and the last case (5) is clearest:

(1) P. 25 1st para: "Rabin (2000) … Although *primarily* used as an argument against EUT, it *is now well known* that this logic applies to a much wider range of models that assume the argument of the utility function to be terminal wealth (Cox and Sadiraj, 2006; Safra and Segal, 2008)."

Here it suggests that Rabin himself did not see the wider implication of terminal wealth being violated. Well, Rabin himself, in his conclusion, immediately *suggested that loss aversion (and, therefore, reference dependence) is the most likely cause, which violates terminal wealth.*

(2) P. 25 3rd & 4th para: "We refer to this claim as the HRC, for "*Hansson–Rabin calibration*," acknowledging Hansson (1988) and Rabin (2000). … using the simple example from Hansson (1988) since it is not widely known and illustrates the basic points. The generalization by Rabin (2000) *can then be quickly stated*."

Here it downplays Rabin's contribution by ascribing much to Hansson. Hansson, cited and credited by Rabin, had part of the idea being the calibration effect, but did not convey the wide implications. As an aside, Hansson's work was brought to Rabin's attention by Prelec (personal communication).

(3) P. 25, 2nd column, 2nd para: "Indeed, the *only* empirical example offered by Rabin (2000) uses a bounded CARA function."

Here it suggests that Rabin was weak on empirical evidence.

(4) Rabin (2000) draws the implication that P must then be false, and that one should employ models of decision-making under risk that relax proposition Q, such as Cumulative Prospect Theory. As a purely logical matter, of course, this is *just one way* to resolve this calibration puzzle.

Here it suggests that Rabin's conclusion is arbitrary.

(5) 2007). "Rabin and Thaler (2002, p.230) make exactly this mistake in misunderstanding the existing experimental literature:

"We refer any reader who believes in risk neutrality to pick up virtually any experimental test of risk attitudes. Dozens of laboratory experiments show that people are averse to far more favorable bets for smaller stakes. The idea that people are not risk neutral in playing for modest stakes is uncontroversial; indeed, nobody to our knowledge interprets the existing evidence as arguing that expected-value maximization (risk neutrality) is a good fit'.'

The authors here insult not only Rabin, but also the 2017 Nobel prize winner Thaler. There is nothing wrong with the content of the text by Rabin & Thaler, although I would have preferred a different style. The text by R&T is fully relevant to the issue at stake here, which escapes Harrison et al. because they are confused on the role of the reference point.

The paper overstates its (claimed) novelty of doing within-subject on p. 25 2nd para ("the absence of empirical tests is remarkable") and 1st para in §3 ("All of the evidence claimed to support the premiss that decision makers in experiments exhibit small stakes risk aversion for a large enough finite interval comes from designs in which subjects come to the lab with varying levels of wealth and are faced with small-stakes lotteries.") because Cox et al. (2013) tested within-subject variations before. The authors only cite Cox et al. for this in a footnote, Footnote 2 on p. 25. (Comes to it what I wrote before, that the authors are doing a within subject test of constant absolute risk aversion which has been done in dozens of papers before. But this is a matter of confusion, rather than deliberately ignoring preceding work.)

As do most papers on individual choice today, the authors use the Random incentive system (RIS), called RLIM by them, to implement real incentives. This is even though the first author, Harrison, has tried to criticize RIS on many occasions by erroneously claiming that it is valid only under expected utility (e.g., Harrison & Swarthout 2014, abstract). Footnote 9 gives a supposed justification. First follows the justification there that motivates everyone. But then, to be consistent with the EU claim made elsewhere, the footnote writes a weak claim: "The second reason was that the null hypothesis being tested is normally stated assuming EUT [expected utility, which I abbreviate EU], and RLIM is valid under EUT." This claim is weak because many studies have shown that expected utility is empirically violated. The stated null hypothesis can immediately be rejected based on an ocean of literature, making further tests redundant!

P. 27 ℓ. −5: for higher levels of wealth, the authors seem to find a tendency for risk seeking (they do not state statistical level), deviating from the common findings of weak aversion. %}

Harrison, Glenn W., Morten I. Lau, Don Ross, & J. Todd Swarthout (2017) "Small Stakes Risk Aversion in the Laboratory: A Reconsideration," *Economics Letters* 160, 24–28.

{% **random incentive system between-subjects** (paying only some subjects): Footnote 16 reports a little side experiment to test the random incentive system by, in one treatment, of each subject one choice was paid, and in the other treatment for each subject at the end the payment was done with probability only 1:10. They found no significant difference of RRA coefficient.

decreasing ARA/increasing RRA: find bit of increasing RRA but close to constant;

253 people from general population, and real incentives; relate to demographic variables; mean power of utility found is 0.36 (= 1 − RRA coefficient). They only

do EU data fitting, and no nonEU.

The Appendix discusses Rabin's calibration argument. The authors correctly cite Rabin's text pointing out that loss aversion is the main explanation and also correctly equate this with what experimental economists call utility of income. That Cox & Sadiraj and Rubinstein then have nothing to add anymore, is not stated clearly but is left ambiguously.

gender differences in risk attitudes: no difference %}

{% One point is that if you randomize subjects then by coincidence one group may have more risk averse subject than the other, which can be prevented by measuring the risk attitudes of the subjects. %}

Harrison, Glenn W., Morten I. Lau, & E. Elisabet Rutström (2009) "Risk Attitudes, Randomization to Treatment, and Self-Selection into Experiments," *Journal of Economic Behavior and Organization* 70, 498–507.

{% Although the paper

Harrison, Lau, & Rutström (2007) "Estimating Risk Attitudes in Denmark: A Field Experiment," *Scandinavian Journal of Economics* 109, 341–368

has been criticized for using the term field experiment for nothing other than that the sample were no students, this paper continues to use the term (smoking is not enough of being a field activity, and is more of a demographic variable).

They use the same data set as Harrison, Lau, & Rutström (2007), and the same estimation of discounting (taking as intertemporal utility the risky utility estimated from risky decisions assuming EU), but now add relations with smoking. I hoped that §2, entitled "Identifying risk and time preferences" would discuss the identification of one with the other, but it did not. Instead, the title refers to just identifying each without looking at the relation between them.

Male smokers discounter more than male nonsmokers. No difference with women. If I understand right, they find no relation between smoking and time inconsistency (parameter of hyperbolic discounting). %}

Harrison, Glenn W., Morten I. Lau, & E. Elisabet Rutström (2010) "Individual Discount Rates and Smoking: Evidence from a Field Experiment in Denmark," *Journal of Health Economics* 29, 708–717.

{% **Prospect theory not cited** (p. 28): "We employ a simple experimental measure for risk aversion called a multiple price list (MPL) developed by Holt and Laury (2002)."

Measure risk attitudes of individuals over own risks, and over risks for others. Is done by usual choice list and assuming EU, as in Holt & Laury (2002). Find no difference if risk attitudes of others are unknown, but more risk aversion for choices concerning others if the risk attitudes of others are known. %}

Harrison, Glenn W., Morten I. Lau, E. Elisabet Rutström, & Marcela Tarazona-Gómez (2012) "Preferences over Social Risk," *Oxford Economic Papers* 65, 25–46.

https://doi.org/10.1093/oep/gps021

{% **real incentives/hypothetical choice, for time preferences**: Use real payments, for discounting of 6 months or … or some three years. Find average discount rate of 28%. Discusses censoring effect, that for too low interest subjects may refuse because the market gives it better, i.e., subjects may arbitrage between experiment and market. Cite a Coller & Williams (1989) paper for this point.

The only text to explain how the future (could be 3 years later) payments were implemented is on p. 1610 near end.

random incentive system between-subjects (paying only some subjects) was used. The authors write:

> Subjects were then told that a single payment option would be chosen at random for payment, and that a single subject would be chosen at random to be paid his preferred payment option for the chosen payoff alternative. The payment mechanism was explained as follows:
>
> > HOW WILL THE ASSIGNEE BE PAID?
> > The Assignee will receive a certificate which is redeemable under the conditions dictated by his or her chosen payment option under the selected payoff alternative.

This certificate is guaranteed by the Social Research Institute. The Social Research Institute will automatically redeem the certificate for a Social Research Institute check, which the Assignee will receive given his or her chosen payment option under the selected payoff alternative. Please note that all payments are subject to income tax, and information on all payments to participants will be given to the tax authorities by the Social Research Institute.

Pp. 1612-1613 acknowledges the point that the subjects may not trust the implementation of the real incentives and may, therefore, discount extra. P. 1613 points out that experiments with hypothetical choices typically find discount rates of even more than the 28% as found here. %}

Harrison, Glenn W., Morten I. Lau, & Melonie B. Williams (2002) "Estimating Individual Discount Rates in Denmark: A Field Experiment," *American Economic Review* 92, 1606–1617.

{% §2.1, p. 1012, gives six criteria for when a study can be considered a field experiment:

The nature of the subject pool;
the nature of the information that the subjects bring to the task;
the nature of the commodity;
the nature of the task or trading rules applied;
the nature of the stakes;
the nature of the environment that the subject operates in.

P. 1027:

"by some arbitrator from hell."

P. 1028 has nice discussion "Context is not a dirty word." About whether choice alternatives should be abstract, or have a concrete context. Is related to my lesson to learn when teaching to medical students: When I tried to attach real diseases etc. to branches in decision trees, the students would start discussing the diseases and not the decision-theoretic risk-tradeoffs. So, I learned to use abstract diseases (disease 1, 2, …, etc.) to designate the branches.

Bardsley et al. (2010 §5.7) properly criticize pp. 1027-1028.

P. 1031, in reply to the criticism of real incentives that they are too small, makes the common mistake of many experimental economists to put forward Holt & Laury (2002) as counterargument. For any practical purpose, the amounts in Holt & Laury (2002) of some hundreds of dollars are SMALL! No one would do a decision analysis for such stakes. Below three months of salary, utility should be linear and nothing going on.

§10 signals a difference of opinion between the two authors, with List (and I) not agreeing with Harrison's qualifying his studies with general population (in Denmark) instead of students, and completely artificial otherwise, as field studies. %}

Harrison, Glenn W. & John A. List (2004) "Field Experiments," *Journal of Economic Literature* 42, 1009–1055.

{% Much of the paper, such as the first half of the abstract, is a general discussion of the pros and cons of a controlled laboratory experiment versus less internally valid but more externally valid field data, a general topic extensively discussed in psychological textbooks and elsewhere.

Do not do experiment with students in lab, but in a major coin show in Orlando with attendants of that show who could participate voluntarily receiving $5 participation fee + performance-contingent payment, serving as an intermediate step between laboratory experiments and real field situations. They consider monetary prizes, and prizes in terms of special coins that have extra uncertainty regarding their value. The finding of this paper is that there is more risk aversion for the second outcomes than for the first. The authors discuss this finding in detail.

They also discuss background risk in detail, in particular that it cannot be ignored. Their study, however, takes background risk in the narrow sense concerning only the extra uncertainty of the special coins and not in the grand sense of all risks that we are facing regarding our investments etc., so that they are overclaiming.

In footnote 3 on p. 434 they argue that regarding the Rabin (2000) paper, they side with the Cox & Sadiraj (2006) and Rubinstein (2002) criticisms (that I strongly disagree with).

SPT instead of OPT: unfortunately, they do not use the correct formula (for x > y > 0)

$$x_py \dashrightarrow w(p)U(x) + (1-w(p))U(y)$$

which is the correct one not only for the 1992 updated ("cumulative") prospect theory BUT ALSO for the original 1979-prospect theory (Kahneman & Tversky 1979, p. 276 Eq. 2). Instead, they make the well-known mistake of using the formula x_py --> w(p)U(x) + w(1-p)U(y), which is separable prospect theory. See their footnote 23 on p. 448 where they apparently think that the correct formula only applies to the new cumulative version, and p. 451 below Eq. 7.

equate risk aversion with concave utility under nonEU: P. 455 makes the same mistake as do so many economists of equating risk attitude with utility curvature if the working hypothesis is not EU but is a nonEU model, prospect theory in this case. When on p. 455 the authors report the results of prospect theory (taking the Tversky & Kahneman 1992 parametric families), they discuss dependence of the (power-) utility parameter in detail, but of the probability weighting parameter they only report the average value of 0.83.

They test power utility $U(x) = x^r/r$ but also the translated power utility $U(x) = (x+w)^r/r$ with w an extra parameter, but find only small values of w (p. 455) (they have no loss outcomes).

Footnote 31, p. 456, shows how far the authors got carried away in their interpretation that their coins with extra risk represent everything relevant in life outside the lab, including every possible background risk, because they apparently feel it necessary to negate this suggestion and explain that for instance for health outcomes things may be different than for their special coins …

P. 456 illustrates again how the authors got carried away with their mission: "Indeed, in transferring the insights gained in the laboratory with student subjects to the field, a *necessary* first step is to explore how market professionals behave in strategically similar situations." [italics added here].

They measure probability weighting but use the RIS, something strongly criticized by Harrison & Swarthout (2014). %}

{% **random incentive system**: uses it but, to my regret, pays three choices to each subject (p. 138 beginning of §2) so that the main purpose of the system, avoiding income effects, is not served.

Fits mixture model to data, where the mixture is of PT (in fact SPT as explained below; I from now on write SPT) and EU. EU and SPT are not nested because another utility function is taken for EU ($(s+x)^r$ with x the lottery payment and s the prior endowment (**losses from prior endowment mechanism**) at the beginning of the experiment) than for SPT (x^r for gains and $x^{r'}$ for losses). P. 137 has nice history of mixture models in other fields. They measure probability weighting but use the RIS, something strongly criticized by Harrison & Swarthout (2014).

Because the statistical techniques of the authors, apparently, can only handle preference data they, strangely enough, do not use indifferences in their data, even though indifferences are more informative than preferences (p. 139 end of §2 ("indifferences .. to simplify we drop those", with footnote 14 there: "For the specification of likelihoods of strictly binary responses, such observations add no information.") If the technique cannot draw info from indifference, then this is a problem of the technique!

Unfortunately, what this paper calls prospect theory is not prospect theory, neither in the new (1992) version nor in the original (1979) version. The paper writes, incorrectly (p. 140) (**SPT instead of OPT**):

"There are two variants of prospect theory, depending on the manner in which the probability weighting function is combined with utilities. The original version proposed by Kahneman & Tversky (1979) posits some weighting function which is separable in outcomes, and has been usefully termed Separable Prospect Theory (SPT) by Camerer & Ho [1994, p. 185]. …"

True, that 1979 OPT cannot be used for more than two nonzero outcomes. However, the separable Edwards-type version used here, as used by Camerer & Ho (1994), does not work at all for three and more outcomes, leading to great over- and underweightings and violations of highly unrealistic stochastic dominance. All the more reason to turn to the new 92 version of prospect theory!

They suggest that 60 choice questions is about the maximum that can be asked in one experiment.

The mixture model is WITHIN each subject and within each choice. That is, there is a mixture probability π. Consider a single subject. We specify both an EU model and an SPT model for this one subject (specify means choosing a utility function, probability weighting function, and loss aversion parameter, as the case may be). For each choice, there is a probability π such that the subject does EU with probability π and SPT with probability $1 - \pi$. All choices within the subject are independent here. (Later an error theory will be added where the errors for different choices of one subject are related, so that within a subject in that sense there is no complete independence, but this only concerns the choice error and not the theory choice.) Thus the subject is not described by one model, but has a dual self. It is a bit like quantum mechanics, where properties such as location of a particle may be a probability distribution over the locations that in no way can be pinned down deterministically. Conte, Hey, & Moffat (2007) consider a between-subject mixture where a subject with probability π is EU and then does EU for all choices, and with probability $1-\pi$ is SPT and then does SPT for all choices.

I would actually interpret the approach of this paper as representative agent because the same mixture model with parameters will be fit to each subject. It is indeed not one fixed model for all subjects the same, but it is a mixture of two models for all subjects the same.

The authors find that a mix of EU and SPT works well and, hence, the funeral is for the representative agent. Can reinterpret it as a resurrection of the representative agent, where we only need two of them.

If they fit SPT with T&K'92 parameters and with representative agent, then they find loss aversion of about 1.38. If they do a mix model with about half EU and about half the subjects SPT, then for the SPT subjects a loss aversion parameter of 5.78 results. A problem then is that power for losses is different than for gains, so that loss aversion is not well defined. Probability weighting has parameter $\gamma = 0.91$ if not as mixture model.

Intro p. 136 writes that primary methodological contribution is … co-existenc of EUT and SPT …, but §1 describes many applications of mixture models used before in the literature, also in decision under risk (Wang & Fischbeck 2004). Such speaking with two tongues happens in many papers co-authored by Glenn Harrison. So, he can claim things but if criticized can say "look I already wrote this myself on p. …." %}

Harrison, Glenn W. & E. Elisabet Rutström (2009) "Expected Utility Theory and Prospect Theory: One Wedding and a Decent Funeral," *Experimental Economics* 12, 133–158.

{% **backward induction/normal form, descriptive**; **random incentive system**

The paper essentially redoes the test of Starmer & Sugden (1991 American Economic Review) for probability weighting, but, unlike S&S, finds differences. It is written in a misleading manner. First it claims that RIS (the authors call it RLIM) needs EU and that, therefore, all researchers using RIS to investigate probability weighting or other violations of EU are completely wrong (bipolar), for instance in the abstract. But later it points out that RIS can also be justified without EU. Even, in the 3rd para of p. 436, they state that they will continue to use RIS themselves (as do all others in the field, in the absence of a better alternative), which they indeed do in all their other papers. Here is a detailed account:

The authors (H&S henceforth) criticize researchers who estimate deviations from expected utility (EU) but still use the RIS. This would be a valid criticism if those researchers were to defend RIS by assuming EU. Such people could be called bipolar, as proposed by this paper. But this does not happen. Researchers justify RIS assuming something often called isolation. H&S mention this, and counter that violations of a general isolation exist. But the point is, the researchers need not assume general isolation, but only for their particular stimuli, presented in ways that minimize the risk of violations of isolation. This is in fact what H&S do themselves. In the following text, take the first independence condition as just general independence giving EU, and the second as only isolation for the particular stimuli and presentation of the experiment considered. Then H&S write, on p. 436 3rd para:

"A final implication is to just be honest when presenting experimental findings on RDU and CPT models about the assumed neutrality of the experimental payment protocol. In effect this is just saying that there might be two independence axioms at work: one for the evaluation of a given lottery in a binary choice setting, and another one for an evaluation of sets of choices in 1-in-K settings. If one estimates RDU and CPT models with a 1-in-K protocol one might claim to be allowing the first axiom to be relaxed while maintaining the second. It is logically possible for the latter axiom to be empirically false while the former axiom is empirically true. In the absence of better alternatives, we do this in our own ongoing research using 1-in-K protocols."

Another good reason for using RIS, despite any problem it has, is that other mechanisms only have bigger problems. H&S in some places suggest to let each subject make only one single choice, but properly mention the drawbacks: (1) it is very expensive, (2) it gives too little info within any individual, so that one can only make inferences about group averages, and (3) the revealed data may in fact be of low quality because subjects should learn stimuli before revealing their true preferences. H&S (p. 435) also suggest alternative procedures by Cox et al. (2011), now appeared as Cox, Sadiraj, & Schmidt (2015 EE), which concern for instance paying all choices or the average over all choices. I add here that those procedures have obvious problems. In the second, subjects know beforehand that they get about the average payoff, and that whatever choice they do affects their payoff very little.

To check out that the first author himself invariably uses the RIS, also when measuring probability weighting (I had to do this for another purpose), I typed the search words

Glenn Harrison probability weighting

into google scholar on 8 March 2018 and then checked out the five most cited references:

Harrison, Glenn W. & E. Elisabet Rutström (2009) "Expected Utility Theory and

Prospect Theory: One Wedding and a Decent Funeral," *Experimental Economics* 12, 133–158.

P. 138: "After all 60 lottery pairs were evaluated, three were selected at random for payment." [small variation of RIS] Figure 6 last panel reports results on probability weighting.

Harrison, Glenn W., John A. List, & Charles Towe (2007) "Naturally Occurring Preferences and Exogenous Laboratory Experiments: A Case Study of Risk Aversion," *Econometrica* 75, 433–458.

P. 439: "The subject chooses A or B in each row, and one row is later selected at random for payout for that subject." P. 455: "The probability weighting parameter γ is estimated to be 0.83"

*Harrison, Glenn W., Steven J. Humphrey, & Arjen Verschoor (2010) "Choice under Uncertainty: Evidence from Ethiopia, India and Uganda," *Economic Journal* 120, 80–104.

"*At the end of the experiment one of the eight tasks was selected at random for each subject and the lottery chosen in that task was played-out for real money.*" Figure 2, P. 90, reports results on probability weighting.

Andersen, Steffen, John Fountain, Glenn W. Harrison, & E. Elisabet Rutström (2014a) "Estimating Subjective Probabilities," *Journal of Risk and Uncertainty* 48, 207–229.

P. 213: "One choice was selected to be paid out at random after all choices had been entered." P. 219 Figure 3 reports results on probability weighting.

Andersen, Steffen, Glenn W. Harrison, Morten I. Lau, & E. Elisabet Rutström (2014b) "Discounting Behavior: A Reconsideration," *European Economic Review* 71, 15–33.

P. 21: "There were 40 discounting choices and 40 risk attitude choices, and each subject had a 10% chance of being paid for one choice on each block." [small variation of RIS] P. 24:

"*We model lottery choices behavior using a Rank-Dependent Utility (RDU) model, since all choices were in the gain frame, and find evidence of probability weighting*"

I also checked out a recent (at this moment of writing, 8 March 2018) study co-authored by the first author:

Andersen, Steffen, James C. Cox, Glenn W. Harrison, Morten I. Lau, E. Elisabet Rutström, & Vjollca Sadiraj (2018) "Asset Integration and Attitudes toward Risk: Theory and Evidence," *Review of Economics and Statistics* 100, 816–830.

A footnote writes: "For each type of decision task the subjects had a 10% chance of getting paid. If they were paid in the part of the experiment analyzed, one of the 60 decision tasks was randomly selected and the chosen lottery was played out for payment."

The conclusion writes:

"we find evidence of modest probability weighting"

Weird is that in the beginning the authors do not acknowledge ways to reconcile RIS with violations of EU, as properly written in many places later in their paper, but misleadingly write the opposite, overly eager to score their point on claimed bipolarity. Here is the beginning of their abstract:

"If someone claims that individuals behave as if they *violate* the independence axiom (IA) when making decisions over simple lotteries, it is **invariably** on the basis of experiments and theories that **must** *assume* the IA through the use of the random lottery incentive mechanism (RLIM). We refer to someone who holds this view as a Bipolar Behaviorist, exhibiting pessimism about the axiom when it comes to characterizing how individuals directly evaluate two lotteries in a binary choice task, but optimism about the axiom when it comes to characterizing how individuals evaluate multiple lotteries that make up the incentive structure for a multiple-task experiment." [italics from original; bold added]

This text directly contradicts the 3rd para on p. 436, where they write that they themselves will continue to use the RLIM. Therefore, the term bipolar applies to the authors themselves. The authors were so eager to write negative ("bipolar") about others that they allowed themselves this inconsistency. %}

Harrison, Glenn W. & J. Todd Swarthout (2014) "Experimental Payment Protocols and the Bipolar Behaviorist," *Theory and Decision* 77, 423–438.

{% Subjects usually prefer new medical treatments over existing ones. But, if they are pointed out that the new treatment comprises more ambiguity about downsides, then this preference disappears. %}

Harrison, Mark, Carlo A. Marra, & Nick Bansback (2017) "Preferences for 'New' Treatments Diminish in the Face of Ambiguity," *Health Economics* 26, 743–752.

{% **discounting normative**: Argues that discounting is irrational. Unfortunately, the author uses complete discounting, where the future is completely ignored, as a straw man and most of his paper only argues against that. As usual with philosophical writings, clarification and abbreviation could have been obtained by formal notation. The author points out (e.g. p. 47) that discounting often does not result from time per se but from other factors such as uncertainty. Compares discounting of the future with discounting of the past. Direct "psychological" utility with utility derived from future consequences, even if after one's death. P.

56, next-to-last paragraph, brings up a good argument, which is that "reason" (something like normative appropriateness) should be irrespective of time. This argument amounts to **dynamic consistency** (forgone-branch independence), the optimal decision should not depend on the timepoint of decision. %}

Harrison, Ross (1981-1982) "Discounting the Future," *Proceedings of the Aristotelian Society* 82, 45–57.

{% **cancellation axioms**: the authors show that in absence of completeness, the weakest version of cancellation is really weaker than some other versions. %}

Harrison-Trainor, Matthew, Wesley H. Holliday, & Thomas F. Icard III (2016) "A Note on Cancellation Axioms for Comparative Probability," *Theory and Decision* 80, 159–166.

{% **discounting normative**: seems to argue so. %}

Harrod, Roy F. (1948) "*Towards a Dynamic Economics: Some Recent Developments of Economic Theory and Their Application to Policy*." MacMillan, London.

{% Uses the veil of ignorance, mentioned before by Vickrey (1945, p. 329). The term veil of ignorance seems to have been introduced only later, by Rawls. People should accept a social arrangement independently of the position they will have in it. Everyone should be able to imagine that the positions will be exchanged one day. Thus, it should be guided by a probability distribution over these positions. From this Harsanyi derives that welfare- cardinal utility is equal to risky cardinal utility.

risky utility u = strength of preference v (or other riskless cardinal utility, often called value): Harsanyi derives that from his result. %}

Harsanyi, John C. (1953) "Cardinal Utility in Welfare Economics and in the Theory of Risk-Taking," *Journal of Political Economy* 61, 434–435.

{% Individual utility of a social state is consequentialistic in the sense that it can depend on the commodity bundles of the other individuals, equity in the social state, etc. The latter is described as "owing to external economies and diseconomies" (e.g. p. 311 Footnote 5).

P. 311 footnote 5: "the utility enjoyed by each individual will, in general, depend not only on his own income but also, owing to external economies and diseconomies of onsumption, on other people's incomes." This can be taken as defense against ignoring inequality considerations: They should be incorporated into utility. But the drawback is that then utility becomes too general, to the extent of being useless. P. 312 $\ell\ell$. 11-14 reiterates this point, as does the last para of the 1st column.

P. 313 ℓ. 2/3 of first column claims that EU is normative.

P. 315: the individual utilities to be aggregated should be the subjective ones, not the ethical ones.

P. 316: veil of ignorance has equal chances to end up in each position.

P. 317 suggests the term "principle of unwarranted differentiation": If you have observed everything of two individuals that you can think of, and it was all identical, then you can assume that they have the same level of utility. A nice term!

A nice paradox that I like to give to Ph.D. students: Let X be the set of social states, U_i : X --> Re the utility of individual i, n the number of individuals, and W : X --> Re the utility of society. Harsanyi only assumes expected utility for individuals and society (postulates A and B), and Pareto (postulate C); i.e., society is indifferent between two prospects over social states if all individuals are indifferent. How is it possible that this rules out equity considerations, and generates utilitarianism $W(x) = a_1U_1(x) + \ldots + a_nU_n(x)$? Pareto is completely harmless and self-evident, and so are the expected utility assumptions. Harsanyi's paradox! Assume richness; i.e., for every n-tuple of individual utilities, a social state exists that generates this n-tuple.

After a while, I add a hint: Assume the above three postulates, and $W(x) = U_1(x) + \ldots + U_n(x) + U_j(x)$ where j is the individual with lowest utility, $U_j(x) \le U_i(x)$ for all i. W comprises some equity and clearly is not utilitarian, violating joint independence (for $n = 3$ and coordinates utilities, $(1,3,0) \sim (2,2,0)$ but $(1,3,4) \prec (2,2,4)$). Which axiom of Harsanyi is violated??

Answer: Pareto is violated. For $n = 2$, social states denoted as pairs of individual utilities, 0.5 a probability, and prospects written between [], the prospect $(1,1)_{0.5}(0,0)$ is strictly preferred to the prospect $(1,0)_{0.5}(0,1)$ by society, but both individuals are indifferent.

Pareto is strong. It implies that for society the evaluation of a prospect over n-tuples of individual utilities depends only on the marginal distributions and not on correlations etc., which is Fishburn's (1965) additive independence condition. This implies additive decomposibility of W and rules out equity considerations. It also follows that Anscombe & Aumann (1963) is a corollary of Harsanyi (1955).

All these classical theorems are corollaries of a mathematical result, stated as follows by Wakker (1992, Economic Theory): "A linear function is a function of linear functions if and only if the linear function is a linear function of the linear functions."

Harsanyi is a bit sloppy on the domain assumed. Domotor (1979) corrects it. %}

Harsanyi, John C. (1955) "Cardinal Welfare, Individualistic Ethics, and Interpersonal Comparisons of Utility," *Journal of Political Economy* 63, 309–321. https://doi.org/10.1086/257678

{% This work has often been praised, and was a big reason for Harsanyi's Nobel prize in 1994. I never thought much of it. Randomizing something by bringing in an underlying probability space is completely routine for everyone with a training in probability theory. It is not a big move. Then, Harsanyi did something what I even qualify as a mathematical mistake: He has circularity in the definition of types. Types should specify probability distributions over types. Mertens & Zamir (1985) were the first to provide a sound mathematical model, with infinite hierarchies of beliefs, but their paper is almost impossible to read. Several other authors later wrote more accessible papers. Zamir (personal communication) once defended Harsanyi when I criticized him: "Harsanyi made the right mistakes." %}

{% This paper axiomatizes α maxmin EU in the Anscombe-Aumann framework for α ≠ 0.5. Not exactly that. More precisely, for an α given beforehand, it axiomatizes the model given that α. The two new axioms that modify the Gilboa-Schmeidler axioms consider α mixtures of pairs of complementary acts. Two acts are complementary if they provide perfect hedges against each other. That is, in utility units, one is minus the other plus a constant.

The paper can identify the αs in the sense that for each α it can verify whether

the α maxmin model holds for that α. And α and the set of priors can be identified if the other of the two is specified. But there can be several αs and sets of priors that represent the preference relation.

A useful reference is Shiri (2022), with an appealing axiomatization of maxmin EU. %}

{% The authors assume the Anscombe-Aumann (AA) framework for decision under uncertainty with simple acts, and consider *obvious dominance*, a condition that I have known under the name internality: $f_* \preccurlyeq f \preccurlyeq f^*$ where f_* is the worst outcome of the act and f^* the best. Assuming a utility function u on consequences, some continuity as in AA, and V(f) the utility of f's certainty equivalent so that V represents preference, we have $V(f) = \alpha(f)u(f^*) + (1-\alpha(f))u(f_*)$ for some $0 \le \alpha(f) \le 1$, for all f. We can nicely organize preference conditions in terms of α(f), and this is what the authors do for expected utility, Choquet expected utility, and the latter with convex or neo-additive weighting functions, biseparable utility, and monotonicity. %}

Harvey, Charles M. & Lars-Peter Østerdal (2010) "Cardinal Scales for Health Evaluation," *Decision Analysis* 7, 256–281.

{% The authors axiomatize discounted utility where the discount function can be general and need not be constant, for continuous outcome streams over a time interval that can be bounded or unbounded, which is useful to have available. It amounts to a special case of Savage's subjective expected utility, with the time interval as state space.

Techniques of Wakker (1993), who like this paper assumes continuous utility, can be used to get countable additivity (his Proposition 4.4), absolute continuity w.r.t. the Lebesgue measure (every Lebesgue null set of timepoints should be preferentially null and then Radon-Nikodym; this is an easy solution to the open question that the authors state at the end of the first column of p. 286), and only outcome streams with finitely many discontinuities (take algebra of finite unions of intervals and simple functions there, next extend by truncation continuity).

The authors use an alternative route, more directly targeted towards their objective. Note that, as the authors indicate, Kopylov (2010) is the first to have characterized the important special case of constant discounting. The authors use the usual Debreu-Gorman type separability to get general additive decomposability, and then a midpoint axiom to get proportionality (their Condition (E) on p. 287 which can also be done by bisymmetry or tradeoff consistency).

The only real mathematical difference between general (nonconstant) discounted utility and subjective expected utility is that in the former case the total measure of the time space need not be finite (if impatience does not decrease much), whereas under subjective expected utility it always is finite. This complication is delt with in §6.

P.s.: on a personal side, I am happy to see that Harvey, many years after retirement, and after his many solid contributions to intertemporal choice including for instance his valuable and underappreciated Harvey (1990

Management Science), together with his younger co-author who encouraged him, made this work see the light of day. %}

They propose as index of fear the Pratt-Arrow index of w, which they define for general p but apparently only want to use near p = 1. Indexes of hope and aspiration are also proposed. Numerical illustrations and applications to portfolio optimization are given. %}

He, Xue Dong & Xun Yu Zhou (2016) “Hope, Fear, and Aspirations,” *Mathematical Finance* 26, 3–50.

{% **event/outcome driven ambiguity model: outcome driven**

Considers a two-stage model, called TSE, with backward induction, which is a case of recursive expected utility. An equivalent formulation, actually used here, is a one-stage model with separable events, partitioning the universal event, upon which one can condition. Then one can take them as endogenous endowed with a “there exists” quantifier, a way in which exogenous concepts can always be endogenized. Therefore, I consider the model of this paper to be a case of recursive expected utility.

Say, C_1, …, C_n is a partition of the universal event with separable events. Because the terms “first-order” vs. “second-order” are ambiguous in the literature, I call the C_j events conditioning events. Whereas in the Anscombe-Aumann framework, most commonly used in the literature, the C_j are ambiguous and their subevents are risky, this paper does it the other way around, and has the conditioning events risky. Thus, it is not a horse-lottery, but a lottery-horse, or, as Machina once said, jokingly, the Aumann-Anscombe framework. Jaffray (personal communication) argued in favor of it because the separability required for the conditioning events is more convincing for risky events than for uncertain events. The author nicely cites Jaffray’s view.

Acts depending only on the C_js are called *risky*. The author assumes SEU both for risky acts and acts conditional on every C_j, where the utility functions of the conditional SEU models can depend on C_j. Conditional on each C_j there is ambiguity. Axiomatizations can readily by devised, but are not given in the paper and only in the online appendix. I usually do not read those and they cannot serve to get credit (or to provide proofs of theorems). For a good view on this point, see Spiegler (2023). I could imagine that the events C_j could be taken as risky if they were given beforehand, so were exogenous, with probabilities known. But the author emphasizes the opposite, that they are endogenous. Then why they would be taken as risk I do not understand.

The uncertainty conditional on every Cj is taken as a separate source by the author. Thus, a source partitions only a subset of the universal event. Such a concept of source appeared also in Chew & Sagi (2008). In He's paper, different sources even concern disjoint events. This is different in papers by Tversky and papers by me. There, a source always spans the whole universal event. Different sources can be different algebras of events.

The author does not give experimental evidence, or a preference foundation, in the main text, but discusses many economic applications. Proposition 3 presents an implication that Gul & Pesendorfer's (2014; GP14) expected uncertain utility theory would be a special case of his TSE theory, but it is not clear to me to what extent this is rather for a generalization of his theory with maybe something like hedge-dependent probabilities added. The more so as, conditional on each C_j, GP14 deviate from EU, and the model of the author does not.

The author spends most of the paper on elaborating on economic applications. %}

He, Ying (2021) "Revisiting Ellsberg and Machina's Paradoxes: A Two-stage Evaluation Model under Ambiguity," *Management Science* 67, 6934–6945. https://doi.org/10.1287/mnsc.2020.3835

{% This paper considers a variation of the smooth ambiguity model, or recursive expected utility (EU), with a difference being that the ambiguous events come at the end and not at the beginning. It continues on He (2021 *Management Science*), and in my annotations there I argue in favor of this approach. It gives a dynamic extension to multi-periods. The paper axiomatizes its model. At every intermediate period, agents only have to determine the current probabilities of reaching the first-next node, and not yet of reaching nodes farther in the future. At every intermediate node, there is another two-stage recursive EU model with node-dependent risky events. %}

He, Ying (2024) "Recursive Two-Stage Evaluation Model for Dynamic Decision Making under Ambiguity," *Journal of Mathematical Economics* 113, 103022. https://doi.org/10.1016/j.jmateco.2024.103022

{% **ambiguity seeking**: football & politics study reveals ambiguity seeking.

PT: data on probability weighting;

This paper was the first to introduce the basic ideas of source dependence (a term not yet used in this paper) into ambiguity. It is great to see these valuable ideas expressed. Unfortunately, the experiments are not good, having too many confounds, and not being incentive compatible. Tversky & Kahneman (1992) mention the concept source and do use the term, but do not elaborate much on it. Hence, I usually cite Tversky & Fox (1995) for it. This 1991 paper still keeps things narrow by having source dependence driven by competence. There can be many other factors. Tversky & Fox (1995) also quite narrowly focus on the competence effect.

P. 6 $\ell\ell$. 6-7: point out that ambiguity had better be called vagueness.

P. 6: Cites Raiffa (1961) affirmatively on the irrationality of ambiguity: "Several authors, notably Ellsberg (1963), maintain that aversion to ambiguity can be justified on normative grounds, although Raiffa (1961) has shown that it leads to incoherence." It suggests that Tversky considered expected utility to be rational. One can discuss Raiffa's arguments, primarily because it implicitly assumes dynamic decision principles à la Hammond (1988) that are known to imply EU, and that are questioned by nonEUers (not by me Bayesian).

P. 6 penultimate para: "Ellsberg's example, and most of the subsequent experimental research on the response to ambiguity or vagueness, were confined to chance processes, such as drawing a ball from a box, or problems in which the decision maker is provided with a probability estimate. The potential significance of ambiguity, however, stems from its relevance to the evaluation of evidence in the real world. Is ambiguity aversion limited to games of chance and stated probabilities, or does it hold for judgmental probabilities? We found no answer to this question in the literature, but there is evidence that casts some doubt on the generality of ambiguity aversion." (**natural sources of ambiguity**) The next para cites studies casting doubts on ambiguity aversion. The authors use the term chance event for what I often call artificial ambiguity, and judgmental problems involving epistemic uncertainty for (a subset of?) what I often call natural ambiguity.

P. 7 has argued, narrowly, that ambiguity attitude is driven by competence. Then: "We assume that our feeling of competence[1] in a given context is determined by what we know to what can be known. … There are both cognitive and motivational explanations for the competence hypothesis." The text then explains the competence effect as an irrational carry-over from other situations. Suggests that it is more motivational than cognitive, and comes from credit/blame. Then suggests that experts can augment credit after good decision, and reduce blame, suggesting that judgments by others (or other part of the self) is what drives these things.

P. 9 first full para suggests that Ellsberg might be due to difference between pre- and post-diction. Throughout Tversky's writings one sees that he does not believe that the Ellsberg paradox says something substantive about uncertainty/ambiguity attitude.

P. 10, §1.1: Experiment 1 asks for judged probabilities and then matches those with objective probabilities, which is a way to control for beliefs when studying ambiguity. (It is not manipulation-proof if known ahead.) Subjects betted both on events and on their complements (**source preference directly tested**). Part of the subjects were paid for real. They use the term regression hypothesis, referring to Einhorn & Hogarth, for what I now call likelihood insensitivity or **inverse S.** For high probability judgments subjects prefer to bet on the ambiguous events, which is explained by competence. Experiment 5 also considers bets on events and on their complements, but does so between subjects. Tversky (personal communication) pointed out that a problem in the Einhorn-Hogarth studies was that they did not control for (statistical) regression. I think that this Heath & Tversky study, while providing great ideas, has similar problems in its experiments.

P. 14: "We next took the competence hpothesis to the floor of the Republican National

Convention": swollen language.

P. 22 near bottom: points 1 and 2 are similar to the separation between probabilistic sophistication and expectation maximization.

P. 23 ℓ. 8 ff. has a nice sentence: "under the standard interpretation of the Bayesian theory, the two concepts coincide. As we go beyond this theory, however, it is essential to distinguish between the two."

Section 2.1 criticizes Einhorn & Hogarth studies for not properly controlling for belief when studying ambiguity (p. 26 ℓ. 3):
"a regressive shift in the perception of probability".

P. 26: "If willingness to bet on an uncertain event depends on more than the perceived likelihood of that event and the confidence in that estimate, it is exceedingly difficult—if not impossible—to derive underlying beliefs from preferences between bets." %}

Assumes that society starts with subjective probabilities for each individual. At each next timepoint, people update their probabilities by mixing with subjective probabilities of others. People with similar subjective probabilities are incorporated, those with probabilities more different than some ε-distance, are ignored as too different. Then simulations demonstrate how the viewpoints of society develop. Depending on the weights assigned to others' subjective probabilities, and ε, society converges to one common viewpoint, or to two

extreme viewpoints, or to other things. Nice graphs illustrate this development.
This nice work could be in prominent general-public journals, on tv, etc. %}

{% Beautiful data set of 190,000 traders over 150 countries, who had to submit plans of trading in future situations.

P. 331: "We find that a dynamic framework that features the overweighting of small probabilities, reference dependence, and diminishing sensitivity such as cumulative prospect theory (Tversky and Kahneman 1992) is most consistent with the observed behavioral patterns. As Barberis (2012) demonstrates theoretically, the discrepancy between static and dynamic environments is not driven by the intrinsic nature of the environments per se, but by the fact that people's "loss-exit" strategies in the latter can generate a level of positive skew that is unavailable in the static case. The overweighting of low probability outcomes leads to a greater willingness to accept a risky bet as part of a "loss-exit" strategy than the same bet in isolation."

P. 332: "We document a robust dynamic inconsistency in risky choice. Using a unique brokerage dataset and a series of experiments, we compare people's initial risk-taking plans to their subsequent decisions. Across settings, people accept risk as part of a loss-exit strategy—planning to continue taking risk after gains and stopping after losses. Actual behavior deviates from initial strategies by cutting gains early and chasing losses. More people accept risk when offered a commitment to their initial strategy. Our results help reconcile seemingly contradictory findings on risk-taking in static versus dynamic contexts. We explore implications for theory and welfare." They confirm the disposition effect, and the reflection effect of prospect theory.

In an experiment with prior commitment, subjects are more risk-seeking when they integrate all their decisions rather than when they take them in isolation. Confirms also that people do backward induction rather than resolute. (**dynamic consistency**). P. 336 relates findings to the pretty Cubitt, Starmer, & Sugden (1998 EJ), finding only their time independence violated, in agreement with their finding. %}

Heinemann, Frank, Rosemarie Nagel, & Peter Ockenfels (2004) “The Theory of Global Games on Test: Experimental Analysis of Coordination Games with Public and Private information,” *Econometrica* 72, 1583–1600.

{% **probability elicitation**: applied to experimental economics.

Imagine the 2-player game where each can choose safe (A) or risky (B), with payoffs, for some parameter $0 < x < 15$

	A	B
A	x^x	x^0
B	0^x	15^{15}

The notation A, B is used in the paper. It is a coordination game. If both go risky, they gain $15 > x$. There are two pure NE (Nash equilibria), (A,A) and (B,B). The randomized NE is ((15–x)/15: A, x/15: B) for both players. It has the counterintuitive property of decreasing probability of choosing the safe x as x increases. (Because the more the opponent must be deterred from always choosing x.) It is symmetric but not stable. All NE are symmetric, so, conceivable if both players are chosen randomly from one “uniform/symmetric” population.

The authors measure, for several values of x, whether players prefer A or B. Unsurprisingly, increasing the safe x decreases willingness to choose the risky B. The authors consider variations with $N > 2$ players and a minimum of k B choices needed to get the reward 15 for all who entered (and 0 for the enterers if too few entered), but default below is that I consider only the two-player version.

For each player, the switching value x is called the certainty equivalent (CE) of the player for the game. This is an unconventional interpretation because x itself is part of the definition of the game. With increasing x the probability of sufficiently many others choosing B will decrease, affecting the optimal strategy in the game, as the authors point out in some places (e.g. p. 213 just above the displayed formula “when the alternative safe payoff from A is X_c”).

The authors also measure CEs, conventional now, of lotteries (p:15, 1–p:0), for various parameters p. If a lottery (p:15, 1–p:0) and a game with parameter x have the same CE, and if (subjective) expected utility is assumed (also for the game, and with the same utility function U always (U player-dependent)), then it does follow that p is the subjective probability of an opponent choosing B *in the game with x*, even if x is not a CE in a conventional manner. So, p is a matching probability in this sense. This method of measuring CEs and matching probabilities cannot be applied very generally because of the unconventional nature of CE x (contrary to the authors' suggestion of generality in the final para on p. 219), but here it works. One restriction is, for instance, that the authors can derive the CE only for games that have a sure constant as option, where that constant furthermore has to be exactly the CE. I just derived the matching probability from a kind of transitivity that, in fact, could do without the assumption of EU. The authors, instead, assume EU and derive a utility function U from the risky CEs, which they then use to derive matching probabilities and so on for the game. P. 189 penultimate para discusses this, mentioning that they want to measure risk attitude also. Unlike my transitivity reasoning, the authors' derivation will be distorted by violations of EU. I would interpret the matching probability as capturing ambiguity attitude + beliefs, rather than only beliefs. Working with SEU, the authors suggest, following some other economists, that, the moment subjective probabilities have been assigned, the case is (like) decision under risk. In the source method for ambiguity that I like to work with, this is not so, and there can be different ambiguity attitudes in the game for instance than for the risky lotteries (where it is ambiguity neutrality), even though there are subjective probabilities describing beliefs in the game.

Pp. 189-190 argues that a separate measurement of belief (with an extraneous parameter not part of the (definition of) the game) has the problem of income effect and even influencing the game. P. 213 ℓ. 4/5 reiterates the point. But, procedures have been developed to avoid this, involving that randomly only the game or the belief measurement is implemented. Belief only concerns what the opponent will do, something a player cannot influence. P. 191 4th para writes that, in sessions where beliefs were measured with proper scoring rules, the authors paid both for one randomly chosen game and for one randomly chosen belief measurement.

The authors find plausible results when x, k, or N are varied. Page 182 3rd para (& p. 213 3rd para from below) describe how small probabilities are overestimated and high ones are underestimated (comparing derived subjective probabilities to percentages of subjects choosing B). This confirms likelihood insensitivity (**ambiguity seeking for unlikely**).

Pp. 182-183 discuss the application of individual risk theory to game theory. (**game theory can/cannot be viewed as decision under uncertainty**). They take strategic uncertainty as a case of ambiguity (they call it endogenous uncertainty), relating it to Knight (1921).

P. 213, the derivation in §7.1 could be simplified by normalizing U(0) = 0, U(15) = 1. Some steps in the analysis I did not understand, where I conjecture typos.

P. 216 3rd para points out that altruism/social preferences could lead to more willingness to play B, and overestimation of probabilities. %}

{% This paper displays so-called Vancouver rules of co-authorship in Box 1 on p. 334, which seems to target the health domain although the rules seem to be way too restrictive given the general leniency in the health domain to include many co-authors. It discusses to which extent this can be applied to deceased authors. The paper seeks to be careful but is verbose and slow.

One important argument that I found missing concerns the reputation and fame of the deceased co-author. The authors still alive may wrongly put up a famous deceased person as co-author just to benefit from it. Hence, for famous deceased co-authors the academic community should be extra careful to have him/her appear as co-author, and the role of good proxies (people representing the interests of the deceased author) are then extra important.

I once was a referee of a paper where someone, say X, misused the co-authorship of a famous deceased person to overly praise his own past works and claim wrong priorities in a way that the deceased person would never have allowed. Fortunately, the editor was a good proxy and the paper, which got accepted, had to remove all those wrong claims. %}

{% **updating under ambiguity with sampling**

Urn 1 contains 7 white and 3 orange balls, and Urn2 has these reversed, as is known to subjects in an experiment. As the subjects know, one is randomly chosen by a computer, but which one subjects do not know. A ball is randomly sampled with replacement 7 times. Each time its color is revealed to the subjects, and then they are asked to specify their subjective probability of the urn being Urn1. This whole procedure is in fact done seven times. Thus, every subject does 49 updatings. For so many updatings the correction method of Offerman et al. (2009) is worthwhile, and it is done here.

It is considered if and how subjects deviate from Bayesian updating. The authors consider a double hurdle model. This is a general term for models where people first consider if at all they act (the first hurdle) and then to what extent (the second hurdle). Here the first hurdle is whether at all subjects update, and the second is to what extent. As for the second hurdle, subjects update insufficiently, multiplying by likelihood ratio to the power 0.8 on average, whereas Bayes formula wants it to the power 1. They also consider a complexity treatment, in which info is given in a complex manner, and an inattention treatment, in which a distracting task is given to generate inattention, and these treatments of course bring more deviation from Bayesianism.

The discussion at the end of §2.3, where on the one hand the authors want inattention but on the other they don't, was hard to understand.

There have been many experimental papers on updating in 1960-1990. I was glad to see that the authors cite Phillips & Edwards (1966). (This journal has a bad tradition of ignoring such literature.) %}

{% For ambiguous events, asks people to give best-estimate probability, but next asks for interval around it to express uncertainty about it (taken as ambiguity). This is like multiple priors, although strictly formally speaking probability intervals is a bit different than sets of priors. The paper also manipulates the ambiguity of events by moving them more into the future, making them more ambiguous. It also elicits ambiguity indexes as in Baillon, Bleichrodt, Li, & Wakker (2021 Journal of Economic Theory). The order of measuring the indexes and eliciting

subjective probability intervals is randomized, and no order effect is found. This defends against subjects being framed into probability-interval-thinking. The paper finds that the insensitivity index is strongly positively related to the size of the sets of priors, which provides good empirical evidence of what many theoretical papers have conjectured. It is also positively related to the ambiguity of events, again, as is plausible. The author also finds no relation between ambiguity aversion and ambiguity perception. %}

paternalism/Humean-view-of-preference: they argue that normative theory can help to correct deviations.

P. 207: "When we make decisions for ourselves, consideration of our own regret may be rational (especially if we think we cannot avoid it)." The bracket remark is, I think, the essence.

P. 208 argues that standard gamble utility measurement may be distorted because of certainty effect. "In particular, many people prefer sure things to gambles on general principles, as it were." (**PE doesn't do well**)

Suggest direct measurement of utility difference as alternative.

P. 208: "On the other hand, a feeling of ambiguity is often a sign that there are additional data we ought to be seeking or waiting for."

paternalism/Humean-view-of-preference: p. 210: "Subjects should be confronted with their discrepancies from normative models —or discrepancies between decisions resulting from different ways of presenting the same problem —and asked to explain themselves." %}

Hershey, John C. & Jonathan Baron (1987) "Clinical Reasoning and Cognitive Processes," *Medical Decision Making* 7, 203–211.

{% **inverse S**, **utility elicitation** results suggest such probability transformations; **PE higher than CE**: probability equivalents give more risk aversion than CEs (certainty equivalents).

insurance frame increases risk aversion: some nice things for **Z&Z** on p. 949/950: people are more risk averse when a choice question is formulated as taking insurance than as gambling.

nonlinearity in probabilities %}

Hershey, John C., Howard C. Kunreuther, & Paul J.H. Schoemaker (1982) "Sources of Bias in Assessment Procedures for Utility Functions," *Management Science* 28, 936–953.

{% **PT falsified** & **reflection at individual level for risk**: They present data that violate reflection by measuring risk attitudes for both gains and losses, both between and within subjects. There are no clear patterns and findings, and there are relations in all directions. Unfortunately, they do not report correlations, but only patterns of risk seeking/risk aversion, which is similar to median splits. Tversky & Kahneman (1992, p. 308) will criticize this research for underestimating the unreliability of individual choices.

Table 3 and p. 409: more risk aversion for gains than risk seeking for losses.

risk averse for gains, risk seeking for losses: Table 3 is nice way to inspect data. Fourfold pattern is confirmed with one exception: For gains with probabilities below .01, down to .001, they do not find risk seeking. For probabilities .1 and .2 they do. For losses they do find the fourfold pattern of risk aversion for small probabilities but risk seeking for moderate and high probabilities.

insurance frame increases risk aversion: seems they have that. %}

{% Comments on version of version of 10 June 2024.

Unlike NR (Nielsen & Rehbeck 2022), they do not seek to examine or incentivize the adoption of general axioms or proper ways of reconciling with such axioms, but instead to find out precisely when violations of an axiom were intentional or not (“mistakes”). Hence, in stage 3, all subjects repeated all choices, being completely free to change any way. Roughly, a difference in violation at repetition than at first signals no intention somewhere. The authors develop a more refined classification, for which I refer to the paper. It did not in any way involve the stage-1 prior commitment to an axiom.

The authors retain NR’s “mechanistic” presentation of axioms (calling them choice assistants), letting prior choices automatically imply later ones. Btw., which in itself more often will worsen rather than improve decisions even if the axiom is rational, contrary to NR’s claims, but Herweg et al. do not intend to get into this point and put their focus elsewhere. Thus, they just stay close to NR, and axiom endorsement is implemented as follows, in separate choices only for that in a separate part. In that part, a choice situation is chosen where an axiom would bring an implication based on a prior choice made in stage 2. If the subject chose to endorse the axiom, the implied choice is automatically (“mechanistically”) implied without the subject reconsidering or choosing anything. If the subject did not endorse the axiom, the subject has to “independently” choose again. I disagree with NR and think that also here (if we can ignore decision costs) rational subjects should NEVER endorse an axiom, also if they, like me, think that axiom is rational. Later intuitive choices are, other things equal, better than early choices because of learning and, hence, later choices better overrule early choices than the other way around.

I think that NR's finding of wide acceptance of axioms was a combination of experimenter demand and incomprehensibility of explanations to subjects. Herweg et al. avoid discussing the issue by writing in footnote 7 (in version of 10 June 2024): "In our analysis, we take as given the insight of NR that axiom selection is not driven by experimenter demand effects, avoidance of responsibility or algorithm aversion but reflects a manifestation of genuine preferences over axioms."

Herweg et al. did carry out several improvements in NR's experiment, such as explaining lotteries at first appearance, using graphical presentations, avoiding mixtures, and letting choice axioms truly reduce decision costs. Thus, axioms could be better understood by subjects and their acceptances were not just driven by experimenter demand. Accordingly, unlike NR, Herweg et al. found that subjects could distinguish between the axioms, treating some as more convincing than others. And axioms were considerably less often accepted and way more violations were intentional than with NR. Herweg et al. find that 24% of subjects adhere to the axioms, 24% make occasional mistakes, and 52% deliberate violate axioms.

Herweg et al. use a matrix presentation and a verbal presentation of lotteries (the latter specifies events and not just probabilities, so gives info on correlations). They do not find differences between the two presentations.

Axiom endorsement was taken in badge, i.e., either the axiom was followed in all relevant situations, or not.

Both tests of branch independence involve the certainty effect.

As the authors properly explain, the different violations of stochastic dominance in NR was because NR used tricky stimuli there. %}

Herweg, Fabian, Svenja Hippe, Daniel Muller, & Fabio Romeis (2024) "Axiom Preferences and Choice Mistakes under Risk," working paper.

{% The authors study mathematical relations and differences between regret theory and salience theory of Bordalo, Gennaioli, & Shleifer (2012 QJE). However, they do not use original salience theory, but a continuous variation of it. (I regret that the authors do not state this.) Then it is a special case of generalized regret theory, as explained in my annotations there:

$(p_1{:}x_1,\ldots, p_n{:}x_n) \succcurlyeq (p_1{:}y_1,\ldots, p_n{:}y_n) \;\Leftrightarrow\; \sum_{s=1}^{n}\psi(x_s,y_s) \geq 0$

for a bivariate function Ψ satisfying natural conditions. This paper derives this formally. It also shows that original regret theory is a special case of continuous salience theory.

Here is the authors' definition of salience theory in Eq. 5, p. 7. The decision weight of state s is

$$\frac{f(\sigma(x_s, y_s)),}{\sum_{r=1}^{S} f(\sigma(x_r, y_r))p_r}\, p_s$$

where S denotes the number of states of nature r, each with probability p_r. Note that the normalization in the denominator does not matter because the preference functional is unique up to multiplication by any positive funtion g(x,y) that can entirely depend on the gambles x,y. Only its sign matters. But this is essentially different than salience theory. In salience theory, instead of the above functions $f(\sigma(x_s, y_s))$, there is a function depending also on $\sigma(x_r,y_r)$ for r different than s, through the ranking of $\sigma(x_s,y_s)$ among the $\sigma(x_r,y_r)$. This leads to an essentially different theory. Generalized regret theory as above, and then the authors' Eq. 5, satisfy a strong separability condition across disjoint events. Salience theory does less so, for one reason because the sure-thing principle, that it does satisfy, is not very strong in the absence of transitivity. Diecidue & Somasundaram (2017) introduced a weakening of transitivity, called d-transitivity (dominance-transitivity), saying that the implication of transitivity still holds of one of the two premise preferences is based on dominance. The preceding generalized regret theory satisfies it, but, as can be shown, Bordalo, Gennaioli, & Shleifer's (2012) salience theory does not.

The authors write below eq. 5 that f preserves ranking, which is trivially equivalent to f being strictly increasing, and does not help for the above problem. %}

{% **dynamic consistency**; Test the dynamic decision approaches, resolute, naïve, sophisticated, empirically, in a nice design to disentangle them. Also ask for evaluations of trees so as to test for indifference versus strict preference. Unfortunately, the data are noisy and give no clear pattern. The stimuli may have been too complex. There is a confound in their design. In Trees 3 and 4 (p. 8) there is an alternative that clearly dominates one other. It is well known that this generates a context effect of attracting subjects to take the dominating alternative more than the nondominated alternative, as demonstrated by Tversky & Simonson (1993) and many others. It is indeed what happens in the data.

deception when implementing real incentives: I regret much that the authors used deception, not playing for real what is suggested to the subjects in the beginning. There is no good reason for doing so, and the authors did it only to reduce their work load; i.e., the number of subjects to be run and the money to be paid to subjects (p. 13 last para).

Unfortunately, the second sentence of §2 incorrectly claims that the authors are the first to test the conditions with real incentives. They next modify by saying that they will only consider studies with “appropriate” real incentives. (**real incentives/hypothetical choice, explicitly ignoring hypothetical literature**) This is characteristic of a bad convention among experimental economists: If person A first developed some idea, and tested it with hypothetical choice, and then person B does all the same but with real incentives, then experimental economists will credit all priority to person B and completely ignore person A. Even if we ignore this point, the authors have a second problem: Contrary to what they write in footnote 13, Busemeyer et al. (2000) did use real incentives, in their experiments 2 and 3. This paper by Hey & Lotito has enough extra to offer, such as the nice considerations of strengths of preferences. %}

Hey, John D. & Gianna Lotito (2009) “Naïve, Resolute or Sophisticated? A Study of Dynamic Decision Making,” *Journal of Risk and Uncertainty* 38, 1–25.

{% Incentives: use RIS; **losses from prior endowment mechanism** (subjects can lose £10, but are paid £10 a priori).

Use nice bingo blowers, a transparent device containing balls in three colors that are continuously moved around, so that subjects can only vaguely see the composition of the urn and have degrees of ambiguity. The more balls the harder to assess, so, the more ambiguity.

Urn 1 (15 subjects): 2 pink, 5 blue, and 3 yellow balls;
Urn 2 (17 subjects): 4 pink, 10 blue, and 6 yellow balls;
Urn 3 (16 subjects): 8 pink, 20 blue, and 12 yellow balls (p. 90).
Each subject sees only one urn. Each next urn is more ambiguous than the one before.

Nicely, they test all kinds of theories of uncertainty/ambiguity. They consider three outcomes, being –£10, £10, and £100. They use cross-validation: one part of the data set is used to calibrate the parameters of the models, and then another part is used to test predictive performance.

The data set, and the general scheme of testing many popular ambiguity theories, making them all tractable, are great, and could have led to a top paper. Unfortunately, there are many theoretical mistakes. The authors use several wrong formulas especially regarding the two versions of prospect theory. This invalidates the results and claims made.

I here use their notation CPT for the new 92 prospect theory, rather than my own (and Tversky's!) preferred PT. And I use their PT instead of my preferred OPT for the 79 version of prospect theory.

They test:

1. EV, 3 parameters: 2 probabilities and error variance s.

2. EU, 4 parameters: EV-ones + one U parameter (U(−10) = 0; U(100) = 1; U(10) is only U-parameter; p. 89);

3. CEU (Choquet expected utility), 8 parameters: EU-ones + 6 − 2 (instead of 2 subjective probabilities, now 6 for the capacity for six of the eight events, with the empty and universal event not counting because there the capacities are fixed at 0 and 1);

4. CPT of '92, 9 parameters: CEU parameters +, supposedly and incorrectly, one more for loss aversion.

5. PT of Kahneman & Tversky '79, 6 parameters: The EU ones + one more because subjective probabilities need not sum to 1 (or any other constant) + one more for loss aversion. This time loss aversion does genuinly generate an extra parameter, unlike with their CPT, because the decision weights need not sum to 1 implying that the 0 point of U matters.

6. DFT (Decision Field Theory of Busemeyer & Townsend 1993; called random SEU there), 4 parameters: As EU but different error theory. It, nicely, has the randomness on statewise utility differences and their probabilities.

7. Maxmin EU, 5 parameters: like EU, but with 3 minimum probabilities per state (so, the family of all priors where each state has at least that min. probability; the mins are supposed to add to less than 1) instead of 2 subjective probabilities (p. 95 footnote 16 and p. 109 are not clear on whether it is min or max probability, but it is min, as reanalyses by Amit Kothiyal showed).

8. Maxmax EU, 5 parameters: like maxmin.

9. α-maxmin (EU), 6 parameters: like maxmin but α is one more.

10. Maxmin, 1 parameter, probability of trembling-hand theory.

11. Maxmax, 1 parameter like maxmin.

12. Minimal, 1 parameter regret like maxmin.

They do not test the smooth model because they have no multiple stages. P. 103 top, correctly points out that with the two-stage decomposition endogenous, as in the smooth model of KMM, there are too many parameters.

There are two problems with their CPT calculation (p. 88 & p. 108).

PROBLEM 1. They have no sign-dependence of weights. CPT in full generality would have all weights for losses completely independent of those for gains. This in its full generality means more parameters, which is not always good. If we don't want to increase the number of parameters relative to CEU, then a plausible special case is taking the nonadditive measure the same for losses as for gains, but then using the formula of CPT rather than of CEU, which means weighting the losses dually relative to gains (à la reflection), and not the same as under CEU. Then the total weights need not sum to 1 as they do under CEU (and then CEU would not be nested in CPT or vice versa). This non-summing to 1 gives empirical meaning to setting utility 0 at a reference point (say, 0). The authors do the weighting fully the same as under CEU, so that the weights always sum to 1. Given that they also have a fixed reference point (0) under what they call CPT, what they call CPT is a special case of CEU. The utility- and loss-aversion-part is further discussed in the next Problem 2, where I will show that what they call CPT is data-equivalent to what they call CEU.

PROBLEM 2. They think to implement loss aversion for CPT by not normalizing U(–10) = 0 and instead normalizing U(0) = 0 (p. 89 ℓ.–5 of middle para), leaving U(–10) < 0 free. But this does not work. What they call CPT is data-equivalent to CEU. It all has to do with, for a fixed reference point as is the case here (0 is the reference point), CPT generalizing CEU only because of sign-dependence of decision weights which they do not have, and for CEU the rescaling of U(0) = 0 having no empirical impact. Here is a more detailed explanation:

Recall that event-weighting in their CPT is done the same way as in CEU. In particular, the decision weights of the events always sum to 1, something typical of CEU. This means that utility is unique up to unit and level (cardinal, interval scale). In other words, adding any constant to utility and multiplying utility by any positive constant at the outcomes –10, 10, and 100 does not affect the preference relation. The former increases all values of prospects by that same constant which does not affect preference, and the latter multiplies all values of prospects by that same positive constant which again does not affect preference.

OBSERVATION 1. Any CPT representation in their paper is a CEU representation.

PROOF. Denote the utility function under CPT by U. I define a U´ leading to a CEU representation as follows:

$$U´(.) \ = \ [U(.) - U(-10)]/[U(100) - U(-10)].$$

U´(–10) = 0 and U´(100) = 1, as desired. Thus, any representation called CPT in their paper can be turned into a representation called CEU that represents the same preference relation.

QED QED QED QED QED QED QED QED QED QED QED

What they call CPT therefore does not generalize CEU.

OBSERVATION 2. Any CEU representation in their paper is a CPT representation.

PROOF. Denote the utility function under CEU by U. I define a U* leading to a CPT representation. There are several ways to do this. At any rate we will have

$$U^*(100) = U(100) = 1.$$

Further

$$U^*(-10) < U(-10) = 0$$

implies that also

$$U^*(10) < U(10).$$

Further

$$U^*(0) = 0$$

implies

$$U^*(10) > 0.$$

So, we can define

$$U^*(10) = z$$

for any value z with

$$0 < z < U(10) \ (< 1).$$

Then we define, at 100, 10, and –10:

$$U^*(.) \ = \ \{(1-z)/[1-U(10)]\}U(.) \ - \ [U(10)-z]/[1-U(10)].$$

We, indeed, have U*(100) = 1, U*(10) = z, and

$U(-10) = -[U(10)-z]/[1-U(10)] < 0$.

So, we can define

$$U^*(0) = 0$$

which does not affect preference but has utility increasing by being between $U^*(-10)$ and $U^*(10)$.

Thus, if we start from a CEU representation as in this paper, then we can choose any value $U^*(10)$ strictly between 0 and $U(10)$, and then get a CPT representation with that U^* that represents the same preference relation.

QED QED QED QED QED QED QED QED QED QED QED

SUMMARY of Problem 1: what this paper calls CPT is, regarding core theory, identical to what it calls CEU, representing the same preference relations.

Another way to put the point is that for three outcomes −10, 10, and 100, only one parameter of utility is relevant when weights always add to 1 (which in fact is CEU): the ratio of utility differences

$$[U(10) - U(-10)] / [U(100) - U(-10)] .$$

In view of the above, differences in predictions (via statistical fittings) of CEU and CPT can result only from the error theory working out differently numerically under the different scalings of utility (although the division by $V(xmax) - V(xmin)$ on p. 91 ℓ. −3 in their probabilistic theory suggests that rescaling of utility will not matter).

Besides the above two problems for CPT, there are more problems.

PROBLEM 3. This problem concerns the implementation of PT (p. 88 & pp. 107-108). PT of KT 79 was originally defined for risk with given probabilities. This paper extends it to uncertainty by assuming subjective probabilities (probabilistic sophistication) and then applying (supposed to be) PT formulas. Extending to uncertainty this way in itself is fine. One problem is that PT is defined only for two nonzero outcomes, and this paper has three. For some prospects (only two outcomes, and both gains, so being 10 and 100) PT as defined by K&T 79 is RDU, using rank-dependent weighting, but this paper does not do that. What his paper does is more like an attempt to use Edwards-type transformation of separate-outcome probabilities (Wakker 2010 Eq. 5.3.3), which is called Separable Prospect Theory (SPT) by Camerer & Ho (1994, p. 185) for instance. (**SPT instead of OPT**)

However, this is still not what they really do. Problem is that for 2-color events they take as weight simply the sum of the weights of the two colors (this appears for instance from only taking weights of the three single-color events on p. 95 -see also p. 108 top para-, and not of 2-color events), whereas a crucial point of the theories mentioned is nonadditivity: The weight of a 2-color event is NOT the sum of the two 1-color events. So, they just have additivity there. Nonadditivity only shows up with the 3-color event involved.

They write on p. 88 ℓ. 4 that, indeed, their theory is like EU the only difference being that the sum of weights of the three atomic ("singular") events, concerning one color, need not be 1. Big question is then how they take the weight of the (3-color) universal event, relevant for sure outcomes. If they take the sum of the three probabilities then this is just data-equivalent to EU, dropping the normalized probability 1, and there is no violation of monotonicity, but also this is just EU which is bad given that it is called PT. It seems that they take weight 1 for the universal three-color event, and not the sum of the three probabilities, and then there can be violations of monotonicity. Their theory then is EU with the only exception being that sure outcomes are over- or underweighted in utility relative to all else. This is in fact a (probabilistically sophisticated version of) a model called utility of gambling. The latter has EU for nondegenerate prospects but degenerate prospects are evaluated using a different utility function, reflecting the utility of (not) gambling. If the utility function for uncertainty is U then the utility function for certainty is kU for a k not equal to 1. Diecidue, Schmidt, & Wakker (2004, JRU, Observation 7) shows that this necessarily violates stochastic dominance. This also happens if k > 1, where k is the reciprocal of the sum of the three probabilities. This means that subadditivity does not help here, somewhat unlike a suggestion, not very explicitly, in footnote 10 on p. 88. That footnote suggests that they assume subadditivity, and erroneously ascribes it to Kahneman & Tversky (1979). Empirically, superadditivity is commonly found and especially Tversky argued for it in support theory.

SUMMARY OF PROBLEM 3. What they call PT is a version of the utility of gambling models. It is too distinct from PT, and even from the separable version of it, to be called PT.

PROBLEM 4. A fourth unsatisfactory implementation concerns the different treatment of the multiple prior models relative to the rank-dependent models. For multiple priors they take a tractable 3-dimensional subset (of all probability distributions for which the probabilities of the single events exceed a lower bound. The three lower bounds are the parameters. But for CEU/CPT they do not do this and take CEU/CPT in full generality. In a 2007 version of their paper they wrote that multiple priors (then taken in full generality) is simply too general to fit any data. Hence, to make it work they were forced to take a subset of the theory. But for CEU/CPT it would have been fair to do the same. Given that their source of uncertainty (one urn per subject) is reasonably uniform in the terminology of Abdellaoui et al. (American Economic Review, 2011), CEU/CPT would be nice with probabilistic sophistication and a one- or two-parameter fitted weighting function, having only 1 or 2 parameters more than EU, and being the same in this regard as multiple priors.

PROBLEM 5. The fifth problem (p. 85) concerns the distinction between direct decision rules and preference functionals. They consider maxmin and maxmax (and minimal regret) to be direct decision rules, but these obviously are preference functionals just as much, with max or min outcome as preference functional value. The distinction becomes unfortunate because they use different error theories for what they call direct decision rules (p. 91). Because the three direct-decision-rule theories are not very important anyhow, this fifth problem is not important.

The main text suggests that there is another problem with MaxMin and MaxMax, that the appendix however seems to put right. Main text: Whereas for the alpha model the authors seem to appropriately take a set of priors, for G&S MaxMin they seem to take minimum probabilities per event, and not minimums of probability distributions, with similar problems for MaxMax. It may, for instance, happen for MaxMax that to get maximum probability at £100, the probability at £10 should not be maximal. The appendix pp. 108-109 puts things right by having MaxMax and MaxMin as special cases of alpha.

END OF FIVE PROBLEMS

Because of the problems mentioned, the empirical conclusions of this paper are not informative. These conclusions are that maxmax priors does best, maxmin and α maxmin do well also, and others do worse. Big pity that such a nice experimental data set has been analyzed incorrectly.

P. 83: when criticizing statistical testing of theories, the authors only consider the case where one theory is nested within another.

second-order probabilities to model ambiguity: p. 84 4th para: they point out that second-order probabilities are not really ambiguity, and nicely explain that implementing ambiguity is not so easy.

suspicion under ambiguity: p. 84 5th para: They claim that their bingo blower is not subject to suspicion, but do not argue clearly why. Why could not the researcher do visual tricks with it, or systematically have few balls of the winning color hoping for overestimation? That the subjects bet both on and against each color can help to rule out suspicion. A small remaining problem is that subjects may not know this and may still suspect that the ball compositions are deliberately unfavorable for the particular choice they consider.

P. 87 footnote 8 incorrectly suggests that the competence effect is [only] relevant for laboratory data. It also suggests that it can play no role in their study, but it can because urn 3 generates the least competence and urn 1 generates the most. P. 101 continues on this point.

P. 88 writes, erroneously, that CPT assign (subjective) probabilities to events and then transform these. Then CPT would imply probabilistic sophistication, which is not correct. P. 93 will write that CEU is nested within CPT, so that they did not assume probabilistic sophistication. P. 95 writes that for CPT the weights (capacities?) are “weighted probabilities,” but I am pretty sure that they treated them just as the capacities for CEU.

P. 89 writes that explaining BDM (Becker-DeGroot-Marschak) is too complex.

P 89: Every subject must make 162 binary choices. Must take at least 30 seconds per choice. So, the experiment takes more than 81 minutes per person. With so many choices for so much time, subjects can be expected to resort to a particularly simple heuristic. With outcomes 100, 10, and −10 it is mostly optimal to just maximize the chance/likelihood at 100. So, subjects are prone to just do this always (suggested by the authors on p. 103 penultimate para). This may explain why the maxmax model does best, and better than maxmin.

The paper sometimes claims, holding it against CEU and CPT, that models with more parameters always predict better and, hence, should be punished for the extra parameters. More parameters always give better fits, but for predicting they may mostly pick up noise (overfitting) and then predict worse, so, they are no clear advantage for prediction purposes.

They use Bayesian information criterion rather than AIC to account for extra parameters. Sometimes (p. 96 penultimate para, p. 98 2nd para) says that theories with more parameters should be judged more negative for it. But this feels like double counting because the info criteria and predictions already punishes for many parameters.

Summarizing, I admire the empirical setup with marvelous stimuli (based on big money and time investments, with the marvelous idea of the bingo-blower), and also the general plan of testing many ambiguity theories. Maybe from now on every new ambiguity theory should be forced to be calibrated on this data set. But there are several problems with the core-theoretical parts underlying the analyses in this paper, invalidating the empirical claims. %}

Hey, John D., Gianna Lotito, & Anna Maffioletti (2010) "The Descriptive and Predictive Adequacy of Theories of Decision Making under Uncertainty/Ambiguity," *Journal of Risk and Uncertainty* 41, 81–111.

{% **Compare different measurement methods**: real incentives: Everything is incentivized, using RIS. N = 24 subjects were interviewed five times, about half an hour per time. Consider 4 outcomes (0, 10, 30, 40 in £), and 28 probability distributions over them. Consider binary choices, bid-prices, ask-prices, and BDM (Becker-DeGroot-Marschak). Fit EU and RDU with an error theory added. Last para of §2 states that they assume all choices statistically independent, also within subjects. Find that RDU does not fit much better. One clear finding is that binary choice has less noise than the other (matching) procedures. In RDU, utility changes more than probability weighting between different elicitation methods. Utility parameters are even negatively correlated between different elicitation methods. %}

Hey, John D., Andrea Morone, & Ulrich Schmidt (2009) "Noise and Bias in Eliciting Preferences," *Journal of Risk and Uncertainty* 39, 213–235.

{% **error theory for risky choice**; **Best core theory depends on error theory**: seems to be inconsistency of 25% (**inconsistency in repeated risky choice**); conclude that expected utility with noise is most plausible explanation.

Probability weighting linear in interior: seem to find this.

I have a small and a big problem with this paper. The small one is that there is no clear conclusion. The authors' conclusion that expected utility works best is out of the blue, unrelated to their data. The big one is that they take the power family for probability weighting. This cannot incorporate the main empirical finding of the fourfold pattern with inverse S probability weighting. %}

Hey, John D. & Chris Orme (1994) "Investigating Generalizations of Expected Utility Theory Using Experimental Data," *Econometrica* 62, 1291–1326.

{% Use bingo blower (as in Hey, Lotito, & Maffioletti 2010) with three colors. Treatment 1 (66 subjects): 2 pink, 5 blue, and 3 yellow balls (66 subjects); Treatment 2 (63 subjects): 8 pink, 20 blue, and 12 yellow balls (63 subjects). Treatments are between subjects.

Subjects can invest an amound of money x in one event and m−x in another, where one event E_1 concerns one color and the other E_2 either one color (then no payment if the 3rd color) or two other colors. They receive e_1x if E_1 happens and $e_2(m-x)$ if E_2 happens, where the exchange rates e_1 and e_2 are set by the experimenter and vary over choices (if I understand right). A problem with such linear multiple-choice sets is that many functionals will usually predict corner solutions. Functionals that don't (such as with power utility because it has infinite derivative at 0, so, no 0 investment in an optimum) don't do so because of a weak point. In reality subjects choose interior solutions because of the compromise effect and maybe experimenter demand effects.

All prospects considered are two-outcome. 60 randomly chosen questions were used to calibrate the functionals, and then 16 for prediction.

The authors consider five theories that are all special cases of **biseparable utility** (see the unnumbered equation between Eqs. 14 and 15 on p. 16), although the authors use different names. For multiple prior theories they use, as sets of priors, sets with lower bounds for the three probabilities: P(pink) ≥ $\underline{p}_1$, P(blue) ≥

$\underline{p}_2$, P(yellow) ≥ $\underline{p}_3$, with the $\underline{p}_j$ summing to less than 1. (As in Hey, Lotito, & Maffioletti (2010), who did not write this point clearly.) So, it gives three free parameters. They consider no losses, so, CEU is the same as PT.

Their theories (with number of parameters specified on p. 17 ℓ. −3) are:
(1) SEU with 4 parameters (2 subjective probabilities, 1 utility, 1 error variance);
(2) CEU (**biseparable utility** in full generality) with 8 parameters; (6 capacities; 1 utility; 1 error variance);
(3) α-maxmin(AEU) with 6 parameters (3 for set of priors; 1 for α; 1 utility, and 1 error variance)
(4) What they call vector expected utility (VEU), but what in fact is **biseparable utility** with $w(p) = p-\delta$ for a δ that usually is positive but that is also allowed to be negative. This violates stochastic dominance if the best outcome has outcome-probability < δ. The authors always restrict δ to less than the minimal probability occurring in their experiment, but this is ad hoc and this specification of binary RRDU is therefore not useful. (I guess a similar restriction w.r.t. maximal probabilities applies for negative δ, but did not check.) It does the opposite of inverse S for small probabilities, not overestimating them but underestimating them. It is in fact neo-additive probability weighting with the two parameters the same except that one has the wrong sign. This theory has 5 parameters (2 subjective probabilities, 1 for δ, 1 utility, and 1 error variance);
(5) The contraction model (COM); note that the contraction model has the sets of priors Π as exogenously given, whereas this paper takes them as endogenous. Thus, the contraction model simply is identical to maxmin EU. The λ factor in their Eq. 13 is unidentifiable. 6 parameters (3 set of priors; 1 utility; 1 for λ, and 1 error variance);

Specification 1 assumes linear-exponential (CARA) utility, and specification 2 log-power (CRRA) utility. Specification 2 does better, and I think that this is because it accommodates the compromise effect better.

P. 3 discusses the difficulty of testing two-stage models experimentally.

P. 4 2nd para does not understand the role of the subjective (also called ambiguity neutral) probabilities used by Abdellaoui et al. (2011), based on Chew & Sagi (2008), because of which it is NOT the same as CEU but a special case.

In their results (p. 18 top), CEU performs poorly, which happens because it is given way too many parameters, as explained for instance by Kothiyal, Spinu, & Wakker (2014 JRU), leading to great overfitting with the parameters picking up more noise than system; COM (= maxmin EU) performs poorly with its unidentifiable λ; AEU does some better because they don't have redundant parameters, SEU yet better (although AEU is better on p. 25 ℓ. 1), and VEU (vector EU) is best. In the results section they describe statistical tests, but I did not understand why they did not just do Wilcoxon to compare the predictive likelihoods of all theories.

P. 28 last para: for the more ambiguous blower the main change is that subjects take subjective probabilities closer to uniform, nicely confirming the cognitive interpretation of inverse S. (**cognitive ability related to likelihood insensitivity (= inverse S)**) %}

Hey, John D. & Noemi Pace (2014) "The Explanatory and Predictive Power of Non Two-stage-Probability Theories of Decision Making under Ambiguity," *Journal of Risk and Uncertainty* 49, 1–29.

{% **dynamic consistency**: Subjects can divide money over two risky prospects (say investments) in a first stage, and then, after risk of first stage resolved, can divide the remainder again over two risky prospects. They must announce beforehand what their second-stage division will be, but in the second stage get the chance to revise. Thus we can test for dynamic decision principles. By looking at investment we get continuum observation and can test more. The authors fit RDU with the usual 4 dynamic types: Resolute, sophisticated, naïve, and myopic (the latter meaning at stage 1 they only optimize the stage-1 rewards, completely ignoring the investment to be made after). They get, roughly, 55% resolute, 23% sophisticated, 13% myopic and 10% naïve.

As always in John Hey's papers, the 1992 probability weighting function family of Tversky & Kahneman (1992) is ascribed to Quiggin (1982). Footnote 22 of H&P refers to Quiggin "proposing" the T&K family without the 1/g exponent in the denominator. However, this family has been well known long before, and Quiggin properly cites Karmarkar for using it. More precisely, Quiggin and Karmarkar consider a normalized version.) Quiggin then in fact criticizes it, for still violating stochastic dominance in the old fixed-probability transformation theory. %}

{%. Commonly taken as the main paper to establish the ordinal view of utility in economics. Seems to show that indifference curves can be employed to reconstruct the theory of consumer behavior on the basis of ordinal utility, and to have emphasized how much one can do with only ordinal utility. Pareto had made such observations before, but there were unclear parts in his analysis, which still referred to nonordinal concepts such as regarding the possibility to compare utility differences and his reference to diminishing marginal utility. Hicks & Allen (1934) got a clear analysis, e.g. by putting marginal rates of substitution central. Edwards (1954): "This paper was to economics something like the behaviorist revolution in psychology."

Zeuthen (1937) cites parts of it, for example from p. 225: "A theory aiming at establishing the results of human choices in terms of quantities exchanged and the ratios of such quantities (i.e., prices) may dispense with any assumption which is not purely behaviouristic, while a theory of human welfare must go back to psychological introspection." He thus in one blow puts everything exactly right.

In relation to that, seems to be a major paper to make economics exclude survey data and introspection from its domain, and rely exclusively on observable choice.

This paper seems to have introduced the ordinal/cardinal terminology (using it only once). Edgeworth had apparently used it before, but only because of this paper it became generally used. Samuelson would later popularize it. %}

{% This paper presents advanced maths, to obtain a state-dependent version of Savage (1954) using useful techniques of Krantz et al. (1971) in an interesting way. It, thus, aims to obtain a genuine state-dependent generalization of Savage (1954). Wakker & Zank (1999, MOR) did some in this direction but, as the author correctly points out, they still needed monotonicity (ordinal state independence). Further, they used richness of outcomes rather than of states.

There still remain some mathematical problems in the results of this paper. A counterexample results from Savage (1954) in his original setup, with the power set of S as sigma algebra (event space). As is well known (Banach & Kuratowski (1929) and Ulam 1930), countable additivity of the probability measure P must be violated here. Then also the EU functional violates countable additivity by considering indiator acts of events revealing the noncountable additivity of P. But, yet, Savage satisfies all axioms (A1-A5) of this paper. The measure U claimed in this paper is supposed to be countably additive though. The problems in the proof leading to this are, first, that the operation 0 for countably many events (p. 2050 line 3 ff.) need not be well defined (it should be shown that it does not matter which countably many representative partial acts are chosen from indifference classes), which gives problems in the derivation of Archimedeanity (point 8 on p. 2053) and in the derivation of countable additivity (Proof of Proposition 2; p. 2053). %}

Hill, Brian (2010) "An Additively Separable Representation in the Savage Framework," *Journal of Economic Theory* 145, 2044–2054.

{% The paper considers preference with a level of confidence in preference playing a role. No uncertainty is considered, but later social choice is considered. A person does not have one preference, but a set of possible preferences; big sets reflect low confidence. For each decision situation an importance level is specified. If the importance is very high, only the most plausible preferences are accepted and, hence, there is more incompleteness. It reminds me of Nau (1992). %}

Hill, Brian (2012) "Confidence in Preferences," *Social Choice and Welfare* 39, 273–302.

{% A generalization of multiple prior models. There is not one set of priors, but there are different levels of confidence (taken ordinally), and for each level of confidence there is a set of priors, being the priors that have at least that confidence. These sets are nested. The level of confidence chosen in a decision problem depends on the stakes of the decision problem. It reminds me of Nau (1992). I wonder how the model of this paper is related to Hill (2012), which seems to be similar. The paper does not discuss this relation. Refining the crude nature of multiple priors (in or out) is desirable of course. The model is very general, in requiring many sets of priors, and assigning such sets of stakes. Given a stake and a set of priors, the paper is pessimistic and does maxmin.

The paper uses Anscombe-Aumann.

P. 681 1st para points out that the paper takes the lowest (nonnull) outcome of an act as stake. So, stake is minimum in this paper. It will suggest an interest in generalizations in §4. Note, to avoid terminological confusion, that stake is the opposite of goodness. Increasing the minimal outcome means decreasing the stake. The paper assumes that decreasing the worst outcome (“increasing the stake”) leads to bigger sets of priors and, hence, more ambiguity aversion. This is empirically violated by the commonly found ambiguity seeking for losses with ambiguity aversion for gains. The model is meant to be normative (Hill 2019 *Economics and Philosophy*). %}

{% **state-dependent utility**

This paper presents a generalization of the maxmin EU model axiomatized by Gilboa & Schmeidler (1989), which used the Anscombe-Aumann framework. This paper maintains the two-stage structure where acts assign lotteries over prizes to states (“horses”), and uses backward induction/CE substitution. It generalizes by not assuming EU maximization over the lotteries. Instead, it assumes a multi-utility representation there. That is, a set v of utility functions over prizes is given, and to each lottery we assign the infimum EU over these. There is state dependence in the sense that the set v depends on the state (horse) s, so it is v(s). This minimization of utility is a bit but not much related to Baucells & Shapley (2008) and Dubra, Maccheroni, & Ok (2004), who also have multi-utility EU, but they let preferences be incomplete by requiring unanimous ordering (rather than taking inf). It is much related to cautious utility (Cerreia-Vioglio, Dillenberger, & Ortoleva 2015), who also take a set of utility functions and minimize over them. Only, the latter minimize certainty equivalents (CE), and Hill's paper minimizes EU. The two would be equivalent if all utility functions in v(s) were normalized the same way, but Hill does not do so, as far as I could see. Hill cites cautious utility as similar but different.

A general problem of state-dependent utility is that the separation of utility and probability/decision-weights cannot be well done. One way out is to assume two prizes state-independent, and they can then be used to calibrate probability/decision weights. This is in a way what this paper does with a best (h-superbar) and worst (h-underbar) act, although the best and worst prizes/consequences can be different for different states. They do exist for every state because utilities are continuous and the set of prizes is assumed compact (p. 1343; i.e., it is bounded and closed in Euclidean spaces). But the best prize x_1 for state s_1 and the best prize x_2 for state s_2 are in a way treated as the same, state-independent, prizes. That is, they are assumed to have the same utility, when the purpose is defining probabilities/decision-weights for events. Then so do all lotteries between them (p. 1345 near bottom). They are, accordingly, called essentially constant on p. 1345 near botrtom. This gives enough richness to get maxmin EU using state-independent techniques. State-dependence can then be arranged afterwards by replacing every lottery by an equivalent lottery between the best and worst consequence, a standard-gamble equivalent so to say.

P. 1348, §4.1: The model is general but can serve as a starting point to derive special cases. One can turn state-dependence, imprecise beliefs, or imprecise tastes (this is how multi-utility is interpreted) on or off by adding axioms to that effect.

criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity:

The state-consistency axiom (p. 1344) means separability of every single state/horse, and is what has often been criticized.

P. 1349 points out that the model with precise tastes (every v(s) has one element, so, we have EU for every state, where the EU model depends on the state) combines state-dependence with uncertainty aversion. Chew & Wakker (1996) is also a state-dependent ambiguity model, and uncertainty aversion could easily be added there.

P. 1350, §4.2, in words explains that the axiomatization can be extended to incorporate variational (Maccheroni, Marinacci, & Rustichini 2006) and confidence (Chateauneuf & Faro 2009) preferences.

§5 gives comparative results. Proposition 4 characterizes more imprecision aversion. It takes best and worst acts for the two agents as (in my interpretation) state-independent and comparable, then has a preference condition of stronger preference for lotteries between the state-independent acts, and shows that this holds iff greater imprecision both and beliefs and tastes. So, here beliefs and tastes are treated jointly. It is in a way assuming that preferences over lotteries between best-worst acts are the same/isomorphic for the two agents. A single-state conditioned version of more imprecision-aversion characterizes greater imprecision for consequences. Restricting the condition to lotteries between the best and worst acts gives greater imprecision of beliefs. %}

Hill, Brian (2019) “A Non-Bayesian Theory of State-Dependent Utility,” *Econometrica* 87, 1341–1366.

{% This paper aims to normatively justify the models of the author of 2013 and 2016.

P. 225 2nd para: “Despite these qualities, the Bayesian hegemony as a normative account of belief and decision making has been increasingly challenged, both by philosophers (Levi 1974, 1986; Bradley 2009; Joyce 2011) and economists (Gilboa et al. 2009; Gilboa and Marinacci 2013), as well as in fields such as decision analysis (Lempert and Collins 2007; Cox 2012).”

P. 225 footnote 2 states exactly my view: “Bayesianism has been argued to reflect something akin to this difference in the resilience of the probability judgements in the face of new information (Skyrms 1977). This claim, which pertains to learning or belief formation, does not affect the central point made here concerning decision, namely that such differences are denied any role in [static] choice.”

P. 228 states what I also think about multiple priors: “As a representation of confidence in beliefs, imprecise probabilities are evidently unsatisfactory, for they treat confidence as an all-or-nothing affair: either you hold a credal judgement with full confidence, or you do not hold it, and have no confidence at all. It does not allow for grades of confidence, of the sort seen above." It is also what I consider more or less to be the definition of multiple priors.

P. 239 2nd para: "The first difference is the subject of a long-standing debate, focusing mainly on whether non-Bayesian models are embarrassed in dynamic or sequential choice situations." To which the author's reply follows some lines later: "it suffices that Bayesianism's limitations in the sorts of severe-uncertainty situations discussed in the Introduction outweigh any advantage it might have as regards dynamic choice."

The author throughout claims to have a separation between doxastic [motivational] and conative [cognitive] attitudes

P. 242 1st para argues that in maxmin EU the set of priors does not separate cognitive and motivational (my terms).

P. 245 ℓℓ. 2-4 argues that for RDU and nonadditive measures there is no clear intuitive story (my opinion: Diecidue & Wakker, 2001, and my 2010 book give such a story, but it should refer to rank-dependent decision weights rather than a nonadditive weighting function), writing: "It has proved difficult to give a solid pre-formal normative intuition or justification for the use of this rule to guide choice under uncertainty."

P. 245 ℓℓ. --6/-1 points out what holds, I think, for many ambiguity models: "As concerns their choice-theoretical properties, they are relatively mild weakenings of the maximin-EU decision rule (3), though we are aware of no defence of their specific weakenings on grounds of rationality. They are motivated by the relationship to the robustness literature …"

P. 246-247 discusses normatively abandoning RCLA, and discusses Marinacci's (2015) justification by taking 1st-order as physical uncertainty and 2nd-order as epistemic (also put forward by KMM). %}

Hill, Brian (2019) "Confidence in Beliefs and Rational Decision Making," *Economics and Philosophy* 35, 223–258.

{% % **dynamic consistency**: This paper adds a further refinement to the dissection of the dynamic principles that imply expected utility and, therefore, cannot all be satisfied under nonEU and ambiguity. It targets dynamic consistency. It specifies the "hidden" assumption that the subjective tree faced by the agent is the same as the objective tree used by the decision theorist.

It is well known in probability theory that, when updating after receiving info on the realization of a random variable, it is relevant to know the whole random variable, or information structure as it can be called. If the info is received that an event E obtains, then the default assumption is that the information structure was that always if E obtains, we are informed about that, and always if E^c obtains we are informed about that. The present paper calls that the objective tree, or objective information structure as I will also call it.

More complex info structures can be, and that can matter. The most well-known example is the three-door problem, also known as Monty Halls problem or the three-prisoner's problem. (**three-doors problem**) Imagine you play it and at first chose door 1. The quizz master opens door 2 and informs you: "the prize is not behind door 2." Then it is relevant to know: Would he always inform you about exactly that if it were the case? Also always if the prize is behind your door 1 here? And if the prize were behind door 2, would he have informed you about exactly that? Under the usual assumptions, the information structure is more complex. If the quizz master gives you the aformentioned info, then it gives more info: That all prior probability mass from door 2 has moved to door 3, so it is better to switch door now.

Now consider the three-color Ellsberg paradox. The common outcome is under the ambiguous event B (black). Arguments are well known that the common ambiguity averse preferences violate dynamic consistency under some assumptions such as consequentialism. This involves conditioning on event B, so, on the info of B, and makes the common default assumption of the objective tree. In the objective tree, we get a violation of dynamic consistency. The starting point of this paper is that we can consider other information structures, i.e., trees, called subjective trees, in which no violation of dynamic consistency is directly revealed then. Imagine that the agent (decision maker) is really in a subjective tree situation of the latter kind. Then at least there dynamic consistency is not violated. Put yet differently, if the agent has the regular Ellsberg preferences, and does not violate dynamic consistency in a subjective tree considered by her, then we can be sure that that subjective tree is not the objective one. The author states it the latter way on p. 292: "whenever he does exhibit the Ellsberg preferences [and dynamic consistency is satisfied in his subjective tree], it follows that the assumption does not hold, so he is not using the tree in Fig.1 [objective tree], and the argument does not apply [to his subjective tree].”

The author investigates how all kinds of preferences can be reconciled with dynamic consistency when restricted to particular subjective trees, and also how such preferences need not exhibit aversion to free info at least in particular subjective trees. (**information aversion**) %}

Hill, Brian (2020) “Dynamic Consistency and Ambiguity: A Reappraisal,” *Games and Economic Behavior* 120, 289–310.

{% This paper considers quite general functionals for decision under ambiguity of the form αV(f) + (1−α)V*(f) where V can be any concave (“pessimistic”) functional and V* is its convex dual. The author rewrites these general functionals by means of inf and sup operators as can always be done according to Cerreia-Vioglio, Maccheroni, Marinacci, & Montrucchio (2011) “Uncertainty Averse Preferences,” *Journal of Economic Theory* 146. And he characterizes them. Big tool is that he assumes objectively generated ambiguity present in the preference domain, through objective probability intervals. The subjective intervals/sets can then be identified by finding matching preference-equivalent objective sets. A special case of this model is the popular α-maxmin, where the well-known identifiability problem of α is solved by adding those objective stimuli. Many other models can be specified and axiomatized as special cases, such as rank-dependent (CEU) models.

Ho, Joanna L.Y., L. Robin Keller, & Pamela Keltyka (2001) “Managers’ Variance Investigation Decisions: An Experimental Examination of Probabilistic and Outcome Ambiguity,” *Journal of Behavioral Decision Making* 14, 257–278.

{% Hypothetical choice.

The paper considers ambiguity about probabilities but also directly about outcomes. (**ambiguous outcomes vs. ambiguous probabilities**)

ambiguity seeking for losses: Find this indeed, and find ambiguity aversion for gains. The ambiguous probabilities are around 0.5, so, not very small. For reference point, the benchmark is taken that is imposed on managers.

reflection at individual level for ambiguity: Table 1 on p. 58 gives info on it. Subjects can choose ambiguous or unambiguous for gains and losses. This can happen for outcome ambiguity and for probability ambiguity.

Outcome ambiguity: The subtable upper right shows that of the subjects ambiguity averse for gains about 2/3 was ambiguity seeking for losses, and for the subjects ambiguity seeking for gains it was about the same. (**ambiguity seeking for losses**) So, this suggests independence of ambiguity attitudes for gains and losses.

Probability ambiguity: The subtable lower right shows that of the subjects ambiguity averse for gains about half was ambiguity seeking for losses, and for the 14 subjects ambiguity seeking for gains a majority was so for losses. So, this provides some counter-evidence against reflection at the individual level, but weak given the small number of ambiguity seekers for gains. The percentages in the table do not correspond with integers (29% out of 40 is strange for instance, because 12 out of 40 is 30% and 11 of 40 is 27.5%), and there may be typos.

The third experiment has only 20 subjects and only 2 ambiguity seekers for gains, and it gives no info on reflection at the individual level.

correlation risk & ambiguity attitude: Section 5.5 reports relations between risk- and ambiguity attitudes. %}

{% **decreasing ARA/increasing RRA**: use power utility;

probability weighting depends on outcomes: seems that they found this.

uncertainty amplifies risk: Although I found no place where this was stated explicitly, it is throughout their model and theory. For inverse S it is p. 786 middle, and Table 1 on p. 789 shows it.

ambiguity seeking for losses?: they use only probabilities .10, .50, and .90, and don't find very clear results for one thing because outcome curvature interferes.

Their model has nonadditive probabilities depend on many things, e.g. sign and size of outcomes.

risky utility u = strength of preference v (or other riskless cardinal utility,

often called value): P. 780: "The view adopted here is that the value of an outcome received following a choice made under certainty does not differ intrinsically from the value of the same outcome received following a choice made under risk or uncertainty."

P. 780: "We therefore model the subjective evaluation of decision outcomes by psychophysical functions while the weights given to probabilities are conceptualized as the end result of mental processes that reflect both cognitive and motivational factors." (**cognitive ability related to likelihood insensitivity (= inverse S)**) This supports: **event/outcome driven ambiguity model: event driven**

reflection at individual level for ambiguity & **reflection at individual level for risk**: although they have the within-individual data for gains and losses to see it in all three experiments, they report it in none of their experiments.

P. 791, Experiment 1: N = 96. Hypothetical choice.

P. 791, Experiment 2: N = 146. Hypothetical choice. Experiment 3: N = 49. Real incentives; **losses from prior endowment mechanism** and RIS.

P. 799: "However, it is important that future experimental work address the exact shape of the value function so that, without having to make *a priori* assumptions about either the value or the venture functions, it will be possible to attribute changes in risk attitudes to the value and venture functions as appropriate." Well, the **tradeoff method** of Wakker & Deneffe (1996) shows how to elicit value function properties!

inverse S; **risk averse for gains, risk seeking for losses**: Table 2 on p. 792 suggests some more risk aversion for gains than risk seeking for losses. Table 4 on p. 795 suggests the same for large outcomes, but the opposite for small outcomes.

risk seeking for symmetric fifty-fifty gambles: Table 4 suggests this strange risk seeking for fifty-fifty gambles. There is much risk seeking for small outcomes, probably because they were cents so that the **utility of gambling** may have caused this.

Real incentives: experiments 1 and 2 used hypothetical payments, experiment 3 used real incentives: **random incentive system**. **losses from prior endowment mechanism**: do this.

real incentives/hypothetical choice: Find small differences between real and hypothetical choices for gains, but large differences for losses. I guess that this may be because for losses they did (as always) from prior endowment mechanism. For real incentives they find more statistical power than for hypothetical choice.

P. 800: the coexistence of gambling and insurance can be explained by the overweighting of small probabilities.

P. 797: no clear relations between risk attitude and ambiguity attitude (**correlation risk & ambiguity attitude**). %}

Hogarth, Robin M. & Hillel J. Einhorn (1990) "Venture Theory: A Model of Decision Weights," *Management Science* 36, 780–803.

{% Exactingness: the degree to which one is punished for suboptimal decisions %}

Hogarth Robin M., Brian J. Gibbs BJ, Craig R.M. McKenzie, & Margareth A. Marquis (1991) "Learning from Feedback: Exactingness and Incentives," *Journal of Experimental Psychology, Learning, Memory and Cognition* 17, 734–752.

{% **inverse S:** They find that for losses; i.e., ambiguity aversion for unlikely losses and seeking for likely losses. They find more inverse S for ambiguity than for chance (**uncertainty amplifies risk**). So also: **ambiguity seeking for losses**;

They study losses and there they find reflection, in accordance with what PT predicts, see above.

reflection at individual level for ambiguity: they have only losses, so, no results on this.

They asked what is a reasonable premium for p-prob at losing $100,000, for various probabilities. They also cite market evidence (earth-quake insurance, flood-insurance, etc.) suggesting much ambiguity aversion for small-prob losses. %}

Hogarth Robin M. & Howard C. Kunreuther (1985) "Ambiguity and Insurance Decisions," *American Economic Review, Papers and Proceedings* 75, 386–390.

{% **PT: data on probability weighting**;

ambiguity seeking for losses & ambiguity seeking for unlikely: they consider losses and there the data confirm all the hypotheses of Tversky & Wakker (1995) perfectly well.

reflection at individual level for ambiguity: does not speak to that because only losses.

inverse S: there is risk aversion for small probabilities and risk seeking for high (not stated explicitly in the paper I think, but visible in Table 2, Fig. 2, Tables 4 and 5) (**Z&Z**!). (**uncertainty amplifies risk**) These phenomena are amplified for ambiguity, by ambiguity aversion for small probabilities and ambiguity seeking for high. (Note that only the consumer data are relevant. The “firm” data consider selling of insurance which means both gains and losses, and loss aversion being relevant. As expected by PT, there more risk aversion etc. is indeed found.) Unfortunately, the data for ambiguous probabilities may be prone to distortion by regression to the mean, which can be an alternative explanation of the overestimation of small ambiguous probabilities and understimation of high ambiguous probabilities. I do not understand the analysis in §3.4, in particular why M(p) + M(1−p) = 1 on page 18. If p and 1−p are ambiguous and subject to second-order distributions, they may, as mentioned by the authors, differ from their “anchor values.” The subjects, however, need not know that these referred to complementary events and may distort both downwards.

real incentives/hypothetical choice: they use hypothetical choice, and discuss it nicely on p. 13 penultimate para. %}

Hogarth, Robin M. & Howard C. Kunreuther (1989) “Risk, Ambiguity, and Insurance,” *Journal of Risk and Uncertainty* 2, 5–35.

{% **ambiguity seeking for losses**; **ambiguity seeking for unlikely**: Ambiguity aversion for unlikely losses: Consider only small probability (.001, .01, .1) losses, and there they find risk aversion, the more so as the probabilities are smaller. The result is amplified under ambiguity (**uncertainty amplifies risk**), which may however have been biased by regression to the mean. For price setting of professional actuaries aspects other than ambiguity attitude, such as asymmetric information and avoidance of winner’s curse (p. 38) can play a role.

reflection at individual level for ambiguity: only losses, so do not speak to that. %}

Hogarth, Robin M. & Howard C. Kunreuther (1992) “Pricing Insurance and Warranties: Ambiguity and Correlated Risks,” *Geneva Papers on Risk and Insurance Theory* 17, 35–60.

{% **ambiguous outcomes vs. ambiguous probabilities**: Study cases in which not only probabilities but also outcomes are ambiguous/unknown. Ask subjects about heuristics used. Known/unknown firms that sell VCRs etc. enhances contrast effect. Only small probabilities.

Nice (also done by Heath & Tversky 1991 and Zeckhauser 2006): P. 32 explains that they ask subjects to estimate unknown probabilities, and then later use objective known probabilities equal to those, so as to avoid the problem of ambiguity being confounded with belief effects, for which some earlier studies were criticized by Heath & Tversky (1991).

reflection at individual level for ambiguity: only losses, so do not speak to that. %}

{% §30.5: For event A with unknown probability, determines the "matching probability" p (without using this term), i.e., the probability p such that (A:x) ~ (p:x), through the BDM (Becker-DeGroot-Marschak) mechanism as follows. The subject chooses a number p for A. So as to give an incentive for truly giving the p satisfying the equivalence just mentioned, a BDM mechanism is used: First a prospect (j/100:x) is chosen randomly, by randomly choosing a number 1 ≤ j ≤ 100. Then the subject gets this lottery if j/100 > p, and (A:x) if j/100 ≤ p. %}

Holt, Charles A. (2007) "*Markets, Games, & Strategic Behavior*." Addison-Wesley, London.

{% A generalization of this paper that, like this paper, uses choices lists to obtain indifferences and utility (OK, CRRA instead of expo-power) to fit data, but that also allows for probability weighting and gain-loss differences and loss aversion, is in Tversky & Kahneman (1992), a paper cited three times moree often than this one, and part of the 2002 Nobel-memorial prize in economics.

They throughout equate risk aversion with utility curvature, as commonly done in economics, which assumes expected utility. I regret this.

This paper has often been cited (e.g., by Harrison & List 2004 p. 1031) as refuting the argument against real incentives that big stakes cannot be implemented, by interpreting the stakes of this experiment as big. I interpret it differently. Stakes of some hundreds of dollars are small. No one would do a decision analysis for those. For such amounts, below two month's salary, utility is close to linear. Whatever risk aversion is found here is due to probability weighting, loss aversion, numerical sensitivity, and other factors, and not due to “real” utility. Big stakes are when buying a house, a car, deciding on mastectomy to avoid risk of breast cancer, etc.

decreasing ARA/increasing RRA: Increasing relative risk aversion and decreasing absolute risk aversion is found. The authors do carefully distinguish between these two.

The paper points out that literature on auctions commonly assumes log/power utility. But then, there is more in this world than auctions …

Choosing between lotteries (p, 2.00; 1.60) and (p, 3.85; 0.10) for p = 1/10, 2/10, ..., 1. These were low payoffs. Also for 20 times higher payoffs, the high payoffs. So, real payments up to $77. (Also 50 and 90 times higher for 19 and 18 subjects, respectively.) So, main group has 20 x 3.85 = $77 as highest possible prize, and the 19/18 subjects have 50 x 3.85 = $192.50 and 90 x 3.85 = $346.50 as maximum outcomes.

real incentives/hypothetical choice: The **random incentive system** was used (good to let know for all the mainstream experimental-economics referees who do not know the individual-choice literature well and start complaining about this incentive system again and again).

Real-incentives low-payoffs and hypothetical high-payoffs had similar risk aversion, and real incentives high-payoffs had more risk aversion (even 40% of subjects doing all choices safe there). Whenever unqualified, these comments, as the paper, take risk aversion in a relative sense. Comparisons were within-subjects. High-real payment came after low-real payment. To participate in the high-real payments, subjects first had to give up their earnings of the low-payment, which they had to declare in writing.

[Failed conjecture of mine] This para is on a failed conjecture of mine. I once conjectured that this procedure might have generated a framing effect, where those who gained $3.85 in the first round will take that as status quo, and because of loss aversion will not want to risk ending up with less in the high-payment choice, which makes them avoid the risky option there in the 20x group (not in 50x and 90x groups because there all payments exceed $3.85). It would imply that those who gained $3.85 in the first round would be more risk averse later than others in 20x. Holt (June 20, 2003, personal communication) let me know that this did not happen in the data. Subjects who gained $3.85 in the first round even seemed to be less risk averse than those who gained the low risky outcome there, \$0.10. So, my conjecture there does not hold.

The idea of this paper that I like best is that they first do low-stake choice for (quasi)real, and then let subjects pay back before doing big-stakes choice for real. Thus, they can observe two real choices without income effect or anything, and do within-subject comparisons of real choices. It has been a fundamental problem of **revealed preference** that only one choice can be really observed, and the authors have found a way around this very fundamental problem. This is impressive. There is a considerable price to pay for what they achieve. That subjects are told that the small-stakes are real incentives even though it is already known at that stage that these incentives will not be paid for real is a mild form of deception (**deception when implementing real incentives**). The having-to-give-back can generate all kinds of emotions such as maybe some kinds of loss aversion, which is another drawback. Yet the fundamental revealed-preference problem solved is such a great thing, that it is worth the price.

The definition of the Saha utility in Eq. 2 is not correct for $r > 1$, when it becomes decreasing. It, therefore, better be divided by $1-r$, similarly to how this is commonly done for CRRA.

My main problem with the hypo-real test here concerns a contrast effect. If subjects have to do hypo but they already know that hypo is surrounded with real before and after, then it is very explicit that there was no necessity for hypo. Subjects will, therefore, not pay much attention to hypo. Because these hypo high-payments came immediately after the low real payments (with the high-real not seen yet), subjects just quickly do there the same as before low real. This is put forward by Harrison, Johnson, McInnes, & Rutström (2003, March) "Risk Aversion and Incentive Effects: Comment," p. 3: "Subjects who are minimizing decision costs are unlikely to think hard about their choices when offered a hypo task even if the payoffs are higher, and thus would be predicted to anchor to their previous response in the first low real task. The responses in the high hypo treatment indeed look much more like the responses in the low real task #1 than they do the subsequent high real task #3."

Hypo can be useful I think, but then subjects have to be well-motivated for it, in other ways than through real incentives. Thus real versus hypo is better tested between-subjects.

The experiment took each subject about an hour (Holt, November 16 '04, personal communication).

The method of eliciting indifferences through lists of ranked choices, where the switching point indicates indifference, while often ascribed to these authors in experimental economics, has been used before in many papers, for example Halter & Beringer (1960), Kahneman, Knetsch, & Thaler (1990), Tversky & Kahneman (1992, described verbally in Subsection 2.1 pp. 305-306, where they do refinement of the indifference interval in a second stage), Tversky & Fox (1995, described verbally on p. 273, with same procedure as in Tversky & Kahneman 1992), Fox & Tversky (1998, p. 882, again same procedure as T&K'92), Coller & Williams (1999), Gonzalez & Wu (1999), with more references in Mitchell & Carson (1989).

gender differences in risk attitudes: women more risk averse than men for low payment but not for high payment (lack of power there!?).

It is unfortunate that this paper ignored decades of preceding literature on risk attitude measurement. (**Prospect theory not cited**) The authors do cite K&T79 on p. 1645 top but only for the question of hypothetical choice, and not for its insights into risk attitudes. The citation of K&T79 on hypothetical choice probably serves to discard them as invalid because of doing hypo. The ignoring of preceding literature reminds me of a quotation by the prominent economist Carver who at the end of his career wrote:

"But if they think that they have built up a complete system and can dispense with all that has gone before, they must be placed in the class with men in other fields, such as chemistry, physics, medicine, or zöology, who, because of some new observations, hasten to announce that all previous work is of no account." Carver wrote this in his paper in QJE in … 1918! %}

Holt, Charles A. & Susan K. Laury (2002) "Risk Aversion and Incentive Effects," *American Economic Review* 92, 1644–1655.

{% **Prospect theory not cited**

Paper confirms and replicates the order effects in Holt & Laury (2002) pointed out by Harrison, Johnson, MvcInnes, & Rutström (2005). It does all choices of Holt & Laury (2002), but between-subjects so that each individual has only one kind of treatment. The increase of risk aversion due to increased stakes indeed becomes smaller but remains. They also do hypo like this, without order effect. Also here, the effects are reduced but do not disappear, although it gets small especially if one compares the random differences between their 2002 and their 2005 data that are of similar size.

real incentives/hypothetical choice: Big problem with hypo here, as in 2002, is that it is surrounded by real-incentive choices, not only for other subjects but also for other experiments that the subjects were involved in simultaneously. So, the order effect due to the preceding low-stake-real-incentive choice of Holt & Laury 2002 was removed, indeed, but there were other order effects because of other experiments, not reported, that the subjects were involved in. This contrast effect encourages the subjects to not take hypo seriously and, hence, what Holt & Laury do here, as in 2002, is not a good hypo experiment. P. 903, footnote 5, cites from instructions for hypo: "Unlike the other tasks that you have done so far today, the earnings for this part of the experiment are hypothetical and will not be added to your previous earnings." That is, the contrast effect is even made explicit. %}

{% **probability elicitation**: Proposes to use matching probabilities to measure subjective probabilities. Then it proposes the two-stage choice list to obtain indifferences, in an incentive compatible way. As with Holt & Laury (2002), it is easy and clean for a general audience of nonspecialists, but novelty and positioning are problematic.

The paper never explicitly writes that it assumes expected utility, but all theoretical analyses assume it. The paper claims that matching probabilities provide subjective probabilities while correcting for risk attitude, giving as argument that only two outcomes are involved and that utility can then be normalized (p. 111). Footnote 16 mentions works that use matching probabilities to asses ambiguity attitudes, but does not discuss what the empirical findings of ambiguity aversion, discussed elsewhere, imply for what this paper does. Dimmock, Kouwenberg, & Wakker (2016 MS, Theorem 3.1) gives a more advanced result.

That matching probabilities are not new is clear, and the paper cites many preceding works, such as Savage (1971). They were commonly used in early decision analysis; see also Raiffa (1968, p. 110, "judgmental probability").

The paper suggests novelty of the two-stage choice list procedure with incentive compatibility, but it was done exactly the same before for utility measurement by Anderson et al. (2006; cited in Footnote 11, but without discussing the overlap). The idea is to elicit, in a first stage, preferences between $\gamma_E 0$ (receiving gain $\gamma > 0$ if event E happens and 0 otherwise) and $\gamma_p 0$ for p = 0/10, 1/10, …, 10/10. If preferences switch between, say, p = 3/10 and p = 4/10, then in a second stage such preferences are measured for p = 30/100, 31/100, …, 40/100. A naive implementation of the RIS (random incentive system) would not work because subjects could manipulate by switching late in the first stage, getting nice options in the second stage. Incentive compatibility is achieved by first randomly selecting a choice from the first stage and implementing it, but when the choice involves the switching value only then a choice is randomly selected from the second stage. Again, this was done by Anderson et al. before.

A small variation of this two-stage procedure was introduced by Abdellaoui, Baillon, Paraschiv, & Wakker (2011 American Economic Review). They implemented somewhat differently, in a third stage. In that third stage they put up all 101 preferences between $\gamma_E 0$ and $\gamma_p 0$ for p = j/100, indicated all preferences implied by monotonicity there, asked the subject to confirm, and then randomly selected one of these 101 choices for implementation. I think that in this procedure incentive compatability is clearer to subjects. Because of space limitations, Abdellaoui et al. only explained their implementation in the Web Appendix to their paper. But the procedure was used in several follow-up papers by Baillon and others, for instance by Baillon & Blechrodt (2015 AEJ) in this same journal.

P. 135: the BDM (Becker-DeGroot-Marschak) method, however, is notorious for being confusing to subjects. %}

{% **PT, applications**, loss aversion & **decreasing ARA/increasing RRA**: Uses power utility; gaines and losses are treated differently; **risk averse for gains, risk seeking for losses** in his model. He reviews some empirical evidence, a couple of studies with each four or five subjects. %}

Holthausen, Duncan M. (1981) "A Risk-Return Model with Risk and Return Measured as Deviations from a Target Return," *American Economic Review* 71, 182–188.

{% This paper uses four well-known methods of measuring risk attitudes. It finds many differences between them, entailing inconsistencies. This has been found by several preceding papers. The novelty ("innovative contribution" they call it on p. 611) of the paper is that they also ask introspective nonrevealed-preference based questions, to see if subjects are aware of it and then maybe prefer to go for consistency. As they write, end of abstract: "subjects are surprisingly well aware of the variation in the riskiness of their choices. We argue that this calls into question the common interpretation of variation in revealed risk preferences as being inconsistent." However, I have difficulties with this. All the questionnaires do (§3.2) is to ask, on a 1-7 scale, to give an index of "riskiness," with several similar questions, e.g., about complexity and boringness, for the various methods and answers. It is completely vague what these terms are meant to mean. The authors argue, for instance, that deliberately consistent subjects should give the same indexes of riskiness (and others) for the four different methods. The authors interpret the differences found as awareness of the subjects that they give "inconsistent" answers but a deliberate choice to do so. Besides the alternative interpretation that subjects are not even aware/deliberate about all this, other alternative interpretations are that subjects

just let riskiness refer to other attributes than consistency of the degree of risk aversion found. In this respect the study is different than Slovic & Tversky (1974) and related studies.

Prospect-theory avocates will regret that the paper only assumes expected utility with logpower (CRRA) utility. True, if one wants no more than one quick index of risk aversion, then fitting EU with logpower utility is the most pragmatic way to go. But with the richer data here, investigating whether inconsistencies in EU can be accommodated by prospect-theory components, before concluding general inconsistency of preference, would have been desirable.

P. 596 top cites Slovic (1972a) as an early study showing that different methods of measuring risk attitudes can give different results. But the whole rest of the page only cites papers by authors defined as experimental economists. (**Prospect theory not cited**) The keyword **PE higher than CE** in this bibliography gives a little bit of the large preceding literature on it, as there are many studies on preference reversals, the constructive view of preference, and so on. A recent related study not cited is the impressive Pedroni, Frey, Bruhin, Dutilh, Hertwig, & Rieskamp (2017).

P. 598 last para, on choice lists, again only cites experimental economists. ((**Prospect theory not cited**))

P. 601: Unfortunately, to assess similarities of different methods, the authors do not use correlations. Instead, they lose power by adopting a sort of median split technique of either qualifying results as consistent (if difference not too big) or inconsistent. They argue for this in footnote 7 by developing one numerical example where correlation does not fare well. %}

{% Some places gave people bonusses (5 cents) when they reused a dispoosable bag rather than use a new one. Food retailers had to start it in Washington DC 2010. Other places charged 5 cents less but then gave no bonusses to people who used no new bag, but instead charged 5 cents tax for people who did. The bonusses had almost no effect, but the taxes reduced the use of new bags by over 40%. The authors explain it by loss aversion.

A large part of the study is dedicated to rule out other explanations, as is always difficult in field or real-world data. One alternative explanation to be ruled out is difference of info. iN the case of bonusses, people may not have known about it, but in the case of taxes they did. With questionnaires the authors check out that this is not the case. Still, I think it probably was. There is a difference between being in one's mind, and being on one's mind. The questionnaire checks out that the info is IN everyone's mind. But I conjecture that there is a difference when it comes to being on one's mind. People who do not get a bonus can know in the back of their mind that they missed a bonus, but just do not think of it when buying, not being reminded of it. So, they don't change. Those who pay a tax do think about it when buying, being reminded of it through the tax, so, they this as signal that they should change.

I am a bit amazed that the paper presents advanced formulas with utilities and optimality conditions. Seems to me that we immediately understand the exchange of 5 cents for a minimal extra effort, and that signaling more than utility is relevant here. P. 201 derives from the utility analysis an estimation of loss aversion of 5.3, which is large.

linear utility for small stakes: p. 182 bottom.

The authors conclude that taxes are more effective than bonusses. This was also suggested by Bentham (1828-43) [1782-7 no 236]; see my annotations there. It was also suggested by Thaler (1980). See my annotations there. %}

{% If the value of a good to be priced can depend on which random prize one chooses in BDM (Becker-DeGroot-Marschak), then, obviously, incentive compatibility can be distorted in just any way. This is the main point of the paper. At the end, it erroneously claims that BDM is incentive compatible under RDU. The mistake in the proof is that the integration that is used there implicitly assumes backward induction ("isolation"), because it just substitutes the value of the good also if it is a lottery. But with backward induction, every nonEU model would have incentive compatability under BDM. If subjects do not use backward induction but RCLA, then BDM need not be incentive compatible under RDU as it need not under any nonEU model. %}

{% Opening sentence: "The assumption that having more of a good will lead an individual to place a lower value on an additional unit of that good, which we call diminishing marginal value, is a pervasive component of economists' belief about human behaviour." Then some sentence after they relative it to the "Marginalist Revolution" of the 1870s. This misled me on first reading to think that the authors were after the much more interesting diminishing marginal *utility*, rather than diminishing marginal "value" (which is something like how much money you want to pay). They do distinguish, by e.g. discussing "Gossen's equivalent marginal utilities" in 2nd para on p. 1. But many readers can easily get confused. In reality they test the much less intesting question of whether marginal rate of substitution decreases in a good, with one special case where one of these two goods is money (the more you have of something the less you pay for an additional unit). They claim that diminishing marginal value has not been tested before but I guess that there must have been many investigations by economists and others into the behavior of marginal rates of substitution, especially if it is about how much money you are willing to pay. %}

{% **proper scoring rules**;

The authors paid three decisions, which generates some income effects.

This paper considers paying in probability of gaining a prize in the context of proper scoring rules, so as to have linear utility, given that under EU we have linearity in probability also if no linear utility in money. Thus, in a way, an EU maximizer is turned into an expected value maximizer. Paying in probability underlies the Anscombe-Aumann (1963) model. Selten, Sadrieh, Abbink (1999) made the nice observation that this expected value maximization is in fact generated for every probabilistically sophisticated agent (they did not use this term) who satisfies RCLA and prefers a higher to a lower probability at a prize, so that it is way more general than EU.

The present paper extends the technique to expected value optimization for eliciting variables more general than the subjective probability of an event or the mean of some variable (basically, subjective expected value of any given transformation) and scoring rules, following a preceding observation of this kind by Bhattachar & Pfleiderer (1985), and basically the same as the simultaneous independent Schlag & van der Weele (2013, *Theoretical Economics Letters*), but more general in allowing every transformation. This of course greatly extends the scope. As an example, if the reported number r is punished by |x(s) - r|, being its absolute distance from the realized value to a general random variable x, then under (induced) expected value maximization r will reveal the median of x. The subjective median of any random variable can be elicited this way. (This had been known before for utility linear in money by Bhattachar & Pfleiderer, 1985.) The paper first derives the results assuming subjective expected utility, and then provides the extension that Selten et al. also made, being that EU need not hold and only probabilistic sophistication should.

The paper implements the probabilities through comparisons with uniform rvs. If the value v = R(r,E) of the scoring rule R, depending on the answer r chosen by the subject and the true event E, is below the realization k of a random draw of an independent uniform distribution, then one receives some prize, and otherwise nothing. This means of course that one receives the prize with probability v. I always have some difficulty and need some time before I understand that the comparison with the uniform variable amounts to paying with probability v.

In an experiment, the method, which involves complex stimuli, gets closer to true objective probabilities (known and given to subjects, implying that they could simply take subjective probabilities equal to the objective probabilities readily available) than payment in money with the quadratic scoring rule, a result opposite to Selten, Sadrieh, & Abbink (1999). The authors discuss this point end p. 987 and pp. 997-998. It would be interesting here, and throughout, to redicuss the point using ambiguity theories and probability transformation with backward induction in the two-stage setup of this paper. %}

{% Characterize Sugeno integral. Axiomatizations can also be used to criticize a model. This paper is remarkable in doing so: It criticizes the axioms (their Axiom 4 is the main one carrying the intuition of the Sugeno integral) and thereby (and also because of inspection of examples) writes (p. 14): "In view of all this, it may be concluded that Sugeno preferences must have a very limited field of application, at least in the realm of decision theory."

The paper does not state uniqueness results. These are, however, interesting, because utility and the capacity//fuzzy measure are jointly-ordinal (if utility is bounded then, after normalization of utility, a common strictly increasing transformation can be applied to the capacity and utility). Hence, the Sugeno

integral can be used as an easy heuristic for an ordinal approach to decision theory. (This point I learned from Dubois in June 2000.) If I remember right (think I saw it proved in some paper for additive measures) the Sugeno integral never deviates by more than 25% from the Choquet integral. So, it can serve as a heuristic. %}

{% Choices are hypothetical.

Let subjects (students) express own preference between a risky and a riskless prospect, let them guess what an anonymous other person would prefer, and let them guess what their neighbor (a concrete other) would prefer. Subjects predict that abstract others are more risk seeking (both for gains and for losses), but concrete others are the same. A risk-as-feeling hypothesis is put forward to explain. It is that subjects perceive of their deviation from risk neutrality as a nontypical emotional point, less applying to neutral others. This works for losses because for losses they find, opposite to prospect theory's prediction (not pointed out by the authors), more risk aversion than risk seeking (see their Figure 1B). This complicates the finding. If, as usual, people are risk seeking for losses, then risk-as-feeling and others being more risk seeking become contradictory and it is not clear from this paper what to expect then. They also consider, but discard, other explanations such as a stereo-type explanation (others are Americans and their stereo-type is, as the authors claim, that Americans are venturous and risk-taking), where then it is apparently assumed that the other is defined as a member of a particular group, being American here.

P. 45 2nd para claims that people consider risk seeking to be an admirable property. But I expect that most people find risk aversion to be more appropriate.

P. 45 penultimate para: I do not understand why the term “risk-as-feelinigs hypothesis” is chosen.

P. 47 penultimate para of 1st column writes: “Consistent with prospect theory (Kahneman & Tversky, 1979), participants were more risk seeking in the loss condition than in the gain condition” but it does not mention that, contrary to prospect theory, they find risk aversion for losses rather than risk seeking.

In study 3 they try to incentivize the prediction of the other choice: Students were paired, seated next to each other, and received $50 if they predicted their neighbor’s choice correctly (p. 51 1st para). However, this is not a good incentive because it encourages everyone to choose, not what one likes, but what one expects one’s neighbor to predict. A practical problem is that it also encourages cribbing and communication. P. 51 end of 3rd para writes that not every right prediction gets rewarded, contrary to the 1st para, but only for 2 students out of 141 students. So, the expected value of this is about 66 cents. Also, for the abstract other, a right prediction of majority-preference was rewarded. %}

{% Degree of ambiguity in choices correlates positively with particular parts of the brains. Complete ambiguity is Ellsberg urn, other extreme is known urn. Then there are questions about temperatures in other cities, which are in between in ambiguity. There is also a guessing game against a better-informed opponent. In studies of ambiguity a difficulty is always how to control for belief. That is, people should avoid the unknown-probability event not because they consider it to be less likely as every Bayesian ambiguity neutral expected utility maximizer would then do the same way, but they should do it for other reasons unlike Bayesians. Unfortunately, this study does not control for level of beliefs. Thus, in the knowledge questions subjects may prefer betting on high temperature in New York to betting on unknown city not because of ambiguity aversion, but simply because they consider it to be more likely in New York. (They can choose to bet on or against so will bet where the event more likely than its complement is most likely.) In the informed opponent game it is even worse, because every ambiguity neutral Bayesian person and every person I can think of should rather play the uninformed opponent, then the probabilities simply being better.

Ambiguity arouses the same effects as the opponent-game. People with a particular brain damage are risk- and ambiguity neutral (although accepting a null with 6 subjects does not mean much), so, what many including me I consider rational.

The data in the electronic web companion is strange. Table S6 reports the parameters of risk and ambiguity aversion. For the card-deck data there is a clear majority of ambiguity seeking! (**ambiguity seeking**) This deviates from common findings in the literature and from suggestions in the main text (p 1681 bottom of 1st column describes ambiguity aversion for the card-deck as the usual thing; p. 1682 bottom of 1st column has a null not rejected which, given 12 (or 16 as in table S6?) subjects, is problematic). For the knowledge question there is a clear majority risk seeking, which is also weird.

When fitting the source function (where in many cases I do not know how they got the input p for the ambiguous events) they use the power family with the power as index of ambiguity aversion. %}

{% **Christiane, Veronika & I**: Subjects ("agents") should maximize the utility for someone else ("principal"), which consists of aggregating three components (ski vacation with price, probability of snow, and quality of slope). They are told exactly how to aggregate the values of the separate components, through a

weighted sum with both attribute weights and attribute values specified. Only, the values are not given numerically, but are indicated through points on a line (i.e., a kind of VAS score) without any ruler provided. So, the whole value system has been specified and only the numerical processing matters. The subjects were first trained through 7 choice and 9 matching questions in the first experiment, and a few more in a second experiment, where they received rewards as they were closer to the true values.

At the end, p. 88, the authors distinguish two steps in preference valuations: (1) Creating an internal representation of the information [values] and (2) expressing these representations through a specific task. I guess that, in our terminology, (1) refers to intrinsic value, (2) to, a.o., numerical sensitivity.

There are three modes of response, matching, choice, and rating. The authors write in the "paternalistic" way that I like, where biases are things to be corrected for (**paternalism/Humean-view-of-preference)**. They consider "negativity bias" (also called level focusing) which may be more general than loss aversion but with these data (three levels per attribute) is the same.

P. 86, on **Choice enhances noncompensatory heuristics**: the authors only mention it in passing by, "Given the noncompensatory heuristics that have been associated with choice," but instruct their subjects so much that in choice they still do compensatory.

Findings (pp. 86-87):

Strong scale compatibility. No prominence effect, if anything, the opposite.

- Choice: Authors are happily surprised that the subjects make compensatory tradeoffs among attributes, rather than resort to noncompensatory heuristics. The authors had deliberately instructed the subjects to this effect. There still is considerable loss aversion.

- Ratings: take less than half of time of other modes of response, have about half the loss aversion of choice, noisier.

- Matching: most difficult. Curvature of scale is best captured, no loss aversion

(rationale on p. 70: Matching pairs provides its own reference points), only problem is much scale compatibility. So, it's good for relative comparisons of the nonmatching dimensions. P. 73, however, suggests that matching enhances looking only at differences of attribute, thus to "overlinearization" (may contribute to: C**E bias towards EV**). Note, however, that linear processing of attributes seems to be rational in this empirical study, given that these are already evaluations of attributes.

Subjects judge that choice (not binary but always from triples) is best, then matching, last rating.

IMPORTANT: As the authors remark on p. 88, 3rd para, their finding is important because it shows that loss aversion occurs not (merely) at the level of intrinsic values, but also is a bias in the weighting of intrinsic values. So, it is not just in utility but alo in weighting: "In many settings, one cannot tell whether loss aversion is a bias or merely a reflection of the fact that losses have more emotional impact than gains of equal magnitude. In our choice and rating tasks, however, we found clear evidence that agents motivated to accurately represent the preferences of others gave more weight to negative outcomes than is appropriate." %}

{% Consider two-outcome prospects. Ambiguity was generated as second-order probability, with reduced probabilities 0.25, 0.50, and 0.75, and in ambiguity always one outcome was 0 (**second-order probabilities to model ambiguity**). It was not explained to the subjects what the reduced probabilities under ambiguity would be but subjects saw several drawings so that after a while they could figure out a bit about different levels of likelihood when deciding under ambiguity. For risky choice they assumed EU with relative risk aversion indexing risk attitude. For ambiguity they took the utility function inferred from risky choice, and then did α-maxmin for α from [0,1]; i.e., the model $(1-\alpha)u(x_1) + \alpha u(x_2)$ with $x_1 > x_2$. It is the usual two-outcome RDU or prospect theory or biseparable model, or Arrow-Hurwicz model (extended to multiple priors by Ghirardato & Marinacci 2004) given that subjects cannot know, apparently, what the level of likelihood is under ambiguity. They find that different parts of the brain get activated under ambiguity than under risk (e.g. p. 772: [risk and ambiguity] "represent two types of decision making that are supported by distinct [brain] mechanisms.". This is indirect evidence that risk and ambiguity are not related (**correlation risk & ambiguity attitude**). Although they have the data, they do not report relations between risk and ambiguity attitudes. %}

{% **conservation of influence**: Part 1, 118 seems to write: "[t]here is implanted in the human mind a perception of pain and pleasure as the chief spring and moving principle of all its actions"

paternalism/Humean-view-of-preference: Part 3 Of the will and direct passions, Sect. 3 Of the influencing motives of the will writes: "What may at first occur on this head, is, that as nothing can be contrary to truth or reason, except what has a reference to it, and as the judgments of our understanding only have this reference, it must follow, that passions can be contrary to reason only so far as they are accompany'd with some judgment or opinion. According to this principle, which is so obvious and natural, 'tis only in two senses, that any affection can be call'd unreasonable. First, When a passion, such as hope or fear, grief or joy, despair or security, is founded on the supposition or the existence of objects, which really do not exist. Secondly, When in exerting any passion in action, we chuse means insufficient for the design'd end, and deceive ourselves in our judgment of causes and effects. Where a passion is neither founded on false suppositions, nor chuses means insufficient for the end, the understanding can neither justify nor condemn it. 'Tis not contrary to reason to prefer the destruction of the whole world to the scratching of my finger. 'Tis not contrary to reason for me to chuse my total ruin, to prevent the least uneasiness of an Indian or person wholly unknown to me. 'Tis as little contrary to reason to prefer even my own acknowledge'd lesser good to my greater, and have a more ardent affection for the former than the latter. A trivial good may, from certain circumstances, produce a desire superior to what arises from the greatest and most valuable enjoyment; nor is there any thing more extraordinary in this, than in mechanics to see one pound weight raise up a hundred by the advantage of its situation. In short, a passion must be accompany'd with some false judgment. in order to its being unreasonable; and even then 'tis not the passion, properly speaking, which is unreasonable, but the judgment."

Seems to have said (p. 413): "Reason alone can never be a motive to any action of the will;" (p. 415): "reason is, and ought only to be the slave of the passions."

"a passion must be accompay'd with some false judgment, in order to its being unreasonable."

A nice citation of the immediacy effect, on p. 536 (may be in a 1896 edition), taken from Cohen, Ericson, Laibson, & White (2020 JEL):

"In reflecting on any action, which I am to perform a twelve-month hence, I always resolve to prefer the greater good, whether at that time it will be more contiguous or remote; nor does any difference in that particular make a difference in my present intentions and resolutions. My distance from the final determination makes all those minute differences vanish, nor am I affected by any thing, but the general and more discernible qualities of good and evil. But on my nearer approach, those circumstances, which I at first over-looked, begin to appear, and have an influence on my conduct and affections. A new inclination to the present good springs up, and makes it difficult for me to adhere inflexibly to my first purpose and resolution. This natural infirmity I may very much regret, and I may endeavour, by all possible means, to free my self from it. I may have recourse to study and reflection within myself; to the advice of friends; to frequent meditation, and repeated resolution: And having experienced how ineffectual all these are, I may embrace with pleasure any other expedient, by which I may impose a restraint upon myself, and guard against this weakness." %}

Hume, David (1740) "*A Treatise of Human Nature.*" (1978, Clarendon Press, Oxford.)

Cohen, Ericson, Laibson, & White (2020 JEL) give the following bibliographic info: Hume, David. 1896. A Treatise of Human Nature by David Hume, Reprinted from the Original Edition in Three Volumes and Edited, with an Analytical Index by L. A. Selby-Bigge, M.A. Oxford: Clarendon Press.
[1738].

{% **conservation of influence**: at the end of the section that deals with causation, Hume states:

"we may define cause to be an object followed by another, and where all the objects, similar to the first, are followed by objects similar to the second. Or, in other words, where, if the first object had not been, the second never had existed."

Second formulation is a difference-making idea. A cause makes a difference to whether its effect obtains: without it, the effect would not have obtained. %}

{% This paper redoes the well-known Slovic & Tversky (1974) study, but better implemented experimentally. P. 2 writes, modestly: "Whilst this contribution is modest in terms of innovation" I think the paper is useful.

P. 2 writes affirmatively: "the widely held view that the normativity of choice principles should be settled empirically (e.g. Tversky & Kahneman, 1986, p. S273; Gilboa, 2010, p. 4; Sunstein, 2018, p. 2)." I disagree. It is best determined by deep thinkers and specialists. The opinion of the average person has little to contribute, similarly as with the best move in a chess position or the best medical treatment of a disease. The citation of T&K86 is incorrect. T&K consider the question of whether incentives etc. can improve rationality, and not what rationality is. At the risk of being rude: T&K are too intelligent to write such a claim. Footnote 1 then adds: "Baron (2004) is a notable dissenter, who argues that normative theory should be determined solely through philosophical debate." Sunstein may only have argued that whether people want to be nudged is an empirical question, in which case the above citation of him would also be wrong, but I did not check in detail. I similarly disagree with the authors' criticism of Friedmann & Savage (1952) in the first two paras of §2 (p. 3 bottom). As I, Bayesian, disagree with the authors' normative conclusion in their Conclusion on p. 11, that they think to derive from their empirical finding: "Our data indicate that Maurice Allais was correct: it can be reasonable to violate the sure-thing principle."

The paper presents subjects both with an argument for satisfying the sure-thing principle, and for violating it as in the Allais paradox because of the certainty effect. It finds that more subjects are convinced by the certainty effect and switch to satisfy it than with the s.th.pr. (e.g., . 8). This finding is quite at variance with the finding of Nielsen & Rehbeck (2022), and the authors discuss it. My opinion: Nielsen & Rehbeck (2022) found purely demand effect. Their claimed test of that effect was way too weak.

Crucial for this paper is how the arguments for Savage and Allais are described. Here they are (p. 7):

Savage's position:

"In problem 1, if a ticket between 26 and 100 is drawn it does not matter whether I choose R or S. I would win € 14 irrespectively of how I choose. So I will ignore tickets 26 to 100. In problem 2 the same is true. If a ticket between 26 and 100 is drawn, it doesn't matter whether I choose R' or S'. I win nothing, irrespectively of how I choose. So I will ignore lottery tickets 26 to 100. Therefore, because I should always ignore tickets 26 to 100, the problems are exactly the same. In both problems, tickets 1 to 25 in options S and S' always pay me € 14. In both problems, tickets 1 to 20 in options R and R' always pay € 20, and tickets 21 to 25 pay nothing. It therefore makes no sense to switch choices between the problems. So I would choose either options R and R', or options S and S'."

Allais' Position:

"I would choose option S over option R in problem 1 and R' over S' in problem 2. In problem 1, I have the choice between € 14 for sure or a gamble where I might end up with nothing. Why gamble? The small probability of missing the chance of winning something seems very unattractive to me. In problem 2, there is a good chance that I will end up with nothing no matter how I choose. The chances of getting € 20 are almost as good as getting € 14, so I might as well go for the € 20 and choose option R' over S'." %}

Humphrey, Steven J. & Nadia-Yasmine Kruse (2024) "Who Accepts Savage's Axiom now?," *Theory and Decision* 96, 1–17. https://doi.org/10.1007/s11238-023-09938-8

{% This paper criticizes nudging techniques because advocates (including me) assume the existence of true correct best values. They assume that there is "something down there" (my words). The authors argue that this assumption is unfounded. For example, p. 13: "Thus, Hausman's analysis does not resolve the problem we identified in the literature of behavioural welfare economics. That problem was to justify the implicit assumption that, for any given individual, there exists some mode of latent reasoning that generates complete and context-independent subjective preferences." P. 22 (conclusion): "We need a normative economics that does not presuppose a kind of rational human agency for which there is no known psychological foundation."

The paper often cites Kahneman as an authority. It takes space to put every possible detail right.

P. 1 1st para describes what I call the Bayesian twin, although here it is broader:

"The task for welfare economics is then to reconstruct the preferences that the individual would have acted on, had her reasoning not been distorted by whatever psychological mechanisms were responsible for the mistakes, and to use the satisfaction of these reconstructed preferences as a normative criterion."

The paper sometimes calls that "preference purification" (title of §2 and elsewhere).

P. 2 3rd para: "Although there is a clear sense in which the choices made (or preferences revealed or judgements expressed) by the person in different contexts are inconsistent with one another, it is not at all obvious which (if any) of these choices is correct – or even how 'correctness' should be defined."

P. 7, on the often cited Bernheim & Rangel (2007, 2009): "Bernheim and Rangel's first line of approach is to propose a criterion that respects the individual's revealed preferences over pairs of objects if those preferences are not affected by changes in ancillary conditions, and instructs the planner 'to live with whatever ambiguity remains' (2009, p. 53). They then suggest that this *rather unhelpful criterion* might be given more bite by the deletion of 'suspect' GCSs. A GCS is deemed to be suspect if its ancillary conditions induce impairments in the individual's ability to attend to or process information or to implement desired courses of action." [Italics added]

P. 13 cites Hausman & Welch (2010 p. 128) pointing out that nudge does not fully 100% respect free will:

"something paternalistic, not merely beneficent …in addition to or apart from rational persuasion, they may 'push' individuals to make one choice rather than another … their autonomy – the extent to which they have control over their own evaluations and deliberations – is diminished. Their actions reflect the tactics of the choice architect rather than exclusively their own evaluation of alternatives. … limiting what choices are available or shaping choices risks circumventing the individual's will." (p. 130)

Infante et al. call the Bayesian twin the "inner rational agent." P. 14:

"We will call this disembodied entity the inner rational agent. … Preference purification can be thought of as an attempt to reconstruct the preferences of the inner rational agent by abstracting from the distorting effects of – by 'seeing through' – the psychological shell. … if the faults in the psychological shell were corrected."

Several parts discuss Bleichrodt, Pinto, & Wakker (2001), abbreviated BPW, in interesting manners. Little surprise that I disagree sometimes, in two places. The first is p. 20:

"BPW's purification methodology treats the non-linearity of the probability weighting function as a reasoning error … But where is the error? …

had used decision weights in the mistaken belief that they were objective probabilities. But that is not a remotely plausible account … remember that when people respond to Allais' problems, they are told all the relevant objective probabilities."

This discussion interprets probability weighting too narrowly. It need not just be wrong cognitive belief about probability. It can also be wrong FEELING while right knowing (imperfect numerical sensitivity), or pessimistic overattention to worst outcomes, or deliberate nonlinear decision weighting, e.g. by researchers who think that nonEU for risk is rational (which I Bayesian then still consider to be a mistake to be corrected for). The overly narrow interpretation of probability weighting here is called the second misunderstanding in Fox, Erner, & Walters (2015 p. 55).

P. 21 3rd para, middle of page, writes that BPW would not go by the preferences of the subject but by those of the professional: "Viewed in this way, what seems to be required is not an inference about the hypothetical choices of the client's inner rational agent, but rather a way of regularising the available data about the client's preferences so that it is compatible with the particular model of decisionmaking that the professional wants to use." However, BPW assume as default that the only thing the professional wants to do is maximize the subject's preferences. The professional does not have an own agenda.

P. 21 penultimate para goes a long way agreeing with BPW, despite the ("religious") difference in view on the existence of true values:

"In the same way, a medical decision-maker might reasonably use BPW's methodology to construct a tractable model of the client's preferences, regularised so as to be consistent with expected utility theory, without claiming that the preferences in the model were latent in the client. The arguments we have developed in this paper would not be objections to a version of behavioural welfare economics that claimed only to regularise revealed preferences that were inconsistent with conventional theory, without interpreting this process as the identification and correction of errors, or as a way of helping individuals to make better choices. But that is not the version of behavioural welfare economics that is to be found in the literature." The authors introduce the term regularisation for the pragmatic application of BPW (so, in fact, EU) described in the above para, where no latent preferences are assumed to exist and EU is not assumed to be normative, but it is done pragmatically in the absence of what else to do. %}

{% **gender differences in risk attitude**: women are more risk averse than men.

They measure risk aversion assuming EU and finding CRRA. They measure subjective discount rate by fitting hyperbolic discounting, where they take some indifferences and assume linear utility. Because they have utility curvature for CRRA risk aversion they could use this utility function to correct discounting for utility curvature, as in Andersen et al. (2008 Econometrica) and others. But they are not clear on whether they did so and probably they didn't, and simply assumed linear utility. The latter is better than the Andersen et al. method because EU utility is more distorted by nonEU risk factors than that it brings true utility for risk, let be for intertemporal.

For risk and time attitudes, they consider two different outcomes: Money and number of plants planted that are good for the environment. They call these monetary and environmental environments. The differences they claim in risk and time attitudes can be due simply to different utility of the two kinds of outcomes. Utility curvature of money can be different than of plants, as these can be different than for apples, pears, quantity of wine drunk, and so on. %}

{% **probability elicitation**: applied to experimental economics. Measures matching probabilities of the right to play a strategic game against an opponent. Interprets playing the game as ambiguity. This is often done. One usually does not know the probability of what the opponent does. But a difference may be that strategic considerations concern more than what is usually called uncertainty (or ambiguity).

Very correctly, points out that we can’t measure ambiguity attitude without speculating on beliefs. However, belief is then simply measured by direct questioning, nonincentivized (discussed in §7.2), and is taken to be additive. This is similar to what some (Fox, Tversky, Wu, Gonzalez) have called the two-stage model, although they allowed for nonadditive beliefs. Given additivity of beliefs assumed, it is in fact the source method.

Next, matching probabilities are measured (if I understand right) from binary choices between playing the game and playing a lottery. From this, subjects are categorized into three categories: Ambiguity averse, ambiguity neutral, and ambiguity seeking. They are also divided into three categories of risk averse, risk neutral, or risk seeking, and in three categories regarding sophistication or naivite (naïve is taken here very strictly to mean not reckoning at all with the opponent's side and taking the probabilities over his strategies uniformly; 10% of the subjects will be that) versus sophisticated (reckoning with other's plans in any way). The percentages of **ambiguity seeking,** ambiguity neutrality, and ambiguity averse are 32/46/22, so that ambiguity aversion is the least prevalent. Not very surprising given that here other, strategic, aspects play a role. (**game theory as ambiguity**)

nonadditive measures are too general: P. 367 4th para rightfully says that nonadditive capacities are too general, and then assumes in fact the source method of Abdellaoui et al. (2011): probabilistic sophistication within the ambiguous (meaning game) source and the risky source, with the weighting function (I would call it source function) different for the two sources so, no global probabilistic sophistication. P. 369 para −4 erroneously cites Epstein for this approach. Epstein took probabilistic sophistication as designating unambiguity (risk), and took deviations from probabilistic sophistication as ambiguity. He with much emphasis did not want any exogenous concept of unambiguous. Thus, if there is probabilistic sophistication within two sources, as is the case here (and as also in Ellsberg 2-color), then he had no tool for saying which is unambiguous (his event-derivatives are impractical in this experiment, as everywhere). Ivanov takes neo-additive weighting functions with only one parameter, the pessimism parameter, by multiplying beliefs by (1−c) (p. 360 para −2). Thus, he can only capture the pessimism component, and only the positive part of it (negative pessimism, i.e., optimism, is excluded beforehand) and he also does not capture the orthogonal insensitivity component.

correlation risk & ambiguity attitude: the author does not explicitly discuss this, but from Figure 2 (p. 384) lowest panel one can see that risk aversion is negatively correlated with ambiguity aversion, where the latter is described above is not just common ambiguity but also involves preference for strategic uncertainty. %}

Ivanov, Asen (2011) “Attitudes to Ambiguity in One-Shot Normal-Form Games: An Experimental Study,” *Games and Economic Behavior* 71, 366–394. https://doi.org/10.1016/j.geb.2010.05.009

Iyanaga, Shôkichi & Yukiyosi Kawada (1977/1980) “*Encyclopedic Dictionary of Mathematics*, Vols 1 and 2.” Mit-Press, Cambridge, MA.

{% One should watch out that probability can mean nonadditive measure in this paper (footnote 4). But the probability measures in the prior set $\mathcal{P}$, and the second-order measure ξ, are meant to be additive (Izhakian, personal communication, April 24, 2017).

The author introduces a new ambiguity model (name: see title of paper), combining ideas of the smooth model with Schmeidler’s RDU. It takes a two-stage approach as the smooth model does. For risk, known probabilities, it still assumes EU so that a vNM utility function U captures risk attitude. But then, unlike smooth, the second order integral does not involve an extra utility transformation, but an RDU Choquet-type integral with the nonadditive measure capturing ambiguity attitude. (Reminiscent of Giraud 2014.) Whereas an ambiguity-neutral person would use goodnews probabilities that are linearly weighted (through 2nd order probabilities) averages of goodnews probabilities, the author here inserts a transformation Υ (this is a capital upsilon and it is called the outlook function) on [0,1] giving a quasilinear mean, doing mathematically with goodnews probabilities what certainty equivalents in EU do with outcomes. This “certainty-equivalent probability” is called perceived probability, and is a matching probability. The expected probability of an event is the probability assigned by the ambiguity neutral twin. Concavity of the transformation Υ pushes down all the resulting goodnews probabilities, bringing extra pessimism and, hence, ambiguity aversion, and with convexity it all is opposite.

Interestingly, if the aforementioned transformation ϒ is S-shaped (opposite of inverse S) in the sense of convex then concave, then this gives likelihood insensitivity: The goodnews probabilities for best outcomes are small and all move in the area where the transformation ϒ is convex, giving overestimation and extra optimism there. For worst outcomes we similarly get underestimation of the goodnews probabilities and extra pessimism. Because these things do not involve direct convex combinations I can't see through the behavioral implications completely. It also seems that not the absolute level of the transformation ϒ, but its local degree of convexity/concavity, determines its effects here. Besides the outlook function there also is a capital gamma Γ function that further affects how the events are weighted in an overall Choquet-type integral.

The model has attitudes referring to (the set of) probabilities and, thus, is event driven rather than outcome driven. (**event/outcome driven ambiguity model: event driven**). For losses, the author does not use a reflected integral, as with PT, but the same integral, as with CEU/RDU. If I understand right, this is taken as reference- or sign dependence.

For the aversion to mean-preserving spreads to which concavity of ϒ is equivalent, we need 2nd order probabilities exogenously given to make this directly observable. %}

Izhakian, Yehuda (2017) "Expected Utility with Uncertain Probabilities Theory," *Journal of Mathematical Economics* 69, 91–103.

{% This paper is criticized by Fu, Melenberg, & Schweizer (2023), with a reply by Izhakian (2024).

event/outcome driven ambiguity model: event driven: The degree of ambiguity depends on the partition generated by the outcome-relevant events, but not on the outcomes otherwise. The author puts this very central. He also emphasizes that it is independent of risk attitude, although his job here is simplified by assuming expected utility for risk so that risk attitude is purely outcome driven. He uses his 2017 EUUP model, and uses a generalized expected volatility of the 2nd order probability distribution as an index of ambiguity. This

paper gives theoretical background to the empirical Brenner & Izhakian (2018).

The more-ambiguous-than ordering of events in Def. 2 can only be done for events with the same (what I would call the) a-neutral probability, i.e., expected probability where the expectation is taken over 2nd order probabilities. Definition 3 gives a behavioral equivalent but one problem is that it still requires the, not directly observable, restriction of same a-neutral probabilities and, further, quantifies over all ambiguity averse agents.

P. 25, last para of §6, correctly writes that the ambiguity indexes of Baillon et al. (2018 ECMA) do not distinguish ambiguity in info/events from ambiguity attitude. Unlike other popular ambiguity theories, the theory of Baillon et al. does not want to claim such a separation. I think that it is too early to claim such separations, and the claimed separations in the literature are ad hoc. %}

{% **natural sources of ambiguity; uncertainty amplifies risk**; **event/outcome driven ambiguity model: event driven**

This paper applies Izhakian's ambiguity theory of expected utility with uncertain probabilities (EUUP) to finance.

Footnote 20 writes that the indexes of Baillon et al. (2018) only work for exactly three events. However, Baillon et al. indicate that the extension to any number of events of three or more is provided in a follow-up paper, now appeared as Baillon, Bleichrodt, Li, & Wakker (2021 JET). The authors are right that the insensitivity index of Baillon et al. is attitude dependent, whereas they take an ambiguity index exogenously generated by data and not by attitude.

P. 4091 claims that most ambiguity models today are outcome dependent, citing the smooth ambiguity model that I also consider to be outcome dependent. However, they claim that maxmin EU is also outcome dependent, whereas I consider it to be event dependent. Other event dependent ambiguity models, such as Schmeidler (1989) and its variations Tversky & Kahneman (1992) or Abdellaoui, Baillon, Placido, & Wakker (2011) are not cited here. Later the authors EUUP is presented as a variation of Schmeidler (1989).

This paper derives the exogenous ambiguity from volatility over time and turns that into a set of priors. Greater risk leads firms to decrease leverage. but greater ambiguity to the opposite, increase leverage. Many people take ambiguity as a sort of increased risk and then this result is surprising. %}

{% **event/outcome driven ambiguity model**: Partly event driven, through belief-function limits of contained objective-probability events, but also partly outcome driven, through the function α that depends on the minimal outcome m and the maximal outcome M.

Gives a separation of ambiguity into information and attitude, and is the first to provide so cleanly. Whereas Jaffray was fine with subjectivity in utility functions, he abhorrored of subjectivity in the processing of information. Hence, he preferred to split up ambiguity into a risk part, where objective probabilities are given, and a part where it is not, but then the latter should also be treated in some objective manner. Combining risk with uncertainty happens in the well-known Anscombe-Aumann (AA) framework, but this is unfortunate because it puts the nonprobabilized uncertainty in the first stage and conditions on it, which is unfortunate because it is better to condition on risk than on uncertainty. (My criticism here applies to the AA framework as used nowadays, 2022 and before, to analyze ambiguity, which is not what AA (1963) themselves did.) Hence, Jaffray put the risk part first, and conditioned on risk. It leads to the following model, where the 1st stage events can be anything but they are called messages. First, with probability p_i, a message M_i is received. The p_i are often called mass distribution (or basic probability). After that a stage of ambiguity results, where there is no more objective info. Jaffray used his model of complete absence of info, in the spirit of Cohen & Jaffray (1980). The only info one receives from the message is what the set of possible outcomes is that will result.

Two-stage info as above, an objective probability distribution over subsets of outcomes, amounts to Dempster's (1967) model of random messages, and can be captured by a belief function. Given the belief function, the probabilities over the subsets of consequences can be gotten back as the Möbius inverse of the belief function. Möbius inverses can be calculated for every nonadditive set function, but they are nonnegative if and only if the nonadditive set function is a belief function. A belief function is very convex/pessimistic, and is a lower probability. One can also capture the info through the dual of the belief function, the plausibility function, which is very concave/optimistic. Shafer's (1976) belief functions are similar, the only difference being that the probabilities over the messages are subjective, which is what Jaffray would not want.

Now follow details and notation. Let X be an outcome set (it is that more than a state space, as it is originally called in this paper), F the set of all belief functions (could be extended to capacities) on X, and let a preference relation over F be given. We can mix belief functions, and impose the usual vNM mixture-independence condition on preferences (this is best conceivable if the belief functions are exogenously given). It characterizes a preference functional over belief functions, linear w.r.t. mixing. Through Möbius inverses, belief functions can be considered linear mixtures of elementary set functions e_B (e_B(A) is 1 if A contains B, and is zero otherwise). Under a monotonicity axiom, amounting to complete absence of information for such elementary set functions, the preference value of B can depend only on its supremum and infimum (like α-Hurwicz but α depends on outcomes). This can be taken as **ambiguous outcomes vs. ambiguous probabilities**, but properly assumed to concern the state space. We can interpret the mixture weights of the Möbius inverse as probabilized uncertainty, and the e_Bs as the nonprobabilized information which is to be treated as total absence of information, so as to avoid any subjective inputs (this latter avoidance is a central point in all of Jaffray's work).

A justification of mixture operation for belief functions can be found in Jaffray's 1991 publication in the FUR-IV proceedings (Chikan ed.). %}

{% P. 165 2nd para describes matching probabilities. 3rd para points out that they can violate additivity.

paternalism/Humean-view-of-preference: P. 165 4th para puts it right: "As in medicine, prescriptions should rest on diagnoses and diagnoses rely on the study of pathologies. Judgment psychology had identified several sources of 'biases,' "

P. 175 Proposition 1, Corollary 1, and p. 176: This paper characterizes the special case of CEU/RDU where the weighting function/capacity a convex combination (with constant mixing weight α) of a lower and upper probability. (P. 168 ℓ. below Eq. 7 points out that in general lower probabilities need not be convex but are only superadditive—what I like to call subadditive.) In the special case of f convex it is, therefore, also a special case of α maxmin. NOTATION: The capacity v is αf + (1–α)F, with f denoting a lower probability and F an upper probability. The upper and lower probabilities are exogenously given.

The main structural restriction (p. 179 (A1)) is that the authors assume a rich set of risky events available, i.e., with known probabilities, that can be used to mix a rich set of ambiguous events in a kind of Aumann-Anscombe model (so, the roulette wheel precedes the horse race, which is better than the more common other way around). This extra structure is called objective imprecise risk. The authors assume that here the Jaffray (1989) model holds. This assumes expected utility for risk.

The paper was not written in an accessible manner because it gives many mathematical derivations and results in the flow of the text. %}

James, William (1884) "What is an Emotion?," *Mind* 9, 188–205.

{% **free will/determinism**

This paper has the lively beautiful style that research papers written before 1930 typically have. The author uses an overdramatic style of writing. Or maybe I should say speaking, because it was a lecture. For example, the opening lines on there not being a less worn out topic than free will/determinism. End of opening para seems to say that whether free will exists cannot be proved by arguments, but is a choice of free will itself.

2nd para seems to confuse "is" and "ought" in "If a certain formula for expressing the nature of the world violates my moral demand, I shall feel as free to throw it overboard," but probably I misunderstand something here, the more so as I do not understand the rest of this para.

The author throughout seems to take the word chance to refer to physical, rather than epistemic, uncertainty, and the latter concept, so central in my thinking, seems to play no role in this text. Hence, forn him, the existence of chance contradicts determinism.

Soft determinism seems to refer to the combination of determinism with free will, which is quite my view (although I more favor not committing to (in)determinism), and I agree with “for freedom is only necessity understood” as the author describes soft determinism, where I side with the cited Mr. Hodgson who is said to call himself a “free-will determinist.” (Later, in a para starting with “So much for subjectivism!”, James will prefer subjectivism (soft determinism) to pessimism (hard determinism).) James cites the nice

“And the first morning of creation wrote

What the last dawn of reckoning shall read.”

This text puts it well: “Both sides admit that a volition, for instance, has occurred. The indeterminists say another volition might have occurred in its place: the determinists swear that nothing could possibly have occurred in its place.”

The authors argues that facts will never show if there are/were several possibilities (i.e., indeterminism) or only one (determinism), but it is our sentiment of what we find more rational. The author uses the term “rational” not in the decision-theory way, but as sort of intellectually acceptable/plausible.

The author seems to consider only one kind of chance; due to due to uncertainty about decisions by others. Not chance purely in nature. This is not really said, but surely suggested, by “Indeterminate future volitions do mean chance.”

conservation of influence: He brings up an essential ingredient in what I call influence: regret. You think about what would have happened had you done something else than you did.

Funny is the story “Hardly any one can remain entirely optimistic after reading the confession of the murderer at Brockton the other day: how, to get rid of the wife whose continued existence bored him, he inveigled her into a desert spot, shot her four times, and then, as she lay on the ground and said to him, ‘You didn’t do it on purpose, did you, dear?’ replied, ‘No, I didn’t do it on purpose,’ as he raised a rock and smashed her skull.” He later nicely describes regret “though it *couldn’t* be, yet it *would* have been a better universe with something different from …” [italics from original]

Nice sentences:

“Not the doing either of good or evil is what nature cares for, but the knowing of them.” James calls this subjectivism, a term he prefers to gnosticism.

“if determinism is to escape pessimism, it must leave off looking at the goods and ills of life in a simple objective way, and regard them as materials, indifferent in themselves, for the production of consciousness, scientific and ethical [subjective], in us."

"But then the moral judgments seem the main thing, and the outward facts mere perishing instruments for their production. This is subjectivism."

"Not the saint, but the sinner that repenteth, is he to whom the full length and breadth, and height and depth, of life's meaning is revealed."

"Look to thyself, O Universe,

Thou are better and not worse,

we may say in that philosophy, the moment we have done our stroke of conduct, however small."

On a philosophy of objective conduct: "But this means a complete rupture with the subjectivist philosophy of things. It says conduct, and not sensibility, is the ultimate fact for our recognition." I must admit that I don't see an inconsistency between subjectivism and the philosophy of objective conduct.

At end James states his own view. He cannot imagine qualifying things as good or bad, and feeling regret about one's (bad) actions, unless the world is indeterministic: "And if I still wish to think of the world as a totality, it lets me feel that a world with a chance in it of being altogether good, even if the chance never come to pass, is better than a world with no such chance at all." I did not discover any more argument advanced by him. He does restate that whether free will exists cannot be proved by arguments, but is a choice of free will itself.

He ends with reconciling indeterminism ("chance") with the existence of the allmighty providence. The allmighty providence gives us small local freedom, but on a larger scale takes care that everything goes his way still. Like a good chess player not knowing what exact moves his weak opponent will make, but yet knowing he will end winning the game. %}

James, William (1884) "The Dilemma of Determinism," lecture to Harvard Divinity School students.

{% **measure of similarity**;

Ideomotor theory: the notion that conscious goals and images are inherently impulsive, and tend to be carried out by default, unless they are inhibited by other conscious thoughts or intentions.

free will/determinism: Seems to have written: "Now how do we ever get up under such circumstances? … We suddenly find that we have got up. A fortunate lapse of consciousness occurs; we forget both the warmth and the cold;… the (spontaneous) idea flashes across us, “Hollo, I must lie here no longer” --- an idea which at that lucky instant awakens no contradictory or paralyzing suggestions, and consequently produces immediately its appropriate motor effects. ... This case seems to me to contain … the data for an entire psychology of volition” %}

{% Table 1 in a nice didactical way indicates relations between discount factor, discount rate, present value, and other things.

They also propose a sort of continuous extension of quasi-hyperbolic. Time is taken continuously. Then first during some period, “extended present” (my term) there is constant discounting (say the period during which present self controls), but after it suddenly drops by a factor, but other than that keeps the same exponential. There are some drawbacks to this model, as I read in a paper by Pan, Webb, & Zank. For instance, to accommodate (day 0: 1 apple) ≻ (day 1: 2 apples) and (day 365: 1 apple) ≺ (day 366: 2 apples), the well-known violation of stationarity put forward by Thaler, the point of change of regime must be either between day 0 and day 1 or between day 365 and day 366. This is too restrictive. %}

Jaspersen, Johannes G. & Marc A. Ragin (2020) "A Model of Anchoring and Adjustment for Decision-Making under Risk," working paper.

{% This paper measures the general introspective risk aversion question (GRQ) used by Dohmen et al. (2011) and others. N = 1730 subjects from Qualtrics and 378 subjects in the lab. It also measures lottery choices through choice lists. For the latter it does PT data fitting with five parameters: Concavity of utility for gains, concavity of utility for losses, loss aversion, likelihood insensitivity for probability weighting for gains, and likelihood insensitivity for probability weighting for losses. GRQ is correlated with loss aversion and concavity of utility for losses, but not with the other three parameters. It suggests that people take the GRQ to primarily concern losses. Linguistically, risk indeed is often taken to refer only to losses. I was glad to see that the authors consider likelihood insensitivity. %}

{% **marginal utility is diminishing**: Jn 1889 edn. seems to be stated on p. 173.

decreasing ARA/increasing RRA: 1889 edn. seems to have stated it on p. 172/173.

Seems that Jevons resolved the paradox of value (water is more useful than diamonds but we pay less for it) by considering marginal utility and, thus, turned utility into a central concept for economics. This constitutes the revolution of marginal utility of around 1870, where also Menger (1971) and Walras (1874) came up with the idea of marginal utility. Sugden wrote that they showed that for any pair of goods and for any consumer who maximises utility, the ratio of the marginal utilities of those goods is equal to the ratio of their prices.

Seems that Jevons used the term hedonic force for utility (**conservation of influence**). Edgeworth later also seems to have done.

P. 6 of 1911 edn. seems to write: “Utility is plainly the subject-matter of economics from beginning to end … the object of Economics is to maximize happiness by purchasing pleasure, as it were, at the lowest cost of pain.”

P. 36 of 1911 edn. seems to express/suggest the thought that a person could find out about his strength of preference through introspection; this str. of pr. then could as well serve as vNM utility, certainly in a normative sense.

Was like Bentham but formalized more/better (Selten grouped these two together) Seems that he was not very good at doing formal analyses.

P. 51:

“Utility may be treated as a quantity of two dimensions.”

Those are intensity and time.

Pp. 61-62 seems to write: “the final degree of utility is that function upon which the whole Theory of Economy will be found to turn.”

Pp. 72-73: d**iscounting normative**: Argues against discounting (unless for uncertainty). Strotz (1956) cites Jevons, pp. 77-80, as: “people of good sense will not discount the future except for uncertainty-but people do discount the future in accordance with its remoteness.”

P. 85 seems to state impossibility of interpersonal comparison of utility.

Stigler cites him as pessimistic on measuring utility. %}

Jevons, W. Stanley (1871) “*The Theory of Political Economy.*” (5th edn. 1957, Kelley and MacMillan, New York; other edn. Penguin, 1970.)

{% Act f is more ambiguous (I) than act g if an ambiguity averse DM prefers g to f whereas an ambiguity neutral replica of himself is indifferent. It is extended to more ambiguous (II) if, the more ambiguity averse the agent, the more compensation he requires for f. Is analyzed for α maxmin and smooth ambiguity model. The use of ambiguity neutral replica is reminiscent of the ambiguity definitions of Epstein and Ghirardato & Marinacci, who chose either probabilistically sophisticated or expected-utility maximizing replicas of the DM as ambiguity neutral, and the difficulty is that such replicas are not easily observable. The separation of ambiguity and ambiguity attitude is by assuming ambiguity attitude constant. %}

{% The Prince method introduced in this paper improves existing implementations of the Random Incentive System (RIS). I consider it to be one of the best papers I ever co-authored, and the time investment was infinite. At the beginning of the experiment, subjects receive a sealed envelope that already contains a description of the choice situation that will be implemented at the end, called the real choice situation. This treatment much enhances the "isolation" perception needed for validity of RIS. It also combines the pros of matching (subjects directly state the value to make them indifferent; takes little time to get precise info) with the pros of choice lists (easy to understand for subjects and to implement). Drawback:

implementing Prince takes nontrivial prior work for the experimenter. In chained/adaptive experiments, it takes predicting what choice situations may plausibly arise, but gives a big pro in return: no possibility for subjects to manipulate, and zero perception at their end of such a possibility.

Some studies used a variation of Prince where not the choice situation is contained in the envelope given beforehand, but only a number indicating what the real choice situation will be. See Loomes, Starmer, & Sugden (1989 EJ) and Epstein & Halevy (2018 p. 674 §3.3). This loses most of the punch. Number of choice situation is-not choice situation. For instance, the experimenter may change the numbering during the experiment, depending on what the cheapest choice is that the subject(s) made. The point is discussed on p. 21 2nd para of §6. %}

{% Consider infinite streams of outcomes, and consider preference orders that are anonymous (which is not easy for infinite streams). Characterize maximization of $\sum_{j=1}^{\infty} x_j$ over real-valued bounded infinite streams $(x_1,x_2,\ldots)$. They consider the more general overtaking criterion $\lim_{j\to\infty}\sum_{j=1}^{n}(x_j - y_j) \geq 0$ and eventually periodic streams, as in their 2015 paper. The novelty of this paper is a generalization: the limit-discounted utilitarian criterion (LDU), which takes liminf instead of lim above but adds a discount factor tending to 1. This generalizes overtaking criteria and refines by having more strict preferences. The main characterizing preference condition is the compensation principle: postposing all outcomes by one period and compensating by giving the average in the first period, leaves the sequence indifferent. Pivato (2022 pp. 8-9) explained how LDU refines AU overtaking representations, by turning some indifferences into strict preferences and thus restoring strong Pareto, which then is reconciled with fairness. These representations do not satisfy completeness on the domain considered. %}

{% **proper scoring rules**; Show that in a mathematical sense scoring rules amount to the same as optimizing particular utility functions in decision situations and to measures of entropy.

They take the family of utility with risk tolerance (reciprocal of Pratt-Arrow index of risk aversion) linear in money x. The slope β is the power of power utility and is index of risk aversion. Exponential utility is when slope β is 0. So, level of absolute risk aversion does not count.

Eq. 1: I guess that the capital delta, described as the gradient of V(r,r) w.r.t. r (also denoted as V(r) or as V by the authors), should be the linear function p --> V(r,p) − V(r,r) (which is its own gradient). %}

Joyce, James M. (1999) “*The Foundations of Causal Decision Theory*.” Cambridge University Press, Cambridge.

{% For subjective probabilities, makes the well-known distinction between balance and weight. Then there is a third dimension, specificity. It apparently means something like whether all pieces of info that led to the probability assessment supported that probability assessment, or if some pieces supported higher probability assessments and others supported lower ones. Probably similar to expert aggregation where a difference is made between imprecise and conflicting expert judgments. In the author’s approach if no probability measure is known then it must be a set of probability measures (as with people who always exclusively think in terms of sets of priors). Then specificity for some event is maximal if all probability measures in the set of priors assign the same probability to that event. I do not really see that this would be a new dimension apart from balance and weight.

The paper assumes that if your credal state is not reflected by one probability measure, then it is by a set of probability measures. (I did not see it refer to higher-order beliefs with 2nd-order probabilities over those probability measures.) It does not look much into alternatives. P. 154 claims to show that it can only be this. The paper also takes Bayesianism not to assume completeness of preference and, hence, not one unique probability measure (§2 ℓ. 2).

The paper uses the term bias not in the sense of mistake, but in the sense of subjective info.

P. 168: U4 is a case of an urn with colored balls with total absence of info on the composition, and the author really does not want the principle of insufficient reason then (“it is clearly wrong in the fourth,” middle of p. 168).

Sentences such as that subjective probabilities accurately reflect total evidence are fine if reflect means the weak depend on, reckon with. They are off if reflect means that they completely capture everything relevant. %}

{% Application of ambiguity theory;

Assume repeated decisions at timepoints 1, 2, …, where at each timepoint the smooth model of KMM holds, and a recursive model is used. They emphasize that they get a clear separation between risk attitude (vNM utility), ambiguity (the 2nd order probability distribution of the smooth model), ambiguity aversion (through the second-order utility function φ of the smooth model), and intertemporal preference. Many models in the literature are special cases of their general setup. They take a tractable version of their model and use it to analyze dynamic asset-price phenomena, where they can accommodate many phenomena. A problem may be that the model is very general.

P. 560 top cites puzzles in asset markets/macroeconomics.

P. 561 Footnote 3 cites ambiguity/robustness for finance.

Pp. 563-564 hits the nail on the head when explaining that the smooth model of ambiguity is popular for being tractable, allowing to analyze ambiguity attitude as traditional risk attitude. (I add: using the familiar utility curvature.) %}

{% **PT, applications**, loss aversion; Presented in Chantilly, 1997; Consider data of 10 years of horse race betting in UK. Note that this concerns a population that is more risk seeking than average. So, for instance, the certainty effect typically should not be expected to occur; it indeed didn't.

They observe what the betting odds are for many races. This and the results of the races is the only data they use, and they do not use data about the stakes bet on various horses. They assume one representative agent, and assume that the betting odds are such that the agent is indifferent between all horses. This follows from market equilibrium: If one horse was better, betting on it would increase and, hence, its prices. From this assumption alone (their Eq. 1), they can derive both the probabilities of horses winning and the (risk-)preference functional of the bettors. It works as follows. First, for each preference functional given, the indifference between all horses gives n–1 equations, enough to get the n probabilities (that add to 1). Then, for each preference functional, a proper scoring rule is calculated relative to the actual winning horses. Finally, the preference functional is chosen with the best scoring rule.

Find that RDU does not improve on EU, but PT does. They cannot incorporate loss aversion (utility more steep for losses than for gains) because the data do not permit. The better performance of PT results from different probability weighting for gains than for losses.

Weighted utility does not seem to fit the data well (p. 528).

The data do not suggest **inverse S.** PT estimations suggest convex (pessimistic) w for gains, concave for losses (also pessimistic, because of dual integration for losses that PT does). For losses they seem to find risk aversion, for gains a little risk seeking. This is contrary to the common empirical findings although their footnote 17 suggests that it is in agreement with common findings. This population of betters can of course not be expected to agree with general findings. %}

{% Distinguish between standard risk aversion, which concerns final wealth, and marginal risk aversion, which concerns taking a prospect as reference point and evaluating changes from there. So, exactly Sugden's (2003) random reference theory. The authors' approach has also been studied under the heading of background risks, as in Barberis, Huang, & Thaler (2006, American Economic Review).

10 interviewers interviewed 290 households in India, asking about real decisions made first, then about hypothetical seeding decisions that were presented as objective probability distributions over outcomes. One sentence (p. 618 last one) says that payment was performance-based, but I did not find how and if it was really real-incentive. The authors consider probability weighting but it is not clear if for three-outcome prospects as considered in their experiment they do rank-dependent or separate outcome transformation. They do not seem to consider loss aversion, only different utility and probability weighting for losses, only mentioning once that they find no "discrete loss aversion" (p. 624 just above Conclusion) without specifying what it means. They measure risk aversion as preference for increasing variance.

risk averse for gains, risk seeking for losses: p. 620 3rd para reports risk seeking for the only loss prospect they consider (relative to the reference prospect). %}

{% **criticizing the dangerous role of technical axioms such as continuity**: the authors explain this well.
This paper brings useful and complete results on the logical dependencies between completeness, transitivity, and connectedness of the order topology, and various weakenings of these conditions. Bits and pieces have been around before in the literature, but this paper brings it all toether. It displays great knowledge of the literature, e.g. by citing the impressive works of Pfanzagl.

The basic result (Theorem 2) is as follows, where continuity of a binary relation means that both weak upper and lower sets are closed, and strict upper and lower sets are open. If a binary relation is continuous in a connected space, and even if it is in a space with no more than two connected components, then transitivity implies completeness, and [completeness & transitivity] is implied by antisymmetry, also by transitivity of the symmetric part with connected sections, and transitivity of the symmetric part with semi-transitivity. Theorems 3 and 4 derive connectedness, or existence of no more than two components, from other properties imposed on all continuous relations.

one-dimensional utility: some results in §4.4.

The authors replace the common terms complete and transitivity by the uncommon terms decisive and consistent. It escapes my why. %}
Khan, M. Ali & Metin Uyanik (2021) "Topological Connectedness and Behavioral Assumptions on Preferences: A Two-Way Relationship," *Economic Theory* 71, 411–460.

{% The experiment in this paper is weak, and the theory not very important, but the discussions and interpretations are superb, showing deep understanding. I therefore like to cite this paper.

P. 268 gives profound text on how people confuse knowledge about process with knowledge about outcome, which I also think is the mistake that Ellsberg-paradox researchers make: "This example shows the "irrational" nature of ambiguity avoidance. For example, if an ambiguity averse subject chooses less than 100 red balls to indicate indifference, then s/he is limiting his/her opportunity of winning to gain the false sense of security of thinking s/he knows more about the outcome. It is true that the subject knows more about the process of winning in the first urn than in the second urn, but s/he does not know any more about the probability of the outcome, information s/he mistakenly thinks s/he is "buying" by sacrificing the number of red balls in choosing an indifference value." This is the essence, I think, of what misleads many researchers to think that ambiguity aversion is rational. I think that in the known Ellsberg urn you do not have better information than in the unknown but, if anything, the opposite: Jn the known urn you are sure to have the worst information that could be.

P. 268 uses matching probabilities to measure weight of ambiguous events. It is similarly done by Viscusi & Magat (1992 Eq. 7).

P. 268/269, ambiguous thumbtack versus fair coin, of 54 MBA students, 18 preferred fair coin, 21 preferred tack; On latter: "This group may represent some people who would pay to seek ambiguity, but does represent some people who believe that they have more information about the probability of winning with the tack and, hence, will pay more for that information." **ambiguity seeking for unlikely** (below .1 or .3 according to Camerer & Weber, 1992) **second-order probabilities to model ambiguity**; generate ambiguity this way, and use a parametric model for that; p. 267 1st column 2nd para

ambiguity seeking for losses; p. 270: "In the gains domain, there is ambiguity seeking at low mean probabilities and ambiguity aversion at high mean probabilities. In the loss domain, a reflection effect occurs with ambiguity aversion at low mean probabilities and ambiguity seeking at high mean probabilities. ... Therefore, the presence of ambiguity may accentuate the attitude toward risk."

uncertainty amplifies risk: p. 270: "Therefore, the presence of ambiguity may accentuate the attitude toward risk."

reflection at individual level for ambiguity: although the last experiment (p. 270) has within-subject data, it is not reported. %}

{% Further comments are in comments on the Kahneman (2003) American Economic Review paper. Here I only discuss things not in American Economic Review.

P. 697: "… that intuitive judgments occupy a position—perhaps corresponding to evolutionary history—between the automatic operations of perception and the deliberate operations of reasoning."

P. 702, 2d para, has a remarkable sentence negating the value of theory: "… accessibility … the lack of a theory does little damage to the usefulness of the concept." I did not find a similar sentence in his American Economic Review 2003 paper. This may agree with Kahneman's opinion that the success of the '79 prospect theory paper is mostly an academic coincidence, where Kahneman ignores the importance of the theoretical content of that '79 paper (p. 702 3rd para), including the essence of that paper: that it could combine empirics and theory.

P. 703: "Guided by the analogy of perception, we expected the evaluation of decision outcomes to be reference dependent."

P. 704 lacks nuances when writing: "I call it Bernoulli's error. Bernoulli's (1738/1954) model of utility is flawed beccause it is *reference independent*:" [italics from original)

P. 705, 2nd para:

"… because the value function is a psychophysical mapping."

Such a universal claim is not in his American Economic Review 2002 paper.

utility concave near ruin: p. 705, 2nd para: "However, the value function is not expected to describe preferences for losses that are large relative to total assets, where ruin or near ruin is a possible outcome."

P. 707 2nd column 1st para: "… people who are confronted with a difficult question sometimes answer an easier one instead." P. 713 4th para nicely follows up on this: "The probability of Linda being a bank teller is an extensional variable, but her resemblance to a typical bank teller is a prototype attribute."

P. 710 2nd para of 2nd column, and elsewhere explains that Kahneman & Tversky emphasized cognitive aspects and not emotional because, in their days, psychologists automatically assumed that everything was emotional, and cognitive aspects were new then.

P. 712 3rd para: within-subjects designs have problem for study of intuitive non-reasoned tasks that they may trigger reasoning.

P. 726, 2/3 at 2nd column: "The concept of loss aversion was, I believe, our [Tversky & Kahneman] most useful contribution to the study of decision making." %}

Kahneman, Daniel (2003) "A Perspective on Judgment and Choice: Mapping Bounded Rationality," *American Psychologist* 58, 697–720. https://doi.org/10.1037/0003-066X.58.9.697

{% In what follows, "AP" refers to Kahneman (2003, American Psychologist), which, like this paper, is a summary of Kahneman's Nobel-lecture.

P. 1453, para on 1st/2nd column: Discussion that distinguishing between good and bad, approach/avoidance, is very basic. Is in AP at p. 701, end of 1st column.

P. 1454, last para, presents reference dependence in perception as universal: "A general property of perceptual systems is that they are designed to enhance the accessibility of changes and differences. Perception is reference dependent …"

paternalism/Humean-view-of-preference: §VII, pp. 1467-1469 discusses corrections/avoidance of biases. AP has it on pp. 710-712.

P. 1456, on prospect-theory's departure from rationality: "One novelty of prospect theory was that it was explicitly presented as a formal descriptive theory of the choices that people actually make, not as a normative model. This was a departure from a long history of choice models that served double duty as normative logics and as idealized descriptive models."

P. 1457, 3rd para (also AP p. 705, 3rd para): "Bernoulli's error—the assumption that the carriers of utility are final states—…"

P. 1457, end of 1st column:

"The core idea of prospect theory—that the value function is kinked at the reference point and loss averse—…" %}

Kahneman, Daniel (2003) "Maps of Bounded Rationality: Psychology for Behavioral Economics," *American Economic Review* 93, 1449–1475.
https://www.jstor.org/stable/3132137

{% P. 726, 2/3 at 2nd column: "The concept of loss aversion was, I believe, our [Tversky & Kahneman] most useful contribution to the study of decision making."

P. 727, top of 2nd column, suggests that the success of prospect theory is by arbitrary processes. I disagree. The success is because 1979 prospect theory was the first rational theory of irrational behavior, which is a major intellectual breakthrough.

dynamic consistency: p. 727, 2nd column, bottom, describes that Amos and he considered dynamic decision principles, which they indeed did in their magnificent Science 1981 paper, way before Hammond (1988) and others. %}

Kahneman, Daniel (2003) "Experiences of Collaborative Research," *American Psychologist* 58, 723–730.

{% §4.5, in a discussion of the Allais paradox, states explicitly that Amos Tversky considered deviations from expected utility as in the Allais paradox to be irrational, and that he developed prospect theory only for modeling irrational behavior. In a preliminary January 2011 version of the chapter that Daniel wrote and that I commented on, Daniel wrote:

"Most theorists, notably including Allais, maintained their belief in human rationality and tried to bend the rules of rational choice to make the Allais pattern permissible. Over the years there have been multiple attempts to find a plausible justification for the certainty effect, none very convincing. Amos had little patience for these efforts – he called the theorists who tried to rationalize violations of utility theory "lawyers for the misguided." We went in another direction: we retained utility theory as a logic of rational choice, but abandoned the idea that people are perfectly rational agents. We took on the task of developing a psychological theory that would describe the choices that people make, whether or not they are rational. In prospect theory, decision weights would not be identical to probabilities." %}

Kahneman, Daniel (2011) book in preparation.

{% P. 300 writes, overselling: "The concept of loss aversion is certainly the most significant contribution of psychology to behavioral economics."

P. 314, in a discussion of the Allais paradox, states explicitly that Amos Tversky considered deviations from expected utility as in the Allais paradox to be irrational, and that he developed prospect theory only for modeling irrational behavior:

"Most theorists, notably including Allais, maintained their belief in human rationality and tried to bend the rules of rational choice to make the Allais pattern permissible. Over the years there have been multiple attempts to find a plausible justification for the certainty effect, none very convincing. Amos had little patience for these efforts; he called the theorists who tried to rationalize violations of utility theory "lawyers for the misguided." We went in another direction: we retained utility theory as a logic of rational choice but abandoned the idea that people are perfectly rational choosers. We took on the task of developing a psychological theory that would describe the choices that people make, regardless of whether they are rational. In prospect theory, decision weights would not be identical to probabilities." %}

{% P. 4 equates Bentham's utility with Kahneman's experienced utility, as if solely to be aggregated over time, even though Bentham also considered aggregations over other dimensions. Argue for various concepts of utility, not one (**risky utility u = transform of strength of preference v**). New contribution of this paper is proposing the U-index: Let subjects categorize all kinds of aspects and specify their intensity. Each timepoint is categorized as negative if the most negative score over attributes exceeds in absolute value the most positive score over attributes. The U-index then specifies the percentage of time with a negative score. The authors point out that in this way information is lost and call the index ordinal in this respect (although it compares positive distances from 0 to negative ones), but reassure the readers by stating that they see this as an advantage. %}
Kahneman, Daniel & Alan B. Krueger (2006) "Developments in the Measurement of Subjective Well-Being," *Journal of Economic Perspectives* 20, 3–24.

{% **total utility theory**. Kahneman argued in several papers that it may be useful not to let people decide/choose over episodes, because there are biases in time aggregation. In such cases, let people only evaluate instant utility through introspection at that moment, and let researchers/policy makers integrate these (total utility or ERM). Getting such introspections can be cumbersome and costly. This paper proposes DRM, a tractable alternative: Let people retrieve from memory their instant utility of the past day, by letting them partition that day into episodes, letting them recall the events and instant utility of those episodes, and let them report those. (This also gives info on time budgeting.) It was done with a convenience sample of N = 909 women who had worked the day before.

Subjects reconstruct experiences of preceding day. For some things, there is a nice contrast between what this method measures and what global overal satisfaction judgment gives. The latter may say "I enjoy my kids," whereas the former shows that all activities related to children were perceived of as a burden. DRM may avoid social desirability, but missing out on global overall value that is not easily allocated to particular time and on valuable long-term things that are not perceived as an instant change (with supposedly flowers bringing more happiness than a couch). %}

Kahneman, Daniel, Alan B. Krueger, David A. Schkade, Norbert Schwarz, & Arthur A. Stone (2004) “A Survey Method for Characterizing Daily Life Experience: The Day Reconstruction Method,” *Science* 306, 1776–1780.

{% This papers discusses, first, the ESM (Experience Sampling Method) where people several times per day receive the request to describe their experiences at that moment, so that instant utilituy is measured truly as meant to be. The authors call this the gold standard (p. 431 ℓ. 1). Then it discusses the DRM (daily reconstruction method), where people at end of day are asked what happened. It is a pragmatic alternative to the ESM. Then it discusses the ERM (Event Recall Method), another pragmatic alternative. Proposes to use these measurements to measure national well being. %}

Kahneman, Daniel, Alan B. Krueger, David A. Schkade, Norbert Schwarz, & Arthur A. Stone (2004) “Toward National Well-Being Accounts,” *American Economic Review, Papers and Proceedings* 94, 429–434.

{% **linear utility for small stakes**: Claim that this is normative although empirically violated. Claim that people are generally too risk averse, for one thing because they isolate choices too much. In this point they preceded the narrow bracketing of Read, Loewenstein, & Rabin (1999) and the myopic loss aversion of Benartzi & Thaler (1995).

Kahneman (January 22, 2008, personal communication, email) pointed out that the arguments in this paper should only concern moderate stakes that are not a substantial portion of total wealth. They wanted to have this restriction. Kahneman checked out the paper and saw that they had forgotten to write it. %}

{% An early version of their 1979 Econometrica prospect theory paper.

Use term uncertainty weight instead of decision weight.

P. 9 ff. lets isolation refer only to outcomes being changes w.r.t. reference point. 1979 paper will take isolation more general.

P. 12: "Hence, it appears that over a reasonably wide range of assets the value function is approximately the same."

Remarkably, for pure prospects (x,p,y) with x > y > 0, they take CE(x,p,y) = y + CE(x−y,p,0), which deviates from their 1979 version and is less satisfactory in the sense that it cannot be defined for nonquantitative outcomes.

P. 14 is explicit on the "two-stage" model (term not used there) where first probability judgments are made and then these are transformed as objective probabilities would. This is not explicit in the 1979 version, only some text on p. 281 paragraph −2.

uncertainty amplifies risk: p. 15 2nd para repeats the two-stage model, and writes: "In these cases, the regressiveness of uncertainty weights with respect to objective probabilities will be further enhanced by the tendency to overestimate low probabilities and

underestimate high ones." This is exactly the condition in my (oh well) 2004 psychological review paper. Wow!

P. 18: (**SPT instead of OPT**): Although they here use a slightly different version of the PT formula than in their published 1979 paper, with utility of outcome differences rather than utility differences, this page and how it extends p. 12 clearly shows what they had in mind for many-outcome prospects.

Pp. 19 ff is very remarkable on **dynamic consistency**, already containing the idea of Hammond (1988) and Burks (1977 Ch. 5), to derive independence from dynamic principles, and preceding both of these. Well, at least, they show it for the Allais paradox, but it is typical of any violation of independence. They first have choices between A_1 and A_2, and then their scaled-down versions B_1 and B_2. Then come the sequential C_1 and C_2. They first explain that from the prior perspective, because of RCLA, C_1 and C_2 are identical to B_1 and B_2. This is analyzing using dynamic consistency + RCLA, optimizing from the prior perspective. Then they explain that subjects, in a figure that presents the decision node in the 2nd stage, ignore the lower branch and take the 2nd stage choice in isolation. This is what Machina (1989) called consequentialism. Thus, they show that to do the Allais paradox one either has to violate DC + RCLA or consequentialism. They claim it more generally, for the certainty effect (which in this paper they formally define as what they will later call subadditivity). They do not claim it in full generality for independence, but they are very close and deserve crediting. I realized this for their 1975 paper (preceding Ch. 5 in Burks 1977!) only 9 Dec. 2012, whereas for their 1979 published version I realized it around 2008.

P. 23: "In this theory insurance and gambling occur in spite of the value function, not because of it." Nice, very explicit, statement.

P. 24: "Utility theory can be viewed as an attempt to eliminate the concept of attitude to risk or uncertainty and to explain risky choices solely in terms of attitudes to money or wealth."

P. 25: "Value theory does not purport to account for all forms of risk-seeking and risk-aversion. Many factors not included in this theory (e.g., regret., social pressure, superstition, magical thinking) probably play an important role in risky choices. Value theory is an attempt to modify those assumptions of utility theory that are most severely violated, so as to achieve a more realistic account of choice behavior."

second-order probabilities to model ambiguity: There is a whole section on

Ellsberg (pp. 30-33) suggesting that Ellsberg is second-order probability (without **RCLA**), and then the somewhat far-fetched idea that people then treat 1st order probabilities of winning as outcomes and process them concavely, suggesting a kind of second-order-probability risk aversion. Note that this is a special version of the smooth ambiguity model of KMM (2005): It is already the smooth model when there are only two outcomes! (**event/outcome driven ambiguity model: outcome driven**)

Whereas the 1979 paper is explicit about expected utility being normative, this paper has a nice discussion on normative implications without ever committing to a normative status of expected utility.

paternalism/Humean-view-of-preference; P. 35: "The observation that people's preference vary with the formulation of problems underscores the need for decision aids to help people make more consistent and rational choices." P. 36 has this argument that, for example, regret must be accepted if it cannot be avoided: "If man is constructed in such a way that he is much more sensitive to gains and losses than to absolute wealth, then any attempt to maximize human welfare must recognize this fact. More generally, a normative approach to decision must take into account the nature of man as a pleasure machine."

They call certainty effect what in their 1979 version they will call subadditivity. %}

Kahneman, Daniel & Amos Tversky (1975) "Value Theory: An Analysis of Choices under Risk," paper presented at the ISRACON conference on Public Economics, Jerusalem, 1975.

Link to paper

{% Merigó, Rocafort, & Aznar-Alarcón (2016) Table 2 and p. 402 wrote that this is the most-cited paper in business and economics. Kim, Morse, & Zingales (2006, Table 2) had it as the 2nd most cited.

I follow this paper here in writing π rather than w for the probability weighting function.

PT: data on probability weighting;

risk averse for gains, risk seeking for losses; **inverse S**; **real incentives/hypothetical choice**, p. 265;

P. 263, abstract: Certainty effect is defined as also implying possibility effect. This deviates from the common terminology in the field, and from most of their own other writings, for instance, their 1975 working paper, or Tversky & Fox (1995 p. 272).

P. 272: In this Allais paradox, in the figure with the decision node after the 1st chance node, the gains are maximally correlated giving a certainty-effect perception, whereas in the figure with the decision node before the chance nodes the outcomes are perceived as independent.

P. 273, in showing reference dependence, the authors take good care that the decision situations are the same in terms of final wealth and that it must really be the change in reference point.

P. 276 Eq. 2: Contrary to what many think, for prospects with two outcomes, both nonzero, and either both gains or both losses, the value of a prospect x_py is NOT $\pi(p)v(x) + \pi\ (p)v(y)$. P. 276 ℓ. 15: "The evaluation of strictly positive and strictly negative prospects follows a different rule." What happens is that for such prospects, PT is RDU w.r.t. w for gains, and RDU w.r.t. the dual of π for losses. That is, for $x > y > 0$ it is $\pi(p)v(x) + (1 - \pi(p))v(y)$. For losses with $x < y < 0$ it is also $\pi(p)v(x) + (1 - \pi(p))v(y)$, meaning it is RDU with reflected π there. See Wakker (2023, Theory and Decision).

paternalism/Humean-view-of-preference: p. 277:

> The equations of prospect theory retain the general bilinear form that underlies expected utility theory. However, in order to accom[m]odate the effects described in the first part of the paper, we are compelled to assume that values are attached to changes rather than to final states, and that decision weights do not coincide with stated probabilities. These departures from expected utility must lead to normatively unacceptable consequences, such as inconsistencies, intransitivities, and violations of dominance. Such anomalies of preference are normally corrected by the agent when he becomes aware that his preferences are inconsistent, intransitive, or inadmissible. In many situations, however, the agent lacks the opportunity to discover that his preferences could violate decision rules that he wishes to obey. In these circumstances the anomalies implied by prospect theory are expected to occur.

Here they state that expected utility is normative. Kahneman (2003, *American Economic Review, Papers and Proceedings*, p. 163) will state the opposite.

P. 277 explains reference dependence by saying that the utility function is a book, each page describing it for a difference reference point, which metaphor was also used by Edwards (1962, p. 116) be it not for utility.

P. 277: Many people erroneously think that, according to prospect theory, preference depends only on the differences of outcomes with the reference point, and not on the reference point otherwise. This is not so. For different reference points the value function and probability weighting function (and loss aversion) can be different. Here is what the authors write: "The emphasis on changes as the carriers of value should not be taken to imply that the value of a particular change is independent of initial position." But they then point out that the dependence is weak: "However, the preference order of prospects is not greatly altered by small or even moderate variations in asset position. The certainty equivalent of the prospect (1,000, .50), for example, lies between 300 and 400 for most people, in a wide range of asset positions. Consequently, the representation of value as a function in one argument generally provides a satisfactory approximation." (The last sentence finished on p. 278.)

P. 277: d**ecreasing ARA/increasing RRA**: it suggests decreasing absolute risk aversion.

Pp. 278-279: that utilities are locally nonsmooth. At wealth level where you can just buy a house, you have a high marginal utility of money.

P. 279 1st para: that concavity of utility for losses is more common than convexity for gains.

P. 279: **risk seeking for symmetric fifty-fifty gambles. The** authors do not think this and speculate that people are highly averse to such risks.

utility concave near ruin: P. 279 says that utility for losses may have concave regions for large losses, that necessitate changes of life style. Do not explicitly relate it to ruin.

P. 280: "decision weights … should not be interpreted as measures of degree or[of] belief."

P. 280: "the decision weight attached to an event could be influenced by other factors, e.g., ambiguity."

P. 281 top: what they call subadditivity in fact is subproportionality.

uncertainty amplifies risk (for **inverse S** probability weighting): p. 281, penultimate para: "It is important to distinguish overweighting, which refers to a property of decision weights, from the overestimation that is commonly found in the assessment of the probability of rare events. … In many real-life situations, overestimation and overweighting may both operate to increase the impact of rare events" This relates to the preference condition in my 2004-Psych. Rev. paper! Similarly, p. 289 $\ell\ell$. 5-6: "Consequently, subcertainty should be more pronounced for vague than for clear probabilities."

P. 281: subcertainty means $\pi(p) + \pi(1\text{-}p) < 1$.

P. 282: "The slope of π in the interval (0,1) can be viewed as a measure of the sensitivity of preferences to changes in probability." Then follows an error. The authors write that subcertainty implies low sensitivity. This is not so. Subcertainty is about the *absolute level* of probability, not about the *change* in probability.

P. 282: "This quantal effect may reflect the *categorical distinction* between certainty and uncertainty." [italics added] Here the quantal effect refers to a smallest unit of perception and discontinuity of π at $p = 1$.

Pp. 282-283: **(very) small probabilities**: that small probabilities can be overweighted or ignored.

P. 283: "probabilities of identical outcomes are combined in the editing or prospects."

P. 283/284 point out that their theory may violate dominance and say that editing can prevent that, but then indirectly (through transitivity) it can still happen.

P. 286 $\ell\ell$. 2-4 point out that utility curvature works opposite to the overweighting of small probabilities.

P. 287 bottom: The authors write that utility, if final wealth is perceived, will be concave. I assume this means that they assume concavity of utility to be more rational than convexity. They also assume that then the reference point is at 0 and all outcomes are perceived as gains. Gains rather than losses seems to be plausible, but I cannot think of a 100% argument why not the reference point then is the maximum wealth level and all outcomes are perceived as losses.

P. 288 4th para claims that the extension of prospect theory to many-valued prospects is straightforward, but does not give the formulas. Wakker (2023 Theory and Decision) explains the case.

biseparable utility: Unlike what many think, biseparable utility is satisfied by the original prospect theory of this paper when restricted to gains or when restricted to losses.

P. 289 ℓ. 1: The text says that PERCEIVED LIKELIHOOD primarily determine decision weights. This does not say that most of the nonadditivity is generated by cognitive factors, but goes a little bit in that direction. Here is the

para: "The decision weight associated with an event will depend primarily on the perceived likelihood of that event, which could be subject to major biases [45] [Their Science 74 paper on heuristics and biases] In addition, decision weights may be affected by other considerations, such as ambiguity or vagueness. The work of Ellsberg [10] and Fellner [12] indeed implies that vagueness reduces decision weights. Consequently, subcertainty should be more pronounced for vague than for clear probabilities." (**uncertainty amplifies risk**)

The journal pushed the authors to produce preference axioms. Hence, the appendix has some, suggested by David Krantz, but it does not really axiomatize the theory. %}

{% A long list of points on which the authors disagree with Gigerenzer’s criticisms. Many are misunderstandings or different wordings. For example, if Gigerenzer criticizes the Linda example for ignoring context and content, he means that the question how likely it is that Linda is a feminist bank teller can be taken by subjects as referring to *conditional probability* rather than unconditional as it is meant. This is different than K&T use the term. K&T reply here that they tested for this confound, but then, this is less clear, and, … In short, hard to judge for

outsiders.

P. 582: "Similarly, the role of availability in frequency judgments can be demonstrated by comparing two classes that are equal in objective frequency but differ in the memorability of their instances."

P. 582, about their biases and heuristics:

"However, it soon became apparent that although errors of judgment are but a method by which some cognitive processes are studied, the method has become a significant part of the message" (Kahneman & Tversky, 1982a, p. 124).

P. 589, last sentence of paper, on Gigerenzer's emphasizing of relative frequencies (reminds me also of the experienced-uncertainty approach of Erev et al.):

"The view that "both single-case and frequency judgments are explained by learned frequencies (probability cues), albeit by frequencies that relate to different reference classes" (Gigerenzer, 1991, p. 106) appears far too restrictive for a general treatment of judgment under uncertainty. First, this treatment does not apply to events that are unique for the individual and therefore excludes some of the most important evidential and decision problems in people's lives. Second, it ignores the role of similarity, analogy, association, and causality. There is far more to inductive reasoning and judgment under uncertainty than the retrieval of learned frequencies." %}

{% **conservation of influence**: seems to open with:

"All of nature, as far as it is within the reach of his power, is subjected to the will of man, with the exception of other men and reasonable beings. From the point of view of reason, the things in nature can only be regarded as means to ends, but *man alone can himself be regarded as an end*. … Animals, as well [as unreasonable things], have no value in themselves, since they have no consciousness of their existence – man is the purpose of creation; nevertheless, he can also be used as a means by other reasonable beings. However, man is never merely a means; rather he is at the same time an end. For example: If a mason serves me as a means to building a house, I serve him, in turn, as a means to acquire money. … The world, as a system of ends, finally has to contain a purpose, and this is the reasonable being. If there existed no end, the means would serve no purpose and would have no value. — Man is an end. It is therefore contradictory that he should be a mere means. — If I am making a contract with a servant, he has to be an end as well, just as I am, and not merely a means." %}

{% By measuring how much people are willing to pay for reducing mortality risk, the income elasticity of the value of a statistical life can be measured. Note here how utility is measured through probability of survival = 1 − mortality risk, very similar through the modeling of utility through the probability of gaining a prize (Roth & Malouf 1979). The income elasticity of statistical life must then also be 1 − power of utility of income; i.e., the RRA index of the utility function of income. Income elasticities of statistical lives typically found in the literature ranges around 0.5. The author now only refers to RRA indexes found in finance and macroeconomics, which are around 2, and considers the discrepancy a paradox. However, in individual choice experiments in laboratories, RRA indexes of 0.5 are typically found, and the paradox is resolved! %}

{% **questionnaire versus choice utility**

Abstract. Since the work of Pollak and Wales (1979), it is well known that demand data are insufficient to identify a household cost function. Hence, additional information is required. For that purpose I propose to employ direct measurement of feelings of well-being, elicited in surveys. In the paper I formally establish the connection between subjective measures and the cost function underlying the AID system. The subjective measures fully identify cost functions and the expenditure data do this partly. This makes it possible to test the null hypothesis that both types of data are consistent with one another; i.e., that they measure the same thing. I use two separate data sets to set up a test of this equivalence. The outcomes are somewhat mixed and indicate the need for further specification search. Finally, I discuss some implications of the outcomes. %}

{% **criticisms of Savage's basic framework**: People usually follow Savage routinely in taking states-consequences-acts as he does, and don't seem to be aware that there is quite some arbitrariness in it, first, in how we define what as function of what mathematically, but second, to what extent things are independent from each other causally. I like Luce's work in the sense that he models these things in a provocatively different way. Karni also challenges these foundational aspects. The present paper makes things tangible because it does not just say things, but it formalizes and axiomatizes. The primary point of the paper is, therefore, for me that it brings new and different insights into the primitives of decision under uncertainty.

Given each action, there is a traditional framework with effects playing much the role of states of nature, not influenced by what the agent does (given the action chosen!). At the same time, there is place for influence of the agent on resolutions of uncertainty, and this is through the influence of actions on the effects. Accordingly, effects can also carry value, and not only be sources of uncertainty. This is clear by the general framework plus a specification where they "happen" not to carry value.) %}

{% This paper considers Schmeidler's CEU (Choquet expected utility), using the AA (Anscombe-Aumann) framework: in a first stage, a horse race takes place giving one winner, and condional on the winner, in the second stage one receives a

lottery, i.e., a probability distribution over prizes, say monetary prizes. Lotteries are evaluated by expected utility, and backward induction is used, i.e., every lottery is replaced by its certainty equivalent. The resulting gamble on the horse race is evaluated through its Choquet expected utility, i.e., the Choquet integral of outcome utilities invoking a capacity which is a nonadditive generalization of probability measures.

This paper considers the special case where the capacity is a nonlinear transformation w of an additive probability measure on the horse space, which I call subjective. The nonlinearity processing of the subjective 1st stage probabilities through w deviates from the linear weigthting of the objective probabilities in the second stage. This difference between uncertainty and risk is usually, for instance in my papers, interpreted as reflecting ambiguity attitude. This paper points out that it can be reinterpreted as a different RISK attitude for the subjective 1st-stage probabilities. In my terminology that would be something like a source-dependent risk attitude, although I do not like that term because it uses the term risk-attitude for something that is not risk.

uncertainty amplifies risk: the paper can be linked to this topic, although the interpretations of the author do not fit with it.

Claims in the paper such as in the abstract: "Consequently, the pattern of choice depicted by Ellsberg's experiments and … **is** an expression of decision makers' risk aversion." [bold enlargement added] are provocative and will draw attention but are, I think, overstatements. Mathematically isomorphic does not mean being identical.

The paper similarly argues that the ambiguity aversion of the smooth ambiguity model could be interpreted as extra risk aversion. %}

{% On what the title says. §2.1 describes Savage's (1954) contribution as the first big bang in decision under uncertainty.

§2.5, p. 229, describes Schmeidler's idea of using the Anscombe-Aumann (AA) framework (properly credited to Fishburn 1970 by the authors) for ambiguity as the second big bang in decision under uncertainty. The authors are very positive about the AA framework. I have often expressed more negative judgments: The AA framework was adopted to simplify the mathematical work, but at a nontrivial cost: expected utility for risk and a backward-induction type optimization over two stages or, equivalently, a separability of singleton ambiguous (horse-race) events, misleadingly called monotonicity, which is not appropriate for nonEU with ambiguous events.

P. 229: "Savage's most brilliant measuretheoretic approach was not so easily extended beyond its original domain and this was a main reason why so little happened in the field for decades after his 1954 masterpiece."

P. 230 argues for the plausibility of quasi-convexity of preference w.r.t. probabilistic mixing, i.e., Schmeidler's (1989) uncertainty aversion, which I again disagree with.

They list all Schmeidler's contributions to decision theory. %}

{% **criticisms of Savage's basic framework**;
updating: discussing conditional probability and/or updating
Acording to the traditional Bayesian framework, every new observation is a subset of the universal state space, which shrinks and shrinks. In this paper, new observations enlarge the state space and open new possibilities not thought of before. Hence the nice title.

They give an axiomatization. They do not use the usual Savage framework where states and consequences are given as primitives, but take acts and consequences as primitives, and then all states are all maps from acts to consequences (à la Schmeidler & Wakker 1987). Thus, discovering new outcomes or new acts enlarges the state space. It can be taken to model unforeseen events or unawareness. They use the Anscombe-Aumann framework. An invariance axiom (awareness consistency) ensures that expanding the model does not affect the preferences already there. %}

{% For loss aversion, Peeters & Czapinski (1990) and others discussed whether people really suffer more under losses than they are happy under gains, or whether this is not so but people still overweight losses, and tested it using introspective measurements. This paper does the same for discounting, whether people (think they) feel less in the future ("anhedonia"), or feel the same but still weigh the future less. The novelty is not in putting up this question, unlike the suggestion in the abstract, because the authors give many references, but it is in testing it. So, the authors conjecture that people underestimate future feelings. In other studies they have investigated the "impact bias," claiming that people overestimate future effects. Footnote 1 on p. 1534 explains that these are "fully consistent" because we may be overestimating future effects but, simply, be overestimating all present effects even more. Experiment 1b tries to demonstrate anhedonia by seeing if WTP in the fuure will be smaller than now. I wonder if WTP in the future is not also subject to anhedonia. In experiment 2a the authors show that not all subjects are completely driven by one bias, which however does not show that the bias would be completely absent. %}

{% **foundations of statistics**

The first sections pp. 177-181, present new ways to detect not only selection bias but also its size. Not of interest to me now. The rest of the paper I enjoyed much. Although I must have read 100 papers on this topic, as this annotated bibliography shows, this paper brings me many new insights. It properly distinguishes between the perspective of helping decision making, for which surprising results are most useful, and giving unbiased info, for which nonsurprising results are useful. P. 184 2nd para has a nice example, in my words: 100 tests, each of a different medicine, all equally clever. If one finds, surprisingly, that its medicine works, and the other 99 unsurprisingly that their medicine doesn't, then the former deserves pages in a top journal, and the other 99 don't. The surprising finding is most decision-relevant.

P. 184 middle: "there is a deep tension between relevance for decision-making and replicability in the design of publication rules."

P. 186 2nd para: "there is little reason to assume that this cutoff provides a good tradeoff between size and power": hits the nail on the head

The paper nicely distinguishes the single-decision maker perspective, in which case prior registration serves no purpose at all because of dynamic consistency, and strategic social aspects, for which prior registration may be

useful (p. 187 penultimate para). Kasy & Spies (2021) provide a mechanism design for the case.

P. 188: "if researchers have many choices (degrees of freedom) for their analysis—there are many forking paths—and if communication costs ar high (there is a lot of private information) [that is not entirely the same!], then pre-analysis plans can improve the welfare (statistical risk) of readers. If, on the other hand, researchers face a small number of choices and private information is limited, the reader might be better off without requiring a pre-analysis plan."

P. 188 3rd para: "publication decisions that do not depend on findings …. is required if our goal is validity of conventional inference. However, such independence is not necessarily desirable if our objective also includes other criteria, such as relevance and plausibility."

P. 188 penultimate para mentions journals for replications and null results.

P. 189 top: "Above, we have argued that aternative objectives—relevance for decision-makers, statistical validity, plausibility of published findings—can lead to conflicting recommendations for reforms of the publication system."

I reproduce virtually the whole p. 190 (of the conclusion):

"Let us conclude by taking a step back to consider what the debates around replicability and selective publication imply for the foundations of statistics. One of the main foundations of statistics is statistical decision theory. The activity of statistics as conceived by decision theory is a rather solitary affair. There is just the researcher and the data, and the researcher has to make some decision based on the data: estimate a parameter, test a hypothesis, and so on. This perspective can be extremely useful. It forces us to be explicit about our objective, the action space, and what prior information we wish to incorporate (for example, in terms of the statistical model chosen, or in terms of a Bayesian prior, or in terms of a set of parameters for which we wish to control worst-case risk). The decision-theory perspective makes explicit the tradeoffs involved in the choice of any statistical procedure.

But this decision-theory perspective also has severe limitations, as evidenced by the discussions around p-hacking, publication bias, and pre-analysis plans. It is hard to make sense of these discussions from the vantage point of decision theory. For instance, why don't we simply communicate all the data to the readers of research? If we took decision theory literally, that would be optimal. After all, communicating all the data avoids any issues of selection as well as any waste of information. In practice, as consumers of research, we of course do prefer to read summaries of findings ("X has a big effect on Y, when W holds"), rather than staring at large unprocessed datasets. There is a role for researchers who carefully construct such summaries for readers. But it is hard to make sense of such a role for researchers unless we think of statistics as communication and unless there is some constraint

on the attention or time or information-processing capacity of readers.

Relatedly, what is the point of pre-analysis plans? Their purpose is often discussed in terms of the "garden of forking paths" of specification searching. But taking the perspective of decision theory literally again, there is no obvious role for publicly committing to a pre-analysis plan in order to resolve this issue. Researchers might just communicate how they mapped data to statistics at the time of publication. To rationalize publicly registered pre-analysis plans, we again need to consider the social dimension of research; in ongoing work (Kasy and Spiess 2021) we do so through the lens of mechanism design."

The authors in some places seem to equate private info with costs of info, and never one, small, argument for publication decisions prior to results: that it is fairer to reward researchers. %}

{% The authors discuss randomization in maxmin EU, e.g. (pp. 1160-1161) the Raiffa (1961) argument that can be taken to remove ambiguity if the randomization is conditioned on the horses but not at all remove ambiguity if ambiguity is conditioned on the randomization. They use the original Anscombe-Aumann framework with randomization both before and after the horse race. They axiomatize a double maxmin EU model. It is like maxmin EU, but there is not one set of priors, but there is a collection of sets of priors, and one also minimizes over this collection. The authors point out that their paper is close to Saito (2015).

The intro is characteristic of traditional ambiguity-literature thinking: Ambiguity aversion is suggested to be universal, is ascribed to Ellsberg even though Ellsberg himself emphasized that ambiguity aversion is not universal, and it is automatically assumed that ambiguity means that there must be a set of priors.

P. 1162 penultimate para: The authors assume that the probabilities used in Anscombe-Aumann need not be objective but can be subjective, to be revealed from preference. Problem is that these probabilities are used as inputs in the axioms, which is undesirable if they are subjective. %}

{% N = 240 subjects. Did individual decisions under ambiguity, decisions after discussions, and group decisions. The interactions with others generated moves in the direction of ambiguity neutrality, which can be interpreted as moves towards

rationality.

Certainty equivalents were obtained for binary gambles, with degrees of ambiguity manipulated by providing probability intervals. The actual compositions were determined by randomly and uniformly drawing the probabilities from the intervals, which is the same as having the midpoint of the interval as objective probability. But subjects were not told this, and were only told that the true composition was "determined by chance" (p. 63). They used random incentive system for real payment.

P. 63 explains that they did not really control for suspicion other than tell subjects that the compositions of the ambiguous urns had really been determined by chance (which had not been specified further), and citing two references that it should be no problem.

P. 64 Table 3 gives the data with average CEs for all the Bayesian-probability (interval-midpoints) levels used: $p = 0.20$, 0.50, 0.80, with also some risky choices at $p = 0.35$ and $p = 0.65$. As the Δ size of the interval increases, so does ambiguity. Decreasing CEs as ambiguity increases (so, ambiguity aversion) happens mostly at $p = 0.5$, but maybe rather than looking at those absolutely we should look at them relatively to risk premium. For $p = 0.20$ it is close to ambiguity neutrality, more than for others, but things are not very clear or pronounced (**ambiguity seeking for unlikely**). Table 5 gives similar things with percentages of subjects/groups being ambiguity averse/seeking. %}

{% Seems to have argued that failures of independence indicate poor structuring of the attributes. Parnell et al. (2013) review papers resulting from Keeney's book. %}
Keeney, Ralph L. (1992) "*Value-Focused Thinking.*" Harvard University Press, Cambridge, MA.

{% Argues that structuring is more important than the quantitative analysis (abstract). P. 195 argues that of 10,000 decisions, 10 can benefit from quantitative decision analysis as things are today. P. 196 writes that it should become 1000 out of 10,000: "The opportunity and challenge of the field of decision analysis is to have its concepts and ideas used on all of those 1,000 problems worth thinking about, rather than just 6 of the very complex ones that have an experienced decision analyst involved." The paper presents an

enthusiastic plea for decision analysis.

Keeney is most known for his 1976 textbook with Raiffa, explaining expected utility, utility independence axioms for multiattribute utility, and applied utility measurements. Expected utility is for decision under risk/uncertainty, a small part of our decisions and life. The quantitative techniques provided by it, and the multiattribute utility measurements, using simple choices to derive more complex ones, and they provide particular quantitative tradeoff techniques that are only of some use in very particular situations. Many researchers too much think, and suggest, that their particular work is relevant to too much in life. This paper went too far that way too (**ubiquity fallacy**). Although the author nicely clarifies that of 10,000 decisions in our life, most don't need decision analysis, he still too much puts the EU techniques forward as important. Again and again he overly quickly goes for his EU-multiattribute techniques (with probabilities to be assessed, for instance) as the one and only thing to do.

To illustrate my criticism, I give three citations:

(1) "To analyze alternatives, one typically requires a list of key uncertainties, assessments of probabilities for these uncertainties, a decision tree, value tradeoffs, and a quantified attitude toward risk [risk tolerance]. Subjective judgment is necessary to specify each of these." (p. 198 2nd column 3rd para)"

(2) "Decision analysis should guide all of our thinking about decisions." P. 200 3rd para

(3) "Decision analysis is useful for resolving all decisions worth thinking about." P. 201 2nd para

There are many other texts like the above ones. Had the author not worked on uncertainty all his life, but on intertemporal choice, then he would have written, instead of the above citation (1): "To analyze alternatives, one typically requires a list of future gains and losses, assessments of approximate times points of receipts of those gains and losses, a decision tree, value tradeoffs, and a quantified attitude toward discounting. Subjective judgment is necessary to specify each of these." Had the author worked in game theory, it would have been: "To analyze alternatives, one typically requires a list of key opponents, assessments of their strategies and interests, a game tree, noncredible threats, and a quantified utlity function for each opponent. Subjective judgment is necessary to specify each of these."

As the saying goes, give a small boy a hammer, and he will find that everything he encounters looks like a nail in need of pounding.

The broadenings in §7 help but stay too close to the techniques. %}

{% Follow up on their earlier experiments, testing predictions by Eichberger & Kelsey (2002). They measure ambiguity attitudes in individual Ellsberg urns. They also consider choices in games where there is an action giving a sure outcome, but not part of a traditional Nash equilibrium. If subjects go for it, then they interpret it as ambiguity aversion. It could also be risk aversion, but they have a good argument against this in the conclusion on p. 403: "Future research on this area should be more careful to control for subjects' risk attitude. However, given the relatively small stakes, Expected Utility Theory would predict that subjects were approximately risk neutral. A similar argument does not apply to ambiguity. Choquet Expected Utility (CEU) orMaxmin Expected Utility (MEU) preferences have a kink. Consequently, ambiguity aversion may be seen even when the stakes are fairly small. Thus, it is not unreasonable to believe that most of the motivation for choosing the certain action is ambiguity aversion."

Abstract: They find more effect of ambiguity in the game than in individual choice. They also find context dependence of ambiguity attitudes, with ambiguity seeking (**ambiguity seeking**) in individual choice but ambiguity aversion in the game, which can be a kind of source dependence. P. 413 (in the Conclusion) writes: "In addition, we note that subjects' ambiguity attitudes appear to be context dependent: ambiguity loving in single-person decisions and ambiguity averse in games." I do not understand the claim of ambiguity loving in individual choice because §5.3, p.

398, reports 73% of subjects choosing in an ambiguity averse way in the standard three-color Ellsberg urn. Probably the slightly negative relation between ambiguity aversion in the game and in the Ellsberg urn (p. 395 last para & p. 396 top) made the authors write this. The ambiguity in the game, about opponent's choice, goes in the direction of natural uncertainty (**natural sources of ambiguity**).

P. 382 end of §3: Subjects liked to gamble on color blue because they like that color. Chinese students like to gamble on the color red. (**testing color symmetry in Ellsberg urn**: violated)

P. 388 ℓ. 3: "Risks are said to be ambiguous if the probabilities of possible outcomes are unknown and it is difficult or impossible to assign subjective probabilities to them."

P. 388 2nd para states the prediction of Eichberger & Kelsey (2002) confirmed here empirically: "In the case of strategic substitutes [competitive], increasing the level of ambiguity would shift the equilibrium strategies in an ex-post Pareto improving direction, whereas for strategic complements [cooperative], an increase in ambiguity would have the opposite effect."

P. 393 last para: for each subject, one randomly chosen game and one randomly chosen individual decision were implemented for real, giving some income effect.

P. 394: They let computers simulate Ellsberg urns. The composition was determined probabilistically, so that it in fact is 2nd order probability (**second-order probabilities to model ambiguity**). It is not clear to me if they informed subjects about this.

P. 395 last para & p. 396 top: Ambiguity aversion in different games was positively related. But it was even slightly negatively correlated with ambiguity aversion in the individual choices in the 3-color Ellsberg urn.

P. 403 last para: "It is our belief that subjects find it more ambiguous to make decisions against other people than against the random move of nature, over which everyone is equally powerless. This might even explain why people are more concerned with scenarios involving political turmoil or war—situations dependent on other people, but appear to discount the seriousness of possible natural disasters or climate change related catastrophes—which are beyond anyone's control." %}

{% **PT, applications**: PT gives some better explanations for paradoxes in transportation theories.

Take outcomes that are combinations of time and money. Do not consider tradeoffs between them, but just consider one pair x, 0, and –x, with $x \in \mathbb{R}_+^2$ assuming that for basic utility u we have u(–x) = –u(x), so that |U(–x)/U(x)| is loss aversion. They took x = (30 minutes, €5), and considered prospects with only outcomes x, 0, and –x. They use Ellsberg urns with 10 colors, where the urns have known or unknown compositions. The unknown urn was generated by a meta-lottery, so that in fact it was two-stage ambiguity. (**second-order probabilities to model ambiguity**). They derived probability weighting with a system similar to the preference ladders of Wu & Gonzalez (also in van Assen 1996), which gives a sequence of probabilities 0, p_1, …, $p_n < 1$ that are equally spaced in probability weighting, and then they did parametric fitting. I am not sure how the weight $w(p_n) < 1$ was determined. They used the Tversky & Kahneman (1992) and Prelec (1998) one-parameter weighting functions, which commit to inverse S.

Probability weighting more pronounced for ambiguity than for risk. (**uncertainty amplifies risk**). Ambiguity neutrality around $p = 1/3$. They find inverse S but used parametric families (one-parameter of T&K’92 and Prelec 1998) that have it. %}

{% The authors measure CEs (certainty equivalents) using choice lists, for money and number of human lives, with losses also involved in mixed prospects, and fit prospect theory. Of course, must be hypothetical. For gains, probability weighting is the same for money and lives.

PT falsified; probability weighting depends on outcomes: For losses, probability weighting is less elevated for lives, suggesting more risk seeking there. They find bigger loss aversion for human lives, suggesting more risk aversion for mixed prospects. %}

Kemel, Emmanuel & Corina Paraschiv (2018) "Deciding about Human Lives: An Experimental Measure of Risk Attitudes under Prospect Theory," *Social Choice and Welfare* 51, 163–192.
https://doi.org/10.1007/s00355-018-1111-y

{% Measure certainty equivalents of 24 lotteries. Everything, deciding, resolution of uncertainty, takes place at present, only outcomes can occur at different timepoints, at present but also in one year. Prospect theory is used to fit data. There is less risk aversion for future outcomes. This is not due to utility, which is the same for those, but due to probability weighting, which is more elevated (source preference) for future payoffs. (**violation of risk/objective probability = one source**) %}

Pp. 332-333: Remarkably, the authors find that linear-exponential (CARA) utility first better than logpower (CRRA) (**decreasing ARA/increasing RRA**). %}

Kemel, Emmanuel & Corina Paraschiv (2023) "Risking the Future? Measuring Risk Attitudes towards Delayed Consequences," *Journal of Economic Behavior and Organization* 208, 325–344.

{% **real incentives/hypothetical choice**: find no difference in patterns, but less error for real incentives.

Fit PT to data of DFE, both for monetary outcomes and for time (waiting time in sense of time lost as with traffic delays). The authors confirm inverse S (§4.3.b) probability weighting (also for what is called the incomplete information condition, meaning that subjects are not informed about what the possible outcomes are), which is remarkable because in DFE people usually find the opposite. The authors do not discuss this point. (**DFE-DFD gap but no reversal**) Utility of time gains is almost linear, but is concave for money gains. Average probability weighting is more insensitive and more elevated for time than for money. It is interesting to see if at the individual level there are many differences between probability weighting. The authors report significant correlations between them, but this is a weak test of identity. They find more pessimism than is usual for risk (maybe explained by ambiguity aversion) and, hence, less overweighting of small probabilities than is usual with risk.

One difficulty I have with all DFE studies is that subjects may have prior beliefs at the beginning of the experiment, before starting the sampling, and the experiments have no control over that. Subjects will believe beforehand that high money gains have small probabilities, and negative money outcomes will not happen. For time outcomes they may have different prior beliefs. %}

{% Most of the experiment uses hypothetical choice.

real incentives/hypothetical choice: §4.2 reports a test of the Ellsberg paradox where real and hypothetical payments gave the same results.

If the traditional 3-color Ellsberg questions are done with losses instead of gains, then there still is ambiguity aversion and it is almost equally strong as for gains (for gains, N = 75, 74.7% prefers unambiguous color, for losses, N = 59, 67.8% prefers unambiguous). For gambling on two colors (so, my subjective probability is 2/3), for gains, N = 60, 71.7% prefers unambiguous color, for losses, N = 64, 79.7%, prefers unambiguous to ambiguous. So, here is clear evidence against **ambiguity seeking for losses**.

Experiment 3 asked the subjects which event they considered more probable. They designated the unambiguous event as more probable. Remarkably, they even did so if the proportions were slightly favorable to the ambiguous urn. Pity it was always asked for the gain (or NOT-losing) event, so that subjects' answers may have confounded likelihood with amount of information.

Reducing ambiguity by providing (second-order probability) info reduces ambiguity aversion correspondingly.

reflection at individual level for ambiguity: paper gives no info because gain-loss was always between-subjects. %}

{% John Neville Keynes is the father of John Maynard Keynes.

P. 86: **conservation of influence; free will/determinism**: “The differentia of economic laws, as contrasted with purely physical laws, consists in the fact that the former imply voluntary human action.” Seems that he distinguished normative from positive economics. %}

Keynes, John Neville (1890) "*The Scope and Method of Political Economy.*" McMillan, London. (2nd edn. 1917.)

{% In Collected Works, Royal Economic Society XIV, p. 124, Keynes seems to have used the term Benthamite school for maximization of expectation.

P. 75 presents the known and unknown Ellsberg urns as illustration of unknown probabilities. Keynes argues for incomparability of some likelihoods, so, imprecise probability even at the ordinal level.

Keynes seems to write:

"The typical case, in which there may be a practical connection between weight and probable error, may be illustrated by the two cases following of balls drawn from an urn. In each case we require the probability of drawing a white ball; in the first case we know that the urn contains black and white balls in equal proportions; in the second case the proportion of each color is unknown, and each ball is as likely to be black as white. It is evident that in either case the probability of drawing a white ball is 1/2, but that the weight of the argument in favor of this conclusion is greater in the first case" (Keynes, 1921, p. 75) It reminds me of the deep point of Kahn & Sarin (1988), that we should not confuse outcome utility with process utility.

And Keynes seems to write, on p. 313:

"If two probabilities are equal in degree, ought we, in choosing our course of action, to prefer that one which is based on a greater body of evidence?"

(Craig Fox pointed out the combination of these two citations to me.) It may seem that Keynes is at an ε distance, with ε only trivially different from zero, from Ellsberg's discovery. But I disagree. First, the citation on p. 313 is for decisions in general. The urn is only an illustration of unknown probabilities without relation to decisions. Had Keynes thought for a split-second what the *decision* in the urn-case had been, he would of course have said immediately what we all know from Ellsberg. But Keynes did not bring decisions up there. Also, he did not notice the funny duality, that you prefer betting on an event as well as on its complement (source preference). Most importantly, he does not relate these urns vaguely to paradoxical behavior. He, of course, cannot show violation of the, then not yet existing, Savage axioms. He therefore preceded Ellsberg only to a little extent, and Ellsberg essentially deserves the novelty of his thought experiments.

The above citation, of p. 313, can be linked to the source method idea that the same probability can be weighted differently for different sources.

P. 309 discusses that in decisions you can't foresee the whole future.

P. 312, para 6, argues against context-independence

P. 348-349 of I think the 1973 edn.: He believes that degrees of belief are not measurable. Even if they are, expected utility may be inadequate. If we take "not measurable" as nonadditive then this suggestion entails the two-stage model; oh well. One should be careful not to impose one's favorite ideas on authors from the past. %}

Keynes, John Maynard (1921) "*A Treatise on Probability*." McMillan, London. 2nd edn. 1948.

{% **marginal utility is diminishing**, about consumption: p. 31:

"the marginal propensity to consume [is] weaker in wealthy community;" also on p. 120 and 349

P. 161-162 seems to write: "Most, probably, of our decisions to do something positive, the full consequences of which will be drawn out over many days to come, can only be taken as a result of animal spirits - of a spontaneous urge to action rather than inaction, and not as the outcome of weighted average of quantitative benefits multiplied by quantitative probabilities. Enterprise only pretends to itself to be mainly actuated by the statements in its own prospectus, however candid and sincere."

Seems to write on p. 161: [A] large proportion of our positive activities depend on spontaneous optimism rather than on a mathematical expectation, whether moral or hedonistic or economic. Most, probably, of our decisions to do something positive, the full consequences of which will be drawn out over many days to come, can only be taken as a result of animal spirits—of a spontaneous urge to action rather than inaction, and not as the outcome of a weighted average of quantitive benefits multiplied by quantitative probabilities.

P. 349:

"with the growth in wealth [comes] the diminishing marginal propensity to consume" %}

Keynes, John Maynard (1935) "*The General Theory of Employment, Interest, and Money*." Harvest/HBJ, San Diego, London, Recent edn.: 1964.

{% Pp. 212-215:

“… at any given time facts and expectations were assumed to be given in a definite and calculable form; and risks, of which, tho [though] admitted, not much notice was taken, was supposed to be capable of an exact actuarial computation. The calculus of probability … was supposed to be capable of reducing uncertainty to the same calculable status as that of certainty itself … Actually, however, we have, as a rule, only the vaguest idea … renders Wealth a peculiarly unsuitable subject for the methods of classical economic theory. … By “uncertain” knowledge, let me explain, I do not mean merely to distinguish what is known for certain from what is only probable. The game of roulette is not subject, in this sense, to uncertainty…. Even the weather is only moderately uncertain. The sense in which I am using the term is that in which the prospect of a European war is uncertain, or the price of copper and the rate of interest twenty years hence … About these matters there is no scientific basis on which to form any calculable probability whatever. We simply do not know. Nevertheless, the necessity for action and for decisions compels us as practical men to do our best to overlook this awkward fact and to behave exactly as we should if we had behind us a good Benthamite calculation of a series of prospective advantages and disadvantages, each multiplied by its appropriate probability, waiting to be summed. … it is subject to sudden and violent changes. … New facts and hopes will, without warning, take charge of human conduct. … All these pretty, polite techniques, made for a well-panelled Board Room and a nicely regulated market, are liable to collapse.” %}

Keynes, John Maynard (1937) “The General Theory of Employment,” *Quarterly Journal of Economics* 51, 209–223.

{% What the title says. Such criteria are usually less quantitative and more heuristic than in (axiomatic) decision theory. The analytical hierarchy process is most popular. %}

linear utility for small stakes: they assume linear utility.

real incentives: **random incentive system between-subjects** (they paid one choice for 1/5 of the subjects)

They use the two-stage model W(E) = w(P(E)) where P is judgded probability which may be nonadditive, and w is a probability weighting function that can depend on the source.

They say that the probability weighting function can depend on the source of uncertainty. It is an unfortunate terminology because the probability weighting function w(p) *is usually taken for risk* and then depends only on p under common terminology, and it is then logically impossible that it would depend on a source or whatever else other than p. If I may be allowed to write about own work, in the three-stage decomposition W(A) = w(φ(P(A))), proposed in Footnote 2 of Wakker (2004, *Psychological Review*, p. 239), φ (and not w) can depend on the source, and this is what may be happening here. In the source method of Abdellaoui et al. (2011) a composition w_S(P(A)) is considered with P additive and w_S depending on the souce, but w_S is not called probability transformation but source function.

They find that pessimism decreases for more familiar sources (competence effect).

Their idea to have risk (rather than ambiguity) attitude depend on source is so confusing that I usually avoid citing this paper, although otherwise it has many valuable ideas. This terminology is just too confusing. I was the AE editor handling this paper for MS, and did everything allowed within the boundaries for editors to make the authors change terminology, but did not succeed. Here is why I think this terminology is bad:

The concept of source dependent risk attitude works best when first explaining things to an uninitiated audience. They immediately understand the model, without having been exposed to new and difficult concepts such as ambiguity or uncertainty. But long-term this terminology is dead-end:

(1) The terminology deviates from common terminology. In the Ellsberg two-color, people call behavior for the known urn risk attitude. Behavior for the unknown urn they do not call risk attitude, but here ambiguity attitude comes in, deviating from risk attitude.

(2) If risk attitude becomes source dependent, then the concept becomes too general to be useful. There is some experimental evidence for source dependence of risk attitudes, so we should restrict to "emotion-neutral" risk. The evidence is not enough to pay the heavy price of giving up source-independence.

(3) The only definition of ambiguity attitude that I think can survive is

ambiguity attitude = uncertainty attitude - risk attitude

This definition is lost if risk attitude no more means one thing. If one calls behavior for Ellsberg unknown urn risk attitude, then I don't anymore see how to use the concept of ambiguity attitude. So, the concept of source-dependent risk attitude is impossible to coherently connect with other concepts. The difference between the unknown and the known Ellsberg urns is due to ambiguity attitude, and not due to changed risk attitude. %}

{% **DC = stationarity**: p. 603 bottom of 2nd column, and p. 604 1st column ℓ. 8.

This paper considers receipt of one nonzero outcome at some timepoint. It proposes not to use a multiplicative model to integrate utility and discounting, but an additive model (Eq. 6). Puts this forward as its central contribution (p. 605 directly following Eq. 6). Although it also argues at length that we should look at utilities of outcomes and not at outcomes and puts this also forward as a similarly central contribution (p. 606 last para of column 1).

One difficulty I have with the additive-multiplicative is that this form, in the absence of other nonzero outcomes, is purely ordinal and we can just apply the exponential function to get back the multiplicative form after all, after which the only point at which this model generalizes classical exponential discounting is that a power transformation of time is added. But it still is multiplicative then.

Another difficulty is that there is a timepoint at which the value of a positive outcome becomes 0. The author view this point from its sunny side, with a numerical example that $250 in 21 years from now should have value 0 (p. 605 middle of 2nd column). These insights are extremely new to anyone who has worked on intertemporal choice so far. P. 611 has another extremely interesting move: The author proposes to use his additive instead of multiplicative model also for risky choice, and sees sunny sides here too. The factual observation that he puts forward on p. 611, 2nd colum, 2nd para:
"Consumers do not multiply the payoff by its probability; they sum utility functions on magnitude and probability" of course provides strong evidence supporting his insight." So, then we get to deal with models where people have a strict preference for increasing an outcome obtained with 0 probability, but the author has his defense in place: "it is a mark of humanity that some individuals can always be found who will take that foolhardy gamble." (p. 611 2nd column 2nd para) So, again, extremely new insights, be it now for all working on risky choice.

I was surprised on p. 602 to find that the derivative of discounting (rather than utility) is taken to be Bernoulli's utility idea.

P. 604 top of 2nd column tells us, citing Luce, that power utility satisfies all empirical and theoretical desiderata for utility.

With this publication the top journal Psychological Review gives us many ideas that we would never have dreamed of otherwise. %}

{% This paper gives the nicest axiomatization of expected utility for risk that I know.

We consider decision under risk with preferences over lotteries. This paper gives necessary and sufficient conditions for an arbitrary finite set of preferences (can be incomplete!) over simple lotteries to be representable by expected utility (EU), improving upon the nice Fishburn (1975, Theorem 3) and the very nice Border (1992 Theorem 2.4). It then uses continuity to extend to larger sets of preferences. For the essence, being the finite case with no continuity involved (finite outcome set and finitely many preferences), the condition says: for the preferences observed, $P^j \succcurlyeq Q^j$, j = 1 ,…, n, where the first is strict, one takes each with probability λ_j ($\lambda_1 > 1$) and then the probabilistic mixture $\sum_{j=1}^{n} \lambda_j Q^j$ should not be the same as $\sum_{j=1}^{n} \lambda_j P^j$. I add: restricting to rational probabilities one can use Scott's (1964) way to get rid of the λ weights and then it is: **conservation of influence**. I further add: such mixings of preferences commonly happen in the random incentive system, used in experimental economics.

Border (1992) adds nice discussions. Such as that Raiffa (1968) also used such "prior" mixing of preferences. I add: so did Raiffa (1961) when commenting on Ellsberg (1961). Border also discusses well that the case considered, finitely many preferences, is the best regarding observability. I agree much with the interpretations of observable choice given by Border. They are in the spirit of Marcel K. Richter, acknowledged by Kim (1996). Ket Richter, as Kim calls him, is the informal name for Marcel K. Richter that he preferred that his friends use. He also told me to use it in our memorable one-time meeting (dinner for two) of 1985 in Karlsruhe where I was the young author inspired by the experienced Ket, in particular on observability.

Kim's Theorem 3.1 generalizes the result that I explained above (finite case) to a compact outcome space (such as any closed bounded interval in $\mathbb{R}$ or any closed bounded Euclidean space) and countably additive probability measures on the Borel sigma-algebra. The topology of the compact X plays a role in the definition of the Borel sigma-algebra and then in countable additivity condition, which is a kind of continuity. It generalizes the above finite case, but makes the result inaccessible to non-mathematicians. Major drawback: it obfuscates the important point that it can do without any continuity, so that it can achieve perfect observability. This is also why I prefer Kim's axiomatization to the von Neumann-Morgenstern and Herstein-Milnor axiomatizations that use the famous and appealing independence condition (well, vNM should have; see Fishburn & Wakker 1996). The latter involve continuity/Archimedeanity, which adds observable restrictions to the other axioms that we do not know or understand well. See the many discussions in this annotated bblipography with the keyword "**criticizing the dangerous role of technical axioms such as continuity**." %}

{% **decreasing ARA/increasing RRA**: paper tests constant relative and constant absolute risk aversion (although the author does not know these terms or concepts) and finds them all violated, arguing that we have to search for different utility families.

Exp. 1 uses matching to infer indifferences, and (p. 465) uses BDM (Becker-DeGroot-Marschak), but nicely follows it up with a choice question to verify, although the latter was not really incentivized. Then he tests constant relative risk aversion, by testing whether or not in indifferences

(⅓:3x, ⅓: x, ⅓:0) ~ (⅓:2x, ⅓: y(x), ⅓:0)

y is a linear function of x or not, finding it falsified. He thus rejects power utility. The experiments all have groups of about N = 20. P. 466 3rd para: BDM is hard for subjects.

Experiment 2 uses choice lists. P. 466 5th para: Those take more time. Now uses indifferences $3x_{½}x \sim 2x_{½}y(x)$ to test constant relative risk aversion.

P. 466 penultimate para: strangely enough, does not allow for convex-utility answers.

Exp. 3 considers indifferences

(⅓:5x, ⅓: 3x, ⅓:x) ~ (⅓: 3.25x, ⅓: 2.75x, ⅓:y(x)) to test constant relative risk aversion, and

(⅓: (x+24), ⅓: (x+12), ⅓:x) ~ (⅓: (x+13.50), ⅓: (x+10.50), ⅓:y(x))

to test constant relative risk aversion. Again, strangely enough, he only allows for concave utility by only considering negative exponential utility.

Experiment 4 considers what I call logarithmic utility, ln(hx+1) with h the free parameter, for which he cites Rachlin (1992) but it dates back from long ago in economics. %}

Kirby, Kris N. (2011) “An Empirical Assessment of the Form of Utility Functions,” *Journal of Experimental Psychology: Learning, Memory and Cognition* 37, 461–476.

{% Seems that:

real incentives/hypothetical choice, for time preferences; more discounting for hypothetical than for real;

DC = stationarity;

Assume linear utility throughout. Mazur discounting. Kept delayed reward constant, varied delay, asked for reward today that yields indifference (matching). Repeated this for several delayed rewards. Delays were from 3 to 29 days. Rewards ranged from $14.75 to $28.50. Real rewards in experiment 1 through an auction (nice). Repeated the study in experiment 2 with hypothetical rewards. Find that hyperbolic discounting fits better than exponential discounting. Discount rates were lower for hypothetical rewards than for real ones. No evidence for reward-size-dependent discounting, so, no magnitude effect.

Fitting of data at individual level; "the most curious result of these experiments was the failure to find reliable decreases in discounting rates as delayed reward size increased." (The decrease was very small). %}

{% **ambiguity attitude taken to be rational**: An accessible account of this model, describing its underlying assumptions, is in Marinacci (2015 §4). Kahneman & Tversky (1975 pp. 30-33) have the smooth model for ambiguity for two outcomes.

event/outcome driven ambiguity model: outcome driven.

source-dependent utility: the essence of their approach, although interpretations may differ.

The authors (KMM) consider a two-stage-expectation representation sometimes called rercursive EU as in Kreps & Porteus (1978), i.e.,

$EXP_{\Delta}[\varphi(EXP_S[U(f(s))d\pi])d\mu]$,

where

1. $EXP_S[\ldots]$ denotes expectation over S. S is a Savagean (1954) state space, f is an act, U is a usual utility function to be used in regular expected utility, and π is a subjective probability measure over S à la Savage.

2. KMM assume that there is ambiguity about what the proper π is. This is reflected by a second-order probability measure μ over the set Δ of all first-order probability measures π over S. This μ reflects subjective perception. Thus, this paper calls the last stage, to the right in the tree, first-order, and the first stage, to the left of the tree, second-order. Both this terminology, and the one with first and second interchanged, exist in the literature.

At each stage KMM assume EU but φ can be nonlinear and, hence, it is not EU overall. It means that they do commit to the backward-induction version of dynamic nonEU (formally stated in their Assumption 3, p. 1857), giving up RCLA.

They also assume that S has an Anscombe-Aumann-like decomposition (§2.1). In other words, they assume that objective probabilities are given in S about which there is no ambiguity, so that all π's considered (in the support of μ) agree there with those objective probabilities. They use these to derive U and, later, to define ambiguity.

A recursive EU-type two-stage model as above (for simplicity we follow the authors in not counting the Anscombe-Aumann part as an extra stage) has been considered before by Kreps & Porteus (1978), who interpreted it as an intertemporal model with a nonlinear φ modeling attitudes towards the *timing* of the resolution of risk. Reinterpreting such a two-stage Kreps-Porteus setup for ambiguity where the two stages reflect resolutions of uncertainty of a different level of ambiguity, was considered simultaneously and independently by Nau (2006) and Ergin & Gul (2009), and before by Neilson (1993, published 2010). Remarkably, also Kahneman & Tversky (1975 pp. 30-33). The Neilson (1993) reference I learned from KMM's citations. The authors cite Segal for the general use of 2^{nd}-order probabilities to model ambiguity (but without a recursive EU), but this has been done in many papers before 1990 (Gärdenfors 1979; Gärdenfors & Sahlin 1983; Kahneman & Tversky 1975 p. 30 ff.; Larson 1980; Yates & Zukowski 1976). As do the aforementioned studies, KMM assume that acts, called *second-order acts*, are available whose outcomes are contingent on the second-order uncertainty resolution; i.e., on which subjective probability measure $\pi \in \Delta$ on S applies. An example of such a second-order act is displayed some later.

The big difference of the present paper (KMM) with preceding ones is that KMM allow the two-stage decomposition to be endogenous. What I mean is that in preceding approaches each first-order probability distribution occurs conditionally on an exogenous explicitly defined 2nd-order event, referring to some physically defined event, such as a composition of an urn in the Ellsberg paradoxes. This greatly limits the applicability because such conditioning events are rarely available in practice. KMM drop the assumption of such conditioning events, and just directly let the subjective 2nd order distribution (denoted μ) apply to first-order subjective probability distributions over the Savagean state space S. So, KMM consider choices between bets (their second-order acts) such as:

EXAMPLE OF 2ND ORDER ACT.

> We are going to derive from your preferences what your subjective probability of rain tomorrow is. If we discover that you consider rain at least as likely as 0.45, you receive $\$10^6$. If we discover that you consider rain less likely than 0.45, then you receive \$0. Would you rather have that gamble or 200,000 dollar for sure?

Thus, KMM consider bets with payments contingent on endogenous aspects of preference. Such bets do exist in the special case where the events pertaining to π are exogenous and physically definable ("identifiable"), e.g. when referring to the unknown composition of an urn (then however the π's are only objective), or maybe to an unknown parameter in statistics. (These, however, while outcome-relevant, are usually not treated as observable in the sense that we can construct any bet on them. Bayesian statisticians who assume priors implicitly assume such bets to be available but are, I suspect, usually not well aware of the problematic observable status of bets on parameter-values.) Such cases are in the domain of Kreps & Porteus, Nau, and others, which includes all examples of this kind put forward in the KMM paper. The generalization added here of allowing the outcome-relevant events for second-order acts to also be endogenous greatly enhances the scope of applicability of the theory, but along with it brings in this observability problem, and tractability problems. It means they have as subjective decision parameter in their model the set of all probability distributions over the set of all probability distributions over Savage's state space S, which is a parameter of a very high cardinality (formalized by Basu & Echenique 2020), leaving the theory very very unspecified. KMM discuss the pros and cons of using the unobservable second-order acts on p. 1856.

With all events regarding π assumed observable etc. via second-order acts, KMM can separate ambiguity-beliefs (this is how μ above is interpreted) and ambiguity-attitudes (this is how φ above is interpreted).

KMM characterize concavity of φ as follows: They take utilities $U(f(s))$ as observable outcomes, which is plausible if we interpret them as standard gamble probabilities: $U(f(s)) = p$ can be taken as a M_pm lottery with M big outcome with $U(M) = 1$ and m small outcome with $U(m) = 0$. Then φ is concave if and only if every act f is less preferred than its μ-expectation U(f(s)). So, this is the usual definition of weak risk aversion. A difficulty of this condition is that the μ-expectation is not directly observable because μ is a subjective probability, only inferrable through elaborate elicitations of preferences over second-order act s (**derived concepts in pref. axioms**; that subjective probabilities are indeed subjective and cannot be direct inputs is argued for instance by Budescu & Wallsten (1987, p. 68). Strzalecki (2011 ECMA p. 61) will point this out. Things are doable from the observability perspective if there exists a subset of Δ with μ probability 0.5 because this is easy to infer from choice and using only this event is enough to characterize concavity of φ. It also implies that two persons can be compared regarding ambiguity aversion only if they have the same risk preferences.

A drawback that all the approaches mentioned, including Kreps & Porteus (1978), have and share with for instance Chew's (1983) weighted utility (sum $p_i f(x_i)U(x_i)/\text{sum} p_i f(x_i)$ for DUR) is that all extra mileage is obtained from a function φ that, like U, applies to outcomes (φ indirectly via utility U). Thus, not only the risk-attitude-like-EU behavior, but also the ambiguity attitude, is driven entirely by the outcome domain we are facing, and not by the uncertainty-domain we are facing. This is apparent from Corollary 3 (p. 1865) with ambiguity attitude described by the Pratt-Arrow measure of φ *at an outcome*, and Assumption 5.ii (p. 1869) with ambiguity attitude specified through the *interval of outcomes*.

The approach of this paper, like most others, cannot separate absence of ambiguity from ambiguity neutrality. Section 4 (pp. 1870-1872) is remarkable in having ambiguity defined through relating it to exogenous known probabilities—which I like. The definition of ambiguity is inextricably linked with ambiguity aversion or seeking. Likelihood sensitivity, with a symmetric capacity, is taken here as unambiguous (Proposition 5). It means that KMM only consider source preference and not source sensitivity. For example, the extreme case of likelihood insensitivity (source insensitivity), with weight 0 for empty event and weight 1 for universal event, and weight 0.5 for all other events, according to the authors' definition means that there be no ambiguity. This is not correct. (**Ambiguity = amb.av = source.pref, ignoring insensitivity**)

Note that an agent can be more ambiguity averse towards source_1 of events that towards $source_2$ in two ways: Either by either taking φ more concave, or by taking the endogenous two-stage decomposition more dispersed. In KMM's interpretation it should only be the second way. φ should be a stable within-person property independent of source. A person's ambiguity aversion should be independent of the source! I expect that most people applying KMM will not work this way, but will vary concavity of φ within a person as in Chew et al. (2008). For descriptive purposes, if we find ways to identify φ and μ from data, then it can become an empirical question.

P. 1859 end of §2, Corollary 1, states that on S the authors need not commit to EU, but could also handle nonEU models, where the authors consider Quiggin's RDU. In the more problematic second stage, where ambiguity is handled, the authors do need EU. For the axiomatization, however, EU on S is used.

I summarize what I consider to be drawbacks of the KMM approach in my comments to Epstein (2010, Econometrica). A detailed comparison on similarities and differences with recursive expected utility is at the beginning of my annotations at Denti Pomatto (2022).

biseparable utility violated %}

Klibanoff, Peter, Massimo Marinacci, & Sujoy Mukerji (2005) "A Smooth Model of Decision Making under Ambiguity," *Econometrica* 73, 1849–1892.

{% Give extension of their 2005 Econometrica paper to a sequential setting. At each timepoint there is a model to substitute certainty equivalents that works recursively, combining the utility of current consumption with that of the certainty equivalent next time through a discounted utility evaluation. They cite preference axiomatizations on discounted-utility evaluations with no need to write it out in their paper.

A big conceptual decision they took is that this is not a sequential setup of their model, but it is their model of a sequential setup. That is, the ambiguity is at the beginning and concerns the future path as a whole (consumption plans). They then do backward induction. But in their model it is reasonable that ambiguity disappears at future nodes because of more and more repeated observations, which they explain repeatedly (e.g. p. 937 §2.4; p. 952 ℓ. 8). They consider a model where there is a clear well-definable objective probability, the only thing being that this is unknown, and this becoming more and more known as more (frequentist!) info comes in over time, as is common in statistics (p. 937 writes “the true process”). In this sense the ambiguity considered here is not purely subjective but it is iid-type.

I was glad to see that p. 958 points out that the Epstein & Schneider (2003 JET) rectangle version of multiple priors was preceded by Sarin & Wakker (1998). %}

Klibanoff, Peter, Massimo Marinacci, & Sujoy Mukerji (2009) “Recursive Smooth Ambiguity Preferences,” *Journal of Economic Theory* 144, 930–976.

{% Discuss, within smooth models, some definitions of ambiguity by Epstein, Ghirardato et al., Nehring, and others. I see things differently in the sense that whether an event is ambiguous is better NOT taken as endogenous. We researchers decide beforehand, without having seen any preference, that it is the unknown urn that is ambiguous in the Ellsberg two-urn experiment. %}

Klibanoff, Peter Massimo Marinacci & Sujoy Mukerji (2011) “Definitions of Ambiguous Events and the Smooth Ambiguity Model,” *Economic Theory* 48, 399–424.

{% For my comments, see Epstein (2010). %}

Klibanoff, Peter, Massimo Marinacci, & Sujoy Mukerji (2012) “Notes and Comments On the Smooth Ambiguity Model: A Reply,” *Econometrica* 80, 1303–1321.

{% Consider the usual Anscombe-Aumann (Anscombe-Aumann) approach for ambiguity. Assume a countably infinite sequence of realizations of the state of nature that in a way are iid, and impose event symmetry which is like de Finett’s (1937) exchangeability. Their main axiom, Axiom 5 (p. 1951, event symmetry) requires, more precisely, that mixing an act with a cylinder-event-A-indicator function does not change preference value if a permutation is applied to A.

They get a kind of multiple prior representation. For every prior on the state space there is an EU representation. The representation then is a general overall aggregation of these EU representations.

What I find typical of multiple prir representations as opposed to two-stage representations is that a prior is in or out of the prior set and those in are treated similarly, as are those who are out, with for instance not one receiving higher weight than the other. (The latter happens in two-stage models.) This need not be the case for the general aggregator here, as it is not for the smooth model, which is why their model for me is more two-stage than multiple prior. The model is not like usual two-stage in that one cannot after every resolution of the 1st stage uncertainty plug in any continuation. Instead, there is only an act contingent on the state space, and the second-stage decomposition is endogenous with everything following conditional on a 1st stage resolution of uncertainty relating to that same act contingent on the state space, as in the smooth model. P. 1946 penultimate para assumes so much richness that they come close enough to the product-space richness of regular two-stage models to do the required maths.

They define a prior as nonnull (or relevant) if every of the open sets containing it is nonnull. One can restrict the set of priors aggregated by G to the set D of nonnull priors if one wants.

They formulate the usual Yaari (1969)-type condition of being more ambiguity averse. It implies that (I would then say can be applied only if) the risk attitude (vNM U in EU) must be the same and if nullness of priors (so, the above set D) is the same. They interpret this as meaning that the set D captures ambiguity, and G ambiguity aversion. This is plausible and a nice direction. Yet I see limitations. First, going only by priors being null or nonnull is crude. For instance, if two persons a priori do not think that any prior is impossible, then according to this definition they perceive the same ambiguity. But one of the two may be fairly sure about what the right prior is, and the other may be more diffuse, so that they perceive ambiguity differently. A second limitation is that the Anscombe-Aumann framework (through monotonicity on p. 1950) imposes an implausible separability on the ambiguous horse states (Wakker 2010 §10.7.1 and Machina 2014 Example 3), precluding many kinds of ambiguity attitudes. It would be more desirable to also compare ambiguity attitudes of agents who have different risk attitudes and different sets of D, using for instance techniques of Baillon, Driesen, & Wakker (2012), and it suggests to me that the Yaari-type condition is too restrictive, in the same way as I consider Yaari (1969) too restrictive for EU. That the condition in this paper restricts to the same set D then does not mean that D has nothing to do with ambiguity aversion, but that the definition is too limited.

I disagree with a text on p. 1955:

"Yaari's definition, under sufficient conditions on the utility function (e.g., differentiability), implies that SEU preferences can be ranked in terms of risk aversion only if they share a common subjective probability measure. Thus, changes in the subjective probability measure can neither increase nor decrease risk aversion. Analogously, our next result provides a sufficient condition so that, when Definition 3.4 is applied to Continuous Symmetric preferences, preferences may be ranked in terms of ambiguity aversion only if they share the same set of relevant measures. In this way, changes in relevant measures are shown to neither increase nor decrease ambiguity aversion."

That Yaari needs identical subjective probabilities is only a limitation of his definition. That a change in subjective probability then cannot lead to an increase or decrease in risk aversion reflects only that limitation, and is not because there'd be no increases or decreases. It is only because Yaari's condition is blind for such, i.e., doesn't give any info of any kind there on how much risk aversion or risk seeking there is. If a blind doctor cannot see a symptom then this does not prove that you are healthy. The same holds for what the authors do. The main result of this paper is no other than that for comparative ambiguity aversion results in the Yaari style one needs identical sets of priors (in the sense of "relevant measures"). This does not prove that they do not interact, but only that the authors' Yaari-style condition cannot detect it. %}

Klibanoff, Peter, Sujoy Mukerji, & Kyoungwon Seo (2014) "Perceived Ambiguity and Relevant Measures," *Econometrica* 82, 1945–1978.

{% They provide axiomatizations of the smooth model and α-maxmin. However, they use a very rich structure, where occurrences of the state space S can be repeated infinitely often, as in the relative frequency interpretation of probability, with symmetry imposed there. %}

Klibanoff, Peter, Sujoy Mukerji, Kyoungwon Seo, & Lorenzo Stanca (2022) "Foundations of Ambiguity Models under Symmetry: α-MEU and Smooth Ambiguity," *Journal of Economic Theory* 199, 105202.

{% **source-dependent utility**: A subjective version of Kreps & Porteus (1978). The authors assume a finite Savage state space. There are T timepoints, and at each timepoint one receives more info about the true state of nature. This can be modeled by T partitions of the state space, each later one getting more refined (a filtration). They assume recursive backward induction with certainty equivalent substitution. At each timepoint SEU holds within that stage. They consider all kinds of cases, such as a fixed filtration (which I find most interesting) or all filtrations. Can be the same SEU model at each stage, or entirely different, or same subjective probability μ all of them but different utilities (this is closest to Kreps & Porteus), or the same utilities also.

I regret that the authors at each stage have an Anscombe-Aumann framework, assumed to derive SEU there. This means there are not T+1 stages, but 2T+2, with at every timepoint first the event of the partition revealed but then also a lottery carried out. It also means that they still need objective probabilities as did Kreps & Porteus. %}

Klibanoff, Peter & Emre Ozdenoren (2007) “Subjective Recursive Expected Utility,” *Economic Theory* 30, 49–87.

{% They fit EU, RDU, and PT to data about call options in the S&P500 index, using representative agent, power utility (same power for gains and losses in PT), Prelec and T&K one-parmeter weighting functions, and loss aversion. PT fits best, and all empirical findings of PT are confirmed. Unfortunately, they do rank-dependent integration bottom-to-top, so, the wrong way, and the parametric families of T&K and Prelec therefore mean something different than is common in the literature. Thus, whereas in Prelec’s paper his one-parameter family predicts no probability weighting if the best of two outcomes receives probability 1/3, as these authors do it there is no probability weighting if the worst of two outcomes receives probability 1/3. For EU they cannot reject risk neutrality. %}

{% **ambiguity seeking for losses**: found

ambiguity seeking for unlikely: found

The original title was better: "Ambiguity Aversion is the Exception." Unfortunately, an insisting referee imposed her subjective opinion on the authors and demanded that they change the title into the much weaker version that it is now. The editor should have intervened and forbid the referee to do this, but unfortunately did not carry out his task here.

Confirm the fourfold pattern af ambiguity attitudes: Find perfect a(mbiguity-generated)-insensitivity with ambiguity seeking for unlikely gains and ambiguity aversion for moderate and likely gains, and ambiguity seeking for losses. They are probably the first to test ambiguity aversion for mixed prospects, and find neutrality there. So, the common loss aversion for risk is not amplified for ambiguity.

They measure ambiguity attitudes from direct choice between an ambiguous and nonambiguous option where an ambiguity-neutral person should be indifferent, and also from matching probabilities. Differences between gains, losses, mixed, high, and low probabilities are between-subjects. They use same implementations everywhere, giving very clean data.

P. 276, §6.2, points out that the smooth model can accommodate sign dependence, but not insensitivity. Multiple prior models as existing today cannot handle sign/reference dependence, but generalizations are straightforward. %}

Kocher, Martin G., Amrei Marie Lahno, & Stefan T. Trautmann (2018) "Ambiguity Aversion Is not Universal," *European Economic Review* 101, 268–283.

{% **decision under stress;**

losses from prior endowment mechanism: They do not do this, but use an interesting alternative, in Experiment 1, that can be called "losses from posterior endowment". Subjects are told that there are two parts, first A and then B. They are told that in A they may lose, and in B they may gain, without being told how much each is. In reality, the gain in Part B will always at least cover the loss in Part A. The endowment is not prior but posterior, so to say. No untrue things are told to subjects here, so, in this sense there is no deception. But subjects can come out saying:

"They may tell you that you may lose but in reality, don't worry."

Another small drawback is that there is an income effect of a weak kind. Part B was not relevant so, it does not matter there, but in Part A subjects know that more money is coming. Because they don't know how much, this income effect is really weak. Despite these two minor drawbacks, this is by far the best implementation of real incentives for losses that I ever saw, in fact the only one in the literature so far that I consider valid. Losses from prior endowment mechanism has drawbacks that are too big, with 1/3 of the subjects integrating the payments. So, this is an interesting new way to implement losses!

Study time pressure (TP) for choices under risk, for pure gains, pure losses, and mixed prospects (both gains and losses). TP does not affect risk aversion under gains, increases it (turning majority risk seeking into majority risk aversion) for losses, and has a mixed effect for mixed prospects: effect 1: when choosing between a nondegenerate pure-gain prospect and a mixed prospect, TP moves preference towards the pure-gain prospect. Effect 2: when choosing between a nondegenerate pure-loss prospect and a mixed prospect, TP moves preference towards the mixed prospect.

The authors claim that their finding on mixed prospects falsifies PT, but I disagree. It only falsifies PT-with-the-added-assumption-that-no-parameter-of-

PT-other-than-loss-aversion-will-be-affected-by-TP. (Then indeed Effect 1 implies increased loss aversion and Effect 2 implies decreased loss aversion. The latter claim is subtle and requires some thinking, but is correct; see Exercise 9.3.8 in my 2010 book.) However, there is too little evidence for the added assumption. For gains they find no change in risk aversion, but this is a null hypothesis accepted, which is weak evidence. Also, they only do particular tests of risk aversion, and not of insensitivity. For losses they do in fact find a change of risk attitude, falsifying the above added assumption. A more detailed investigation of the parameters of PT and their interactions, with possibly more detailed data, would be required before we can draw concrete conclusions about PT and its parameters under TP. The big picture of the results is increased insensitivity under TP, agreeing with PT.

As an aside, the EU-with-aspiration is not really a deviation from PT. It is an extreme degree of PT, with extreme insensitivity towards outcomes. Diecidue & Van de Ven show this in a mathematical sense, with the discontinuity of U at 0. This is a natural extension of the steepness of U at 0 that PT postulates.

Whereas PT is not violated by the data as I see it, EU-with-aspiration is in a way. It is violated by the change in attitude for losses, or at best has nothing to say on that.

In summary, I disagree with both of the following sentences in their conclusion "Our results show that typical nonexpected utility patterns as modeled by prospect theory may not provide an appropriate description of choice behavior if time pressure becomes important. We have shown that recently developed models of expected utility with an aspiration level (Diecidue & van de Ven 2008) may be a useful alternative in such situations."

Experiment 1 had some order effects, but Experiment 2 controlled for them and showed that they play no role.

They also study effects of providing info about expected values. This only had effect for the choices with mixed prospects, moving these choices towards expected value maximization. Besides the awareness explanation proposed by the authors in the last para of the paper, it may also be because for mixed prospects, with loss aversion coming in, preferences are volatile rather than conscious, making subjects more open to any kind of external influence. %}

Kocher, Martin G., Julius Pahlke, & Stefan T. Trautmann (2013) "Tempus Fugit: Time Pressure in Risky Decisions," *Management Science* 59, 2380–2391.

{% N = 379; RIS.

losses from prior endowment mechanism: Because losses were involved and as such were implemented, the subjects after carried out unrelated risky-choice tasks where they surely gained more than what was lost before. They got the reassurance that their net-gains would never be negative, but they did not get more info about those later choices. I don't know to what extent subjects thought that losses would just be recovered later, or questions later were chained in a way to make losses disappear so that one can ignore losses.

They analyze effects of self-selection in time pressure. In experiments on time pressure, experimenters often remove subjects who did not meet the time constraint, which obviously brings biases. This paper also analyzes the slowest subjects who did not meet the time constraint. Further, it relates to demographics. People who take more care without time pressure, suffer more from it. No very clear relations are found.

They consider decisions under risk. That is, choices between mixed and all-gain lotteries, where the mixed have higher EV, and between mixed and all-loss lotteries, where the all-loss have higher EV. EV maximization is taken as best. Heuristics will usually lead to preference for all-gain over mixed and of mixed over all-loss and, thus, to violations of EV.

cognitive ability related to risk/ambiguity aversion: They also measure cognitive ability using Raven's progressive matrices for cognitive ability (IQ) andintellectual efficiency (IE). Time pressure reduces EV maximization, and EV maximization is related with cognitive ability, but not strongly. It increases loss aversion and probability weighting. %}

{% **ambiguity seeking for unlikely**: They confirm this. They also let subjects decide on behalf of others and then find the same. No significant differences with individual choices. Nice thing is that when determining matching probabilities (the authors use the term probability equivalent) for unlikely event they take a choice list that is symmetric for ambiguity neutrality (then p = 0.10; they took 0.10, 0.19, 0.04, 0.16, 0.07, and 0.13; see Table 1) so that there is no center-bias or regression to the mean.

I disagree with the sentence in the final para of the conclusion: "studies, we find that ambiguity attitudes depend strongly on the likelihood range considered." I think that ambiguity attitude is the same for low and moderate likelihoods: Always it is insensitivity. I would agree with the sentence of the authors if they had replaced the term "ambiguity attitudes" with the term "ambiguity aversion." %}

{% **consistency** Observation in §2 (p. 108) shows that under some dynamic conditions, two-stage CEU (Choquet expected utility) must be SEU.

dynamic consistency. NonEU & dynamic principles by restricting domain of acts: C onsiders a two-stage structure with first-stage events $E_1,\ldots,E_n$ with $E_j = \{s_{j1},\ldots,s_{jn_j}\}$ and a ranking such that $s_{(j-1)n_{j-1}} \succcurlyeq s_{j1} \succcurlyeq \cdots \succcurlyeq s_{jn_j} \succcurlyeq s_{(j+1)}$, calling them nest-comonotonic. On this subset we have everything the same as SEU also if we reduce with CE (certainty equivalent) substitution. So, here different ways to evaluate dynamic prospects, and to update (Section 4), agree as they do under SEU. The author shows how restrictive backward induction is.

Then he imposes an axiom requiring that the CE substitution for each event E should be independent of the rank of E. It holds if and only if the weighting function W is an exponential transform of a probability measure (also implying probabilistic sophistication.) He assumes richness both for outcomes and for states.

Corollary 2 (p. 113) characterizes CEU with **state-dependent utility** as in Chew & Wakker (1996). Theorem 2 relates first- and second-stage exponential CEU by the Bayesian update rule for weighting functions. %}

{% They test information aversion in a case of dilation in Ellsberg urns, and its relation to ambiguity aversion. An urn contains 21 balls, 5 numbered 1, 5 numbered 2, and 11 numbered 3 or 4 in unknown proportion. (So, the ambiguous are favored somewhat.) The odd-numbered balls with numbers 1 or 3, have a green color and the even-numbered, 2 or 4, a blue color. Subjects rather gamble on {3 or 4} than on 1 or 2}. However, if they first receive info about the color, so that, under color green, {3,4} becomes ambiguous, then they prefer to gamble on {1,2}, which under green coincides with {1}, than on {3,4}, which under green coincides with {3}. The color info "breaks a hedge," as the authors eloquently put it, against ambiguity. The hedge is close to Raiffa's (1961) deliberate randomization in Ellsberg's urn.

The above is not really a direct test of information aversion. The authors added such by letting subjects choose between gambling on {3,4} with or without olor info provided, where even the stakes were increased by 50 cents if color info was received. Still, 62% of subjects exhibited information aversion (**information aversion**). Information aversion is positively related to ambiguity aversion.

The authors also tested dynamic consistency by letting subjects specify conditional preferences before and after receipt of info. (**dynamic consistency**) They find no correlation between dynamic consistency and information aversion.

This is remarkable because, theoretically, information aversion is about the same as dynamic inconsistency.

A second experiment provided some robustness tests. One replaced the ambiguity in {3,4} regarding {3} versus {4} by two-stage probability, where the proportion of {3} versus {4} is determined probabilistically. This removed all ambiguity and was treated as risk. Although the authors do not cite Halevey (2007), this finding provides counterevidence against his claim that ambiguity is mostly perception of second-stage uncertainty plus violation of RCLA. The second experiment finds less information aversion (35%). Overall, it is 49%.

The concluding sentence: "Our results suggest that counseling on topics like health, financial literacy and others may have to be delivered in a way that takes into account what effect the information has on the subjectively perceived ambiguity in the situation." %}

Kops, Christopher & Illia Pasichnichenko (2023) "Testing Negative Value of Information and Ambiguity Aversion," *Journal of Economic Theory* 213, 105730.

{% This paper investigates the Decision from Experience (DFE) versus Decision from Description (DFD) gap. It states and confirms the Relative Underweighting Hypothesis: There is a DFE-DFD gap (which is trivial), there is less pronounced inverse S for DFE, but it does not reverse into S-shape, but remains inverse S. (**DFE-DFD gap but no reversal**) This is contrary to the big selling point of DFE in its first papers. %}

Kopsacheilis, Orestis (2018) "The Role of Information Search and its Influence on Risk Preferences," *Theory and Decision* 84, 311–339.

{% **Compare different measurement methods**: compare two elicitation methods to calibrate prospect theory: Certainty equivalent measurements vs. choices between two binary lotteries. They thus in effect put the Mccord & de Neufville's (1986) idea to a test. They also compare two methods of statistical analysis: maximum likelihood vs. Bayesian hierarchical.

It should be understood here that comparing different elicitation methods is much more difficult that comparing different theories. The reason is that different theories can be tested on the same data set. One needs to collect only one data set, and then can compare 20 different theories, and 20 different parametric implementations of each theories, readily. With few exceptions, every different elicitation method and every different implementation thereof requires different stimuli and a different data set. Thus, this paper has only two horses participating, and then needs to collect two data sets for it. Another problem is that, because different measurements involve different stimuli, comparisons are hard. Different stimuli can involve different difficulties and biases, and in return be more or less informative, the latter domain-dependent. The authors, indeed, find that CE measurements better predict CE choices, and binary-lottery choice measurements better predict the corresponding choices. So, what to conclude?

As for statistical analysis, the Bayesian hierarchy method does better simply because it uses more information, letting choices of one person be informative about another person's choices. Yet maximum likelihood remains of interest because in many applications we apply theories at the individual level, for only one patient or only one company, and then need to know the performance of maximum likelihood. %}

Kopylov, Igor (2016) "Canonical Utility Functions and Continuous Preference Extensions," *Journal of Mathematical Economics* 67, 32–37.

{% Considers maxmin EU with set Δ of priors exogenously given. Good arguments can be given for using Δ as exogenous. And, as often done, the Anscombe-Aumann framework is used. Model is convex combination of EU and maxmin EU: $(1-\varepsilon)EU_p + \varepsilon \inf_{q \in \Delta} EU_q$ for a subjective probability measure p. So, a special case of neo-additive (**EU+a*sup+b*inf**). §1.3 shows that the model can be rewritten as maxmin EU with ε contamination multiple priors. The set of priors is derived endogenously here. The same model with this set endogenous is in Kopylov (2009).

A monotonicity condition over Δ ensures that p is in Δ. The security level of each act is the EU minimized over Δ. For acts with same security level, vNM independence holds, so that then EU governs. The preference value of an act depends on both the EU mentioned and the security level, leading to the convex combination. Given the linearity present in the Anscombe-Aumann framework, the convex combination results. Note that Jaffray (1994 §3.4.3) also characterizes α maxmin with Δ exogenously given.

The paper also considers updating with a weakening of dynamic consistency (**dynamic consistency**; **updating under ambiguity**). %}

{% Biggest contribution of this paper is to give background to what the reference point is, and doing so in a tractable and implementable manner. Big question in prospect theory is what the reference point is. This paper, as explained p. 1136 end, gives an answer, using common economic-model inputs (besides the gain-

loss function μ and interpretations of utility as introspective rather than revealed-preference measurable).

u(c|r) is utility of outcome c if reference outcome is r. The authors consider U(F|G) with F and G prospects (probability distributions over outcomes), F being the prospect received, and G being the reference prospect. (**conservation of influence**: would be nice to reconsider it from that perspective). So, not only the object received but also the reference point can be random, as in Sugden (2003). G need not be status quo but is EXPECTED prospect. (Here expected could be a natural-language term, but it also is taken as a formal expectation integrating out over a probability distribution over decision situations, where apparently an expectation is the operation to be used but this is only applied to the second-stage probabilities. I will ignore this extra stage in what follows.) If a person decides to choose some F from an available set, then F will also become the expectation, and U(F|F) is the evaluation to be considered. Choosing from an available set then amounts to maximizing the function F --> U(F|F) which, in this interpretation, could be taken as just a consumption utility function of F with no reference dependence involved. Caveat is that F must be a personal equilibrium (PE) in the sense that U(F´|F) should not exceed U(F|F) for the available F´. The best such, maximizing F --> U(F|F), is the preferred personal equilibrium (PPE). F|F is a PE if sufficiently strong assumptions of loss aversion are made, favoring the reference point enough relative to other points. A strange thing is that in all evaluations U(F|G) the authors assume F and G stochastically independent, also if F is G. It means that what is known as disappointment (under regret you compare with other things that could have happened had you acted differently; under disappointment you compare with other things that could have happened had nature, coincidence, acted differently) plays a big role in this model. It is also remarkable that in optimizing F --> U(F|F) (rather than staying put in the first PE one runs into), the reference point is apparently something to choose so as to optimize, and utilities of different reference points are compared to each other. The function U(F|F), with stochastic independence of the one F from the other F, is like the one of Delquié & Cillo (2006). Traditional models only have choices GIVEN a reference point, and endogeneity of a reference point then means no more than that we infer from choices what the reference point is but still without assuming that the reference point was an actual thing to choose.

I next give details about U. The authors propose that utility U(c) consists of two components, first a consumption utility, second a gain-loss component (I would prefer to interpret it as a more general perception component that also captures diminishing sensitivity etc., similar to Sugden's (2003, JET) gain-loss interpretation which in fact also captures more general psychological perceptions), and get $U(c) = m(c) + n(c|r)$, where $n(c|r) = \mu\big(m(c) - m(r)\big)$. They take U as sum of m and n, and not as composition where U(c) would be $u\big(\varphi(c)\big)$ with φ a (mis)perception which would be my preferred way to model. The sum suggests that psychological perception be an additional source (error possibly) of utility, besides consumption, rather than an intervening misperception. This point is essential when they impose the assumptions of prospect theory on the utility-difference transformation μ.

They propose that the reference point is the expectation of future consumption. If this expectation is related to the decision yet to be taken (rather than a decision made before, in the past), then an implicit definition results. Equilibria are formulated for when this can happen consistently. In the case of multiple equilibria, the one with highest utility is selected, which, if not taken as if, would suggest that the consumer is actively choosing between different reference points to take. Traditionally, reference points are not objects of choice, but aspects determining choice.

The authors derive predictions about more or less willingness to buy depending on whether one had long time to get accustomed to new situation with adaptation of reference point. They also get some self-fulfilling results where a consumer wants to buy iff he expects to buy.

They in fact take multidimensional commodity bundles with, for simplicity, additively separable utility (with a common discussion that separability is justified under proper consequentialistic definition of components)

$U(c) = U(c_1,\ldots,c_n) = U_1(c_1) + \cdots + U_n(c_n)$ with each $U_k(c) = m_k(c) + n_k(c|r)$.

For the underlying consequentialism assumption the nicest discussion that I know is in Broome (1991). For the plausibility of this decomposition, separability of the components is crucial, because consumers have to really perceive them separately so as to take reference points for each separately.

Sometimes they take μ linear outside of 0, so that all it does is generate a kink at the reference point. They explicitly assume that nonrevealed-preference based introspective or psychological inputs are used to determine various components of utility. This interpretation is desirable to justify comparisons between (U(F|G) and U(F´|G´) with G different than G', as happening in this paper, because it is hard to give revealed-preference foundations to it. U(F|G) is decreasing in G so that if we were completely free to choose G we would simply choose G extremely low to attain infinite happiness.

Whether status quo is different from what is expected is partly terminological. One could argue that status quo by definition incorporates what one then expects.

We all know from everyday experience that we sometimes manipulate our expectations, e.g. lowering them to avoid disappointment. This looks like choosing the reference point. It is, however, a minor marginal effect to change our utilities just a little bit. It can only justify a small part of utility. Making yourself more happy by choosing a different reference point is no more than an illusion. Loss aversion, on the other hand, can more than double our perception of utility. Hence, these two don't sit together well if treated as the same component as done in this paper.

biseparable utility: the most popular special case, with μ piecewise linear, is biseparable utility, and even RDU (Masatlioglu & Raymond 2016). %}

Köszegi, Botond & Matthew Rabin (2006) "A Model of Reference-Dependent Preferences," *Quarterly Journal of Economics* 121, 1133–1165.

Köszegi, Botond & Matthew Rabin (2007) "Reference-Dependent Risk Attitudes," *American Economic Review* 97, 1047–1073.

{% Dynamic model on plans for future consumption. Meant to be rational. Loss aversion over changes in beliefs. Reference point endogenously resulting from sophisticated optimization as in their other papers. So, one doesn't improve utility by choosing better alternatives, but by changing one's perception. A classical modeling would be that one chooses between pairs (F,G), with G a choice object rather than a reference point.

P. 912 Eq. 1: instant utility is sum of reference-dependent classical consumption utility and gain-loss utility derived from changes in belief about future outcomes.

P. 913 2/3: money in prospect theory is news about future consumption.

Pp. 913-914: belief-comparisons go through quantile-comparisons.

P. 914: loss aversion consists of two parts: (1) Kink of utility at 0 (their A4); (2) U´(-x) > U´(x) for all x > 0 (their A2).

Their (A3) has U convex for losses and concave for gains. But they will often assume utility linear for gains and losses.

P. 930: they write that their model crucially depends on what people believe, which makes it hard to test. %}

A good concise description of the essence of this book is Narens & Luce (1986). If you study this book, then you will be 100 years ahead of your field. The first chapter explains how measurement starts with counting, and how standard sequences capture this. It gives a geneal technique for getting cardinal measurement in ordinal preference models. I was lucky to be exposed to this technique at young age. In my young years I wrote many papers using this technique, using the term tradeoff. Unfortunately, I co-found the right way to market it, using merely indifferences, only in Köbberling & Wakker (2004 JRU), mathematically matured in the follow-up paper Köbberling & Wakker (2003). The present, 2013, generation (I write this para in 2013) working on ambiguity and uncertainty has forgotten this technique of Krantz et al. (1971) and, hence, mostly uses the unsatisfactory Anscombe-Aumann (1963) model to get cardinality. The present 2013 generation does not have the insights of the previous generation that by coincidence had some exceptionally deep mathematicians, being Krantz et al. (1971). Unfortunately, Luce in his return to decision theory in the 1990s had lost his technique, and used the unsatisfactory

joint receipt to get cardinality.

standard-sequence invariance; Fig. 1 in §1.2 (p. 18) depicts the construction of standard sequences.

restricting representations to subsets: p. 276

Pointed out to me by Han Bleichrodt (in Nov. 2003): §6.3.4, p. 266, 3rd and 4th para claim, without any justification, that a local version of triple cancellation implies a global one. In the algebraic approach, no such results are available in the literature though.

Ttm. 4.2: **strength-of-preference representation**.

Kirsten&I: Ch. 6, with finitely many timepoints;

criticisms of Savage's basic framework: §8.2.1 explains Luce's views on the primitives of decision under uncertainty, deviating from Savage (1954).

criticizing the dangerous role of technical axioms such as continuity: §9.1 has the good discussion of the dangerous empirical status of technical axioms such as continuity and solvability, often overlooked. In the presence of other axioms, they do have empirical content but it may not be clear what that content is. See also §6.6 of Pfanzagl (1968), and Schmeidler (1971).

cancellation axioms: Theorem 9.2.1 (p. 430) gives necessary and sufficient conditions for additive representation of finitely many preferences (can be incomplete on any subset of a product set) through cancellation axioms. Unfortunately, the authors use an irreflexivity condition for an extended relation and it takes some time to see that this is equivalent to imposing all cancellation axioms.

§10.9.2 distinguishes between fundamental and derived measurement:

"As we use the term, an attribute is called *fundamental* if its measurement does not depend on the measurement of anything else. … If, as is usual, one places derived in opposition to fundamental, …" Most of the section discusses how other authors used the terms, and some confusions.

SELECTION OF MATERIAL FOR STUDENTS

For students of preference axiomatizations of decision theory, here is a selection of material from the book that is useful to read. The general techniques of this book allow for appealing and mathematically general theorems because they show how to obtain cardinality efficiently. The techniques of this book are mostly based on Hölder's lemma, which is more efficient than the mixture-set techniques of the Anscombe-Aumann framework. This knowledge has been lost by present (2013) generations, which is why nowadays (1990-2023) in decision under uncertainty (ambiguity) the Anscombe-Aumann framework is usually used, to my regret.

Preface: read

Ch. 1 on general measurement procedures: study

Ch. 2 on first derivations of numerical representations: study except:
§2.2.7 (rings) read once. Its ring structure is useful for SEU and discounted utility where, besides an addition operation, also a multiplication operation plays a role.

Ch. 3 on measurement with an operation: study except:
§3.2.2 (periodic case): skip
§3.4 (measurement when operation is incomplete) gives the really powerful mathematical tools from which much in this book is derived. It can however be skipped if only the gist of the book is to be learnt.
§3.6: skim
§3.7 (essential maxima): skip
§3.10.1: skim
§3.10.2: important
§3.12: c onditional connectedness: skip
§3.14 intro: read
§3.14.1 (riskiness): skip

Ch. 4: useful but can be skipped if only the gist of the book is to be learnt.
If you study it, can skip §4.6 (cross-modality), 4.10 (absolute difference), and 4.12 (strongly conditional indifference structures).

Ch. 5: useful but can be skipped if only the gist of the book is to be learnt.
If you study it:
§5.4.1 (QM-algebra) is useful for the study of ambiguity because the set of

unambiguous events will not be an algebra, but can be a QM algebra.
§5.6 (conditional qual. prob): can skim
§5.8 (stochastic independence as a primitive): can skip

Ch. 6: most important chapter
§6.5.1: skip
§6.5.5 important for nonEU that imposes the EU axioms on subspaces.
§6.7: skim
§6.9: bisymmetry is a way to turn additive representations into SEU and discounted utility, alternatively to my tradeoff technique.
§6.11 (many components): most important section in book.

Ch. 7 on polynomial measurement: nice but can skim

Ch. 8 on risk/uncertainty: skip because outdated

Ch. 9 on finite sets: study
§9.1-9.2: important
§9.4 (applications): skip
§9.5: polynomial: skip

Ch. 10 on dimensional laws: skip

{% P. 13 introduces the beautiful and important concept of **relative curvature** for subjective dimensions; i.e., one scale is more curved than another. Unfortunately, it does not pay much attention to it. To define it, let δ denote a distance (or difference) function, and there are scale 1 and scale 2, with elements x_1,y_1, z_1, and x_2,y_2, z_2, respectively. If $\delta(x_1,y_1) = \delta(x_2,y_2)$ and $\delta(y_1,z_1) = \delta(y_2,z_2)$ but $\delta(x_1,z_1) \geq \delta(x_2,z_2)$ then the second scale is more curved than the first. A bit more general: if $\delta(x_1,y_1) \leq \delta(x_2,y_2)$ and $\delta(y_1,z_1) \leq \delta(y_2,z_2)$ but $\delta(x_1,z_1) \geq \delta(x_2,z_2)$ then the second scale is more curved than the first. Note that here we are not comparing different functions on the same domain, as in tyical Pratt-Arrow results, but we compare the same distance function δ (could also be different) on different subdomains. {% **source-dependent utility**: the first paper to have this clearly.

dynamic consistency (DC); p. 189, following Axiom 2.1, states version of context-independence;

Paper does dynamic decision under risk, with consumption at each timepoint; Axiom 3.11 ("Temporal consistency") is what is nowadays (after Halevy 2015) called time consistency, maybe with forgone-branch independence included I am not sure; Theorem 2 on p. 195 then shows the way I always look at the models of Luce/Segal: Given DC, you can consider only prior choice. It is nicely repeated in words following Corollary 2 on p. 196; Axiom 6.1 resembles forgone-branch independence (often called consequentialism) but also requires independence of past consumption which is far less innocuous than real forgone-branch independence.

They assume EU at every single-stage but give up the **RCLA** assumption and, thus, permit nonindifference to the timing of the resolution of uncertainty.

A simplified version can be found in §2 of Grant, Kajii, & Polak (1998, JET)

"Intrinsic Preference for Information," in §1 of Ahlbrecht & Weber (1997, Theory and Decision), and in Ch. 20 of Gollier (2001). According to Grant et al., Kreps & Porteus (1978) were the first to introduce preference for early resolution of uncertainty. The basic model is, for two-stage gambles:

$\sum_{j=1}^{n} p_j VU^{-1}(EU(z_j))$ where: $EU(z_j)$ is expected utility under some utility function U applied to a second-stage lottery z_j. V is a transformation function serving as a vNM utility function in the first stage. Whereas U only captures risk attitude, V also captures attitude towards the timing of the resolution of uncertainty. VU^{-1} is convex iff early resolution is always preferred to late. %}

{% An earlier study reported that asking people in the beginning of a questionnaire to be truthful works better than at the end. This study reports in detail that it fails to replicate.

The paper considers the kind of honesty test where people throw a die, report which number k ($1 \le k \le 6$) came up, and then receive $k. However, no one else can see whether they reported truthfully. Statistically, too many report high numbers. One cannot prove dishonesty at the individual level, but one can prove statistically at the group level. I always have difficulties here. The rewarding system rewards dishonest people and punishes honest people, and if anything is to be called immoral I would say it is the rewarding system. If a subject, fully knowing the design, throws a low number and then reports the low number I

would not call that honest but rather stupid. So, I think that they are not studying honesty but stupidity. %}

{% **foundations of statistics**: A warm plea for Bayesian statistics. Giving nice numerical examples, graphs, and useful software. §1 nicely illustrates the ad hoc (but no better alternative) things that Bayesians can do once they arrived at the posterior distribution. My sympathy is with the likelihood principle, that the likelihood function (= Bayes factors) summarizes the relevant info in the data, and that from there on further things have to be added such as prior distribution and ad hoc things such as described in this §1. P. 577 1st column last para describes ROPE (region of practical equivalence) as a region around 0 taken as negligibly different from 0, where an effect size of 0.1 is qualified as small. It is ad hoc but there is nothing better.

Unfortunately, theoretical backgrounds, while available in the literature, are often lacking in this paper. For many known problems, the author does not cite literature or uses standard terminology, but develops a private terminology. For instance, that p-values depend on sampling “intentions” is the author’s way of writing about violations of the likelihood principle, a term that is never mentioned.

The paper throughout presents richness of info as a pro, e.g. the richness of reporting the whole posterior distribution versus a binary “reject/no-reject” of NHST. P. 587 penultimate para: “Therefore we should use the analysis method that provides the richest information possible regarding the answer we seek. And that method is Bayesian estimation.” By reductio ad absurdem, the richest info, just giving the whole data set with every data point, would then be best to do. This is not so. There should also be tractability and direct relevance for decisions: statistics should present useful *summaries* of data.

The presentation of null hypothesis significance testing (NHST) is overly simplistic:

P. 573, bottom of 1st column, claims that NHST cannot accept (in the sense of arguing for) the null hypothesis. But NHST can do things, such as power analysis and reformulating the null as alternative.

The paper often suggests that NHST can only do t-tests, and cannot handle other distributions. Relatedly,

The paper often suggests that NHST cannot handle outliers.

P. 577 middle of 1st column describes the well-known problem of statistical significance that has no economic/psychological significance. The author uses a strong versus weak theory terminology for this point.

For Bayes factors the author throughout uses the terms model and prior for what I think are parameter value and distribution over observables conditional on parameter.

P. 577 2nd column 1st para criticizes Bayes factor for being sensitive to choice of alternative, but this holds the same for ROPE.

The paper often writes about credible values but never defines them-at least I did not see it. I guess it means putting up a threshold and taking all parameters whose posterior is above the threshold.

The author often claims that one has to correct for multiple testing also if those tests concern unrelated and independent tests of different things, and complains about having to do extra tests ("I have to conduct an additional NHST F test"). %}

{% **tradeoff method**.; **revealed preference**

Assume Savage model but with finite state space. Assume that objective probabilities of the states are given. Then axioms such as my tradeoff consistency can be used to give SEU. Only, this SEU model may use subjective probabilities different than the objective ones. They propose an axiom to then give identity of probabilites, generalizing Werner's (2005) risk aversion: There must exist a sure outcome such that in its neighborhood all acts with EV equal to that outcome are either all more preferred or all less preferred (if U´´ < 0 there). The case of always U´´ = 0 with linear utility also works. Their analysis does need sufficient differentiability of U.

They consider two richer domains: The probabilities of the states can vary, but preferences are only between acts with the same probabilities involved. Then tradeoff consistency can ensure the same utility function for different probabilities. And then, yet more general: Prefs can be between acts with different probabilities involved. Such prefs can be matched through certainty equivalents and transitivity. %}

{% P. 1487 calls prospect theory the leading psychological descriptive theory of "decision making" without there specifying risk. (**Prospect theory/Rank-Dependent Utility most popular for risk**)

This paper uses the term precautionary decision as equivalent to insurance decision, deviating from economic terminology where it means reducing but not entirely removing bad probabilities.

In rank-dependent theories, including PT, one can use two dual ways of using the probability weighting function in the preference functional (top-down or bottom-up), and this paper left me confused on what they do. What is high one way, is low the other way, and what reflects optimism one way, reflects pessimism the other way. (Inverse S is not really affected by it.) In the early days of RDU, bottom-up was most common, but nowadays (1990-2023) top-down is the almost universally agreed upon convention. For PT of Tversky & Kahneman (1992), top-down for gains and bottom-up for losses is the common way. This paper uses PT but, unfortunately, does not specify which way of integration it uses. P. 1491 penultimate para of 1st column claims that the δ parameter of probability weighting represents attractiveness of a lottery, without specifying if this is for gains or losses. The weighting function is given in Eq. 1, p. 1491, and it is the Goldstein-Einhorn (1987) family (they cite Gonzalez & Wu 1999). The authors interpret the parameter δ, the index of elevation, as attractiveness (2nd para below Eq. 1). However, under common PT, for losses, it is the opposite, unattractiveness. And insurance is about losses (although this paper considers both gains and losses). This left me confused. On p. 1501, 2nd column, end of 3rd para, the authors write that overweighting of probabilities means risk aversion for losses, suggesting that they did use the common way of integration. My comments below will, therefore, assume the common way of integration.

It has often been observed that framing a risky choice as an insurance decision increases risk aversion. (**insurance frame increases risk aversion**) The authors mention this on p. 1488. For probability weighting for losses under PT this will increase pessimism; i.e., it will increase the weighting function and the intersection point with the diagonal. This paper confirms this finding in a number of experiments. (**PT falsified; probability weighting depends on outcomes**) The authors take this as evidence against PT. But I find it so much one of the many known framing effects affecting every theory, that I would not interpret it that way.

A general phenomenon with experiments is that subjects often replace the info given by the experimenter with their own experiences. If the experimenter says “assume that this has probability 1” they may reason: “the experimenter may say so, but I think it is different” and they go by their own ideas. This may explain why subjects in this experiment were not only affected by the probabilities given by the experimenters, but also by accessibility. P. 1497 1st column penultimate para writes:

It was not clear to me what accessibility means in this paper, and to what extent it is anything beyond probability/frequency, although it apparently is assumed to happen only with insurance events and not with just probability-gambles. P. 1495 2nd column will give high-frequency events as an example of accessible events.

P. 1495 text from 1st to 2nd column: “When evaluating risks for insurance, people do not usually use statistical evidence about the probability of risky events. Instead, people may commonly rely on inferences based on what they remember hearing or observing about a particular risk (Hertwig, Pachur, & Kurzenha¨user, 2005; Slovic, Fischhoff, & Lichtenstein, 1979; Tversky & Kahneman, 1973).”

P. 1497: “in the low-frequency insurance risk condition, we attached the highest probability levels to those risks judged as less frequent in the norming procedure” Such hypothetical things may be hard to imagine for subjects, and they may rather substitute their own ideas. For such kinds of questions, real incentives are useful. This paper did everything hypothetical, asking subjects over 100s of hypothetical choices.

They did data-fitting on many choices from which CEs (certainty equivalents) were derived using power utility and the Goldstein & Einhorn family (for which they refer to Gonzalez & Wu 1999). They usually confirm **inverse S**. %}

Kusev, Petko, Paul van Schaik, Peter Ayton, John Dent, & Nick Chater (2009) “Exaggerated Risk: Prospect Theory and Probability Weighting In Risky Choice,” *Journal of Experimental Psychology: Learning, Memory, and Cognition* 35, 1487–1505.

{% **criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity**: they find some violations in an experiment. But they do not criticize it, but rather suggest that it is normatively appealing.

P. @ Footnote 5 writes: “One can, in fact, regard ambiguity aversion as a preference for randomization”, which entirely builds on the Anscombe-Aumann (AA) framework and, for instance, Schmeidler’s (1989) definition of ambiguity aversion—which Wakker (2010 §11.6) qualified as a historical mistake.

Subjects are given info about the choice situation and randomization, through a video. In common descriptive terminology, that info changes preferences. However, the authors are interested in a more normative interpretation of preference, where lacks of understanding are not to be part of it. Such normative “underlying” preferences are not affected by such info, but only become better

observable. They thus say that not subjects' preferences, but their understanding of the situation, is affected, and that this may show that classical revealed preference experiments do not measure real preferences but only misunderstandings. Every researcher agrees that an experiment where stimuli are described in a language that the subject does not know, do not measure preferences but only basic mis(not)-understanding. Which misunderstandings one assumes to be incorporated into preference and which not, is a matter of taste and application-relevance. Psychologists such as Kahneman and Tversky incorporate more misunderstandings in their concept of preference than experimental economists such as Plott. The authors of this paper incorporate fewer misunderstandings in preference than commonly done in empirical studies.

If I understand right, if the Raiffa randomization precedes the ambiguous Ellsberg urn color draw, then according to the plausible backward induction, ambiguity aversion remains, and this they find, even that it increases after the informative video. If the Raiffa randomization comes after the ambiguous Ellsberg urn color draw, then according to the plausible backward induction, the usual finding of preference for the unambiguous color is in fact just a violation of AA monotonicity, and this is reduced after the informative video. The authors take this finding as indicating that subjects find ambiguity aversion and monotonicity normative, where normative is taken in Gilboa's sense of sticking with under full comprehension. I did not check out how they provided info in their video, and to what extent it only gives better understanding and to what extent it is "just" suggesting preference. %}

{% The author redoes the Wu, Zhang, & Abdellaoui (2005) study, testing CPT (I prefer to call it PT) against OPT with a probability tradeoff idea, but for losses (WZA did gains). He does not really do OPT for strictly positive or negative prospects, but the separate-probability transformation version (separable prospect theory), which he still calls OPT (**SPT instead of OPT**). His Eq. 1 on p. 541 cites Fennema & Wakker 97 for it, but the latter only considered mixed prospects and not loss-zero prospects as this paper does. Thus, Eq. 1 is not really OPT if $p_3 = 0$ (as for instance in the left-hand side of Eq. 4). But, as with Wu, Zhang, & Abdellaoui (2005), for the tests done here it does not matter. The paper rejects OPT if sure outcomes are involved. Otherwise OPT and CPT are accepted. So, this provides evidence supporting CPT more. Wu, Zhang, & Abdellaoui (2005) supported OPT some more. No real incentives but flat payment. %}

{% This paper presents an impressive data set on risk attitudes of people, well, students (N = 2939), from many (30) countries, turning it into the most authoritative empirical measurement of risk attitudes presently available. It can be taken as representative for the world population. In particular, it can serve as

the central reference for representative parameters of prospect theory. It adds cultural comparisons. A nice finding is that, whereas risk attitudes are problematic for predictions at the between-individual level, they work well for predictions at the between-country level. Poor countries are more risk seeking. Individual characteristics do not predict well at the individual level, but macroeconomic indicators explain between-country variation.

The authors measured certainty equivalents of two-outcome lotteries.

The paper confirms reference dependence.

The authors confirm inverse S probability weighting, with risk seeking for unlikely gains and risk aversion for likely gains, and this reflected for losses, confirming the fourfold pattern.

The authors find that gender, body length, and cognitive ability (**cognitive ability related to risk/ambiguity aversion**; **cognitive ability related to likelihood insensitivity (= inverse S)**; p. 202) correlate with insensitivity and not with aversion. Women are more insensitive both for gains and for losses, are more pessimistic for gains, and have more noise (§5.4, p. 201 bottom).

I regret that the authors use a concept of likelihood dependence. In my interpretation, risk attitude is not likelihood dependent, although risk aversion is. In my interpretation, there is insensitivity, and this is likelihood independent. Insensitivity is the right concept and risk aversion is not, the same way as green and blue are right concepts of color and grue and bleen are not, to cite a well-known example from philosophy.

P. 187 3rd para discusses the related paper Rieger, Wang, & Hens (2015). That paper gave a breakthrough in providing worldwide data but had a number of problems, properly described by l'Haridon & Vieider, because of which its results cannot yet be used.

P. 189 top pleas for **linear utility for small stakes**. They use the Prelec 2-parameter family.

The sample is not representative for all human beings because it is only students. The pro of doing so is that the population is homogeneous here so that other comparisons are more convincing. %}

https://doi.org/10.3982/QE898

{% **suspicion under ambiguity**: The authors could not control for this, as they discuss in detail, and I agree that they had to do without. But here, unlike some other studies, I think it did affect data and increased ambiguity aversion. They cite Dimmock, Kouwenberg, Mitchell, & Peijnenburg (2016, Journal of Financial Economics) who convincingly argued that they need not control for suspicion, and some studies that found no effect. However, this depends much on the study. For Dimmock et al., subjects were clients of a big organization that much worked with them in the past and future and, therefore, could be trusted. Here subjects one time interact with experimenters from other countries and have much more reason to suspect.

The paper considers 3000 students across 30 countries and measures their ambiguity attitudes, using Ellsberg urns. It considers urns with 8 colors, and a-neutral probabilities 1/8, 2/8, 3/8, 5/8, 6/8, 7/8, with one nonzero outcome that can be a gain or a loss. The authors measure CEs of ambiguous and risky prospects, and take their normalized differences as index of ambiguity aversion. Normalization is by dividing by difference between extreme outcomes. In general, this normalization has the drawback that for small stakes it tends to reduce deviations from linearity and neutrality (because utility usually is between CRRA and CARA). In this study, the difference between extreme outcomes, the denominator, was always 20 (once 15) and, hence, did not affect within-study comparisons. I prefer matching probabilities, and elaborate some on the difference between the two.

BEGINNING OF INTERMEZZO

COMPARING MATCHING PROBABILITIES AND NORMALIZED CE DIFFERENCES

I assume the source method, where the ambiguous event E has a-neutral probability p, and consider only gains. I first assume linear utility, which for moderate amounts as considered here ($20, $0) is reasonable. I take normalized stakes 1 and 0. By w_S I denote the source function, and by w the probability weighting function for the source of known probabilities (risk). Then the normalized CE is the CE, and $CE(1_E0) = w_S(p)$ and $CE(1_p0) = w(p)$. The event-dependent index of ambiguity aversion of the authors is

$w_S(p) - w(p)$. (*)

Given that the matching probability is $w^{-1}(w_S(p))$, matching probabilities instead consider the difference

$w^{-1}(w_S(p)) - p$. (**)

If I may be allowed to take (**) as gold standard, following Dimmock, Kouwenberg, & Wakker (2016 Theorem 3.1), then the authors' (*) has brought in the transformation w. It means, roughly, that w´ interferes. It means that (*) amplifies differences where w´ is steep, which is near the extremes (where differences are large anyhow), so that (*) amplifies ambiguity aversion near certainty. If near impossibility there is ambiguity seeking, as there usually is, then it is amplified and (*) is amplifying insensitivity. In this study it is a bit ambiguity aversion near impossibility, so that (*) is again amplifying ambiguity aversion. In the middle region, differences, which are small anyhow, are reduced.

If we assume nonlinear utility, then this also interferes in (*). For example, concavity of utility will reduce the two CEs, but this will not affect their difference much. The normalization by dividing by the difference of the two extreme outcomes, as written before, reduces the indexes for small stakes somewhat.

END OF INTERMEZZO

No surprise that I disagree with the authors' arguments in favor of their index. Their index depends on utility. They argue that, if ambiguity attitude depends on utility, then that is an advantage. One reason I disagree is that dependence on utility does not mean good dependence on utility. The above intermezzo has given analytical details. Another has to do with the authors' claim: "Thus if utility is different between risk and uncertainty but decision weights are not, *the matching probabilities will not detect ambiguity attitudes*, but our ambiguity premia will." [italics added here] The italicized part is not correct. That matching probabilities and indexes derived from those do not depend on outcomes or utilities, is derived *under the assumption that utility is the same for risk and uncertainty*. If that assumption is relaxed, as in the smooth model, then matching probabilities and indexes derived from them do become utility dependent.—Which need not yet mean utility dependent in a good manner. That is yet another question.—

Genetic diversity measures the genetic diversity in a country.

ambiguity seeking for losses & **ambiguity seeking for unlikely**: The authors find strong ambiguity aversion for likely gains and unlikely losses. Insensitivity often means ambiguity seeking for unlikely gains and likely losses. This paper does find reduced ambiguity aversion for unlikely gains and likely losses, but no ambiguity seeking. This may be because this experiment could not control for suspicion, leading to increased ambiguity aversion throughout. Searching this annotated bibliography for the keyword **suspicion under ambiguity** shows that ambiguity aversion for unlikely gains happens almost only if there was no control for suspicion.

At the individual level, they can explain almost nothing of the variance, even less than for risk attitudes, in the data. As the authors write: "[it] could be due either to systematic noise in the responses of some individuals, or to ambiguity attitudes constituting an idiosyncratic trait that is orthogonal to observable characteristics." At the country level (which averages over individuals, so has more reliability) things are much better, and more of variance can be explained.

They also write: "We do not mean to conclude from our results that ambiguity aversion is not an empirically meaningful concept. The use of abstract urns and the comparison of extreme situations of completely known and completely unknown probabilities, however, seem to induce high levels of inconsistencies in responses, which may well result from the salient and artificially induced absence of information from one of the urns (Frisch and Baron, 1988; Fox and Tversky, 1995). These issues may then be further exacerbated by measurement problems, which are also wel known in the risk preference literature. One solution for applied empirical researchers may then be to recur to more natural sources of uncertainty (Abdellaoui et al., 2011; Baillon, Huang, Selim and Wakker, 2016b)."

natural sources of ambiguity: The authors plea for studying those in the concluding text of the paper: "Our conclusions about measuring ambiguity attitudes are rather negative. We do not want to say with this that ambiguity does not matter. The point is rather that processes resembling ambiguity are quite artificial, and may thus have limited real world applications. There furthermore appear to be severe measurement problems. Ambiguity may well matter where it occurs naturally in the real wold—see for instance Kunreuther, Meszaros, Hogarth and Spranca (1995) for evidence that the presence of ambiguity about the precise probabilities underlying a process affects the pricing decisions of insurance underwriters. The way forward may then be to investigate naturally occurring uncertainty, rather than artificial ambiguity that is rare in the real world. This will mean focusing on natural sources of uncertainty, as some studies have already done (Abdellaoui et al., 2011; Baillon, Bleichrodt, Keskin, l'Haridon and Li, 2016a). Baillon et al. (2016b) proposed a method for the nonparametric measurement of ambiguity attitudes and showed that it exhibits high levels of measurement reliability. This may also mean moving away from a comparison point of risk, which can hardly ever be found in

reality, and towards varying degrees of ambiguity underlying outcome-generating processes. Time will tell whether such approaches will indeed perform better in terms of the external validity of experimentally measured preferences.” %}

{% **proper scoring rules**
Make the, reasonable, assumption of linear utility for moderate stakes. Then use quadratic proper scoring rules to measure decision weights. Loss aversion is incorporated in these decision weights. Thus, comparing them at 0 with other outcomes gives loss aversion. In an experiment, the authors find no loss aversion and neither its opposite, gain seeking. They do find probability weighting and ambiguity nonneutrality. %}

{% **real incentives/hypothetical choice, for time preferences**: Investigate it, and find no difference between real and hypothetical choice. 6 students for many weeks had to choose daily either to get something like $0.50 immediately or $1 some days/weeks later (in real incentives maximal delay considered was 1 month, see p. 178 1st column penultimate para). To avoid saving and so on they could not keep the money but had to spend it immediately upon receipt on candies, so as to enforce consuming and avoid saving. This is in itself a nice idea.

Explicitly do not do RIS, but pay all choices. They avoid income effects in the sense that subjects can never get more than one consumption-set per day. They want subjects to first have experienced the options before choosing themselves, so, subjects first got some delayed or nondelayed options just like that. Each subject first did hypothetical choice and when that treatment was over did real incentives treatment.

Although there is a nice basis, there are several problems. One thing is that subjects can resort to outside options. They can buy the candies outside the experiment. So, if they prefer it now then they can still choose the delayed option but buy immediately after in the store.

Problem is that I think that they do not measure so much discounting, which for days or weeks should be very weak, but they rather measure attitudes toward hunger. Big drawback is that subjects who chose the delayed reward had to come back to the lab later just to get the delayed reward which, given the small stake per case, is huge transaction costs. The discussion, top of p. 185, does not account for this properly, suggesting subjects had to come to the lab anyhow. This is not

true. Subjects for future options had to come especially to the lab for getting them and then would get no other choice or anything (p. 179).

For real incentives the starting choice of the bisectionprocedure was the indifference value found with hypothetical (p. 178 end), introducing a strong framing/bias to have real the same as hypothetical. %}

{% The author axiomatizes what I would call regret theory, varying upon preceding work by Fishburn. However, nowadays (2018-2023) this is often described as "continuous" salience theory and this way it can get into QJE. Very unfortunately, QJE publishes proofs only in online appendixes, meaning that maths published in this journal is unreliable. For a good view on this point, see Spiegler (2023).

For regret theory, when choosing between two lotteries, one has to specify the joint distribution. Thus, the choice domain considered in this paper is pairs of lotteries with the joint distribution specified. This is mostly done by specifying an underlying state space *endowed with an objective probability measure*. This paper does not want to do that to avoid, as the author writes, issues of ambiguity about an unknown probability distribution. However, this is no issue at all because one assumes the probability measure on the state space to be given, known, and objective. In Footnote 5 he criticizes state spaces for the requirement of nonatomicity (needed to induce all probabilities), but his assumption of all simple probability distributions available is only more demanding. One can, for instance, take state space [0,1] endowed with the Lebesgue measure (uniform distribution) and it is rich enough to induce all pairs of simple lotteries with any joint distribution. The mathematically-sounding question can be turned into practically-sounding question by asking how all those pairs of lotteries with joint distributions have been generated. %}

Lanzani, Giacomo (2022) “Correlation Made Simple: Applications to Salience and Regret Theory,” *Quarterly Journal of Economics* 137, 959–987. https://doi.org/10.1093/qje/qjab041

{% P. 46 suggests a bit that Jevons introduced outcomes in terms of final wealth, and that Bentham had them as changes w.r.t. reference point. The authors use different terminologies than I am used to, and I should not make the mistake of reading modern ideas into old (Bentham) writings, and it isn’t 100%. The authors write that Jevons turned preferences into “exogenous” and unchanging, and that with Bentham it was “endogenous” and “changing” depending on preceding pains, pleasures (and, hence, decisions which explains the endogenekity). In their formal model later they also bring in time explicitly to capture the changes. This “changing” is a broad term that could mean anything. Yet I think that they really mean changing only in the sense of reference dependence.

P. 46: “Consequently, the agent’s preference order will be viewed as depending on his initial situation, and on asymmetric sensitivity to gains and losses, relative to this situation (§2). Bentham clearly expressed this idea when he argued that ‘the pleasure of gaining is not equal to the evil of losing’ (1785-6: 331).”

Pp. 47-48 acknowledges that there is no direct evidence for “endogenous” (what I call reference dependence) preference in Bentham, but that indirect evidence is conclusive.

P. 50 acknowledges the value of the ordinal revolution (this is my

interpretation): "founding economic calculus on the basis of a given utility function was already a difficult task, which required nearly a century after Jevons to be achieved; but the enterprise would surely have been bound to fail with a utility function submitted to continuous changes."

P. 52: "it opens the path to the possibility that a same final situation of alternative trajectories is associated with different levels of utility."

Pp. 66-67: "the juncture between the positive and the normative aspects of the principle of utility."

paternalism/Humean-view-of-preference: §5 argues that Bentham advocated paternalism where biases (mistakes in felicific calculus) are to be corrected and reduced. %}

{% Paper says that Bernoulli's theory and prospect theory (here the paper is just plainly wrong) do not permit individual differences in risk attitude, are called "universal theories" for that reason, and are contrasted with individual-difference theories, which incorporates EU, Lopes' theory, and Atkinsons theory (latter turns out to consider events under control of the subject) %}

Larrick, Richard P. (1993) "Motivational Factors in Decision Theories: The Role of Self-Protection," *Psychological Bulletin* 113, 440–450.

{% In the 1980s and 1990s there were papers on expert aggregation studying that one does not just take the average of expert opinions, but one determines qualities of the experts and then takes weighted averages and/or removes low-quality experts. But then there came papers showing that just taking averages works surprisingly well, as a sort of paradox. However, this paper is not on that.

This paper is purely empirical, letting subjects (students) do expert aggregation, and seeing whatever they do. That is, it is the typical psychological way of studying things. They find that subjects greatly misunderstand the pros of taking averages of expert opinions. Of course, this result depends much on the subjects taken, and students will not be representative of other people. Students here were INSEAD MBA students, some or all taking statistics courses. They in particular compare the average of the judgments with the judgment of the average expert, where the latter is usually inferior. Unfortunately, I could not find out from the paper what “average expert” means. Other people told me it is the average of the absolute value of the deviation. So, then this paper is based on the principle that the average of absolute values exceeds the absolute value of the average; i.e., absolue value is a convex function. %}

{% Subjects choose between gaining on the unknown Ellsberg urn (50-50 in normative sense) and gaining with probability p, for varying p. So, this is finding matching probability using choice list for the 50-50 Ellsberg urn. The unknown urn is of course chosen less as p increases. Average switch is before p = .50, in agreement with the commonly found ambiguity aversion for .50-.50 Ellsberg

urns.

It is also obvious that most preferences will switch around the normative threshold; i.e., around p = .50. Contrary to the authors' claim, this does not mean that people are more sensitive near .50 than elsewhere in a general sense.

reflection at individual level for risk: p. 117: no relation

reflection at individual level for ambiguity: p. 117: no relation: "Thus there is sufficient reason to argue that loss trials and gain trials tap different processes."

correlation risk & ambiguity attitude: p. 117: ambiguity aversion is positively related to risk aversion for losses, and is not significantly related to risk attitude for gains. %}

Lauriola, Marco & Irwin P. Levin (2001) "Relating Individual Differences in Attitude toward Ambiguity to Risky Choices," *Journal of Behavioral Decision Making* 14, 107–122.

{% Apparently do only hypothetical choice.

Ambiguous urn always is 2-color, but they also vary the total number of balls in the urn, and find that this does something even if normatively it shouldn't. Measure matching probabilities. Claim as novelty that they derive it from bisection, rather than from matching as did Kahn & Sarin (1988).

correlation risk & ambiguity attitude: Find positive relation between ambiguity attitude and risk aversion. Do so by first experiment to measure ambiguity aversion, then taking the very extremely ambiguity averse and the very extremely ambiguity seeking separately (extreme-group design), and comparing their risk attitudes to find significant differences in the latter. This method does not show much of how strong the attitudes are related, only that they are. The second measurement was deliberately done two months later only. The intermediates are control group. The potential selection bias and nonrepresentativeness is discussed on p. 132 middle of 2nd column, referring to social psychology for this technique. %}

{% **random incentive system**. Points out that she does not test the isolation effect because no single-choice situation is involved. She tests a Davis & Holt (1993) conjecture (see there).

Treatment 1: pay one randomly selected choice from 10 choices made (the random incentive system)

Treatment 2: pay all 10 choices made.

Treatment 3: pay one randomly selected choice from 10 choices made (the random incentive system but with payments increased).

Treatments 1 and 2 give the same result, suggesting no income effect here. Treatments 1 and 3 give different results, with treatment 3 more risk aversion.

I think that this finding entails that no income effect occurred, and (**decreasing ARA/increasing RRA**) that there was increasing RRA. It does not directly test the Davis-Holt conjecture because for that it should have scaled the payments down and not up. %}

Laury, Susan K. (2005) "Pay One or Pay All: Random Selection of One Choice for Payment."

{% **real incentives/hypothetical choice**: use high real incentives ($100 etc.) for some of the subjects (all students).

losses from prior endowment mechanism: they do this. For the high payments, they first let subject do another game theory experiment where they made very much money.

equate risk aversion with concave utility under nonEU: p. 406: very unfortunately, the authors do not call concave utility what it is (concave utility), but what it is not: risk aversion. The usual concept of risk aversion (preference for EV over prospect) apparently is also called risk aversion.

concave utility for gains, convex utility for losses: Find it for hypothetical choice. For real choice they rather find risk aversion and concave utility for both gains and losses.

reflection at individual level for risk: P. 419, for hypothetical low outcomes finds reflection, with risk aversion (in their terminology) for gains usually going together with risk seeking for losses and risk seeking for gains mostly going together with risk aversion for losses. For real incentives, however, it is very opposite. Risk aversion for gains has majority risk aversion for losses, and risk seeking for gains has majority risk seeking for losses.

P. 422: For hypothetical high payment and, even more for real high payment, there is also violation of reflection at the individual level. The econometric analysis later gives no results at the individual level.

An attempt to defend reflection against the finding of this paper can be that when implementing **losses from prior endowment mechanism**, subjects integrate the payments especially if they are high. From that perspective, I could hope to convince the authors to change their conclusion into: for losses better do hypothetical? (☺) %}

Laury, Susan K. & Charles A. Holt (2008) "Further Reflections on Prospect Theory." *In* James C. Cox & Glenn W. Harrison (eds.) *Risk Aversion in Experiments,* (Experimental Economics, Volume 12) 405–440, JAI Press, Greenwich, CT.

{% **real incentives/hypothetical choice, for time preferences;**

This paper pays subjects in probability of gaining a prize. The authors assume EU and then (well, + backward induction) this amounts to linear (risky!) utility, as pointed out by Roth & Malouf (1979), Cedric Smith (1961), and many others. They assume (implicitly, as did Andersen et al. 2008), that EU utility for risk also is utility for intertemporal discounting, and then use this to estimate discounting while reckoning with that utility curvature.

real incentives/hypothetical choice, explicitly ignoring hypothetical: p. 182 ℓ. –9 writes that the authors only cite experiments with real incentives, and in this sense the priority claims of this paper are unreliable.

P. 183 writes, on their method:

"we propose and test a new method."

In an email of 13 Feb., 2011, I pointed out to the authors that Takeuchi (2011) had used this method for measuring discounting before. So, the authors now cite him om p. 182 last para: "Takeuchi (2011) uses an alternative procedure to estimate discount rates that is theoretically invariant to utility curvature …"

The authors consider correcting for probability weighting, but it does not do much. One reason can be that they use the T&K'92 family, which has mostly the inverse S component, whereas here the pessimism component is more relevant. Another reason can be that discounting and probability weighting have much collinearity.

P. 190, end of §2.1: because the authors use real incentives, the longest time period they can consider is 12 weeks. (**real incentives/hypothetical choice, for time preferences**) %}

{% Critical discussion of Savage (1954), still calling his theorem beautiful.

P. 142 has a nice text on probabilities through analogies with benchmark random mechanisms, with is similar to matching probabilities although there is no subjective twist:

“Since the classical theory is essentially mathematical and clearly not normative it is rather unconcerned about how one interprets the probability measures P_θ. The easiest interpretation is probably that certain experiments such as tossing a coin, drawing a ball out of a bag, spinning a roulette wheel, etc., have in common a number of features which are fairly reasonably described by probability measures. To elaborate a theory or a model of a physical phenomenon in the form of probability measures is then simply to argue by analogy with the properties of the standard ‘random’ experiments.” %}

{% A forecaster and an inspector play a game, observing one by one realizations x_1, x_2, …of a distribution. Whatever the checking rule used by the inspector, the forecaster can manipulate. Manipulation means that he makes a forecast after observing $x_1,\dots,x_n$ for each n, not using any prior knowledge and using only $x_1,\dots,x_n$, such that he is perfectly calibrated in the sense that asymptotically every

relative frequency in his predictions match the true relative frequencies. The idea is that the infinite sequence $x_1,\ldots,x_n$ contains enough info, if observed long enough, to get that done, without needing prior knowledge. %}

Lehrer, Ehud (2001) "Any Inspection is Manipulable," *Econometrica* 69, 1333–1347.

{% **updating: nonadditive measures**; nice idea to do updating under nonadditive measures analogous to conditional expectations theory. Anomalies can still occur. Can be excluded in a somewhat ad hoc way by excluding them by restricting set of sub-sigma-algebra-measurable functions accordingly.

In traditional additive probability theory, E(f|A), the conditional expectation of a rv f given a sigma-field A is the "averaging out" of f over A. It is the function g that is A measurable and, given that, minimizes expectation of quadratic difference with f. Conditional expectation of rv is the primitive concept to think of. Conditional probability of event B given event C is derived concept, as follows: (1) Take 1_B as rv and $\{C,C^c\}$ as sigma-algebra. You can see only through $\{C,C^c\}$. Conditional probability of B is then what you see of 1_B in event C. In general, it can be proved that E(f|A) has the same expectation as f, in fact it has that over every A event. Also, on every A event it does not exceed max or min f.

Lehrer considers extension of these concepts to nonadditive measures. The starting idea is to, again, let E(f|A) minimize quadratic difference with f.

First problem: Unfortunately, that does not have nice properties such as having same expectation as f, or not exceed max or min of f. So, one restricts attention to the subclass of functions, measurable w.r.t. C, which do have the desired properties, and only over those one minimizes expectation of quadratic difference.

Second problem: The solution need not be unique. Lehrer proposes refinements. %}

Lehrer, Ehud (2005) "Updating Non-Additive Probabilities—A Geometric Approach," *Games and Economic Behavior* 50, 42–57.

{% Takes a variation of the Choquet integral that is always concave. It agrees if the weighting function is convex, but is a concave functional that in a way is closest if the weighting function is not convex. That is, for a prospect X and a weighting function v, min{f(X)} is taken over all concave and homogeneous functions f that dominate w for all indicator functions. A preference axiomatization is given. The same definition can be used if w is not defined for all subsets. %}

Lehrer, Ehud (2009) "A New Integral for Capacities," *Economic Theory* 39, 157–176.

{% Characterizes a subfamily of maxmin EU, with only finitely many priors. The value of an ambiguous act is the supremum of dominated unambiguous acts, which is very pessimistic. An act is fat-free if reducing any outcome strictly worsens the act. In the other case, if there is fat, then an EU minimizing prior can be found making the relevant outcome-event null. Strong fat-free maintains fat-free under mixing with a nonminimal outcome. If two acts have fat, there can be synergy under mixing, and this is a nice way of interpreting things. The model is the decision model corresponding with the functional of Lehrer (2009). The paper applies its model to NE in game theory. %}

Lehrer, Ehud (2012) "Partially Specified Probabilities: Decisions and Games," *American Economic Journal: Microecnomics* 4, 70–100.

{% Every simple act can be written as a weighted sum of indicator functions SUM$\alpha_j 1_{E_j}$, where the E_js may be nested and so on. The model of this paper ("event-separable representation") assumes existence of a nonadditive weighting function v, and a subjective choice of one of the many possible decompositions SUM$\alpha_j 1_{E_j}$ for each act, after which it is evaluated by a separate-event weighting SUM$\alpha_j v(E_j)$ (like separable prospect theory but with events instead of probabilities). It assumes that acts $\alpha 1_E$ with only one nonzero outcome are always evaluated by $\alpha v(E)$. If acts are subjectively similar (same events involved) they provide no hedge against each other and satisfy independence preference conditions. RDU is the special case where the events E_j are nested. %}

Lehrer, Ehud & Roee Teper (2015) "Subjective Independence and Concave Expected Utility," *Journal of Economic Theory* 158, 33–53.

{% Realist interpretation of utility: It is concrete, an object or quality of mental state etc. Instrumental interpretation of utility: only theoretical concept. %}

Lehtinen, Aki (2001) "The Interpretation of Utility Theory,"

{% Keynes distinguished the balance of evidence and the weight, arguing that the latter can matter, and it underlies the modern ambiguity theories. This paper seems to argue that that weight of evidence indeed plays a role, but only when it comes to the dynamic point of updating. (**updating under ambiguity**) This is surely my opinion. Weight of evidence plays no role in static decisions, but in updating. The term "stability" seems to refer to this idea. %}

Leitgeb, Hannes (2014) "The Stability Theory of Belief," *Philosophical Review* 123, 131–171.

{% P. 67 2nd column $\ell\ell$. 1-3 does the typical overselling of DFE of suggesting that everything in life that has no known probabilities must be DFE: "had no alternative but to make *decisions from experience*" (italics from original).

Do DFD (decision from description) versus DFE (decision from experience) for both monetary and medical outcomes. As the authors properly explain, the latter have to be hypothetical, and then for avoiding confounded comparisons the former are also better done hypothetically, which is what they did. As Figure 3 illustrates, they find, remarkably, more optimism for DFE than for DFD, but also somewhat more, rather than less, inverse S. Strongest finding is way more inverse S fror medical than for money. (**DFE-DFD gap but no reversal?**) %}

{% **loss aversion: erroneously thinking it is reflection**: Happens on p. 406. The authors present the Asian disease problem (now in 2024 I find this term politically incorrect), explained by convex utility for losses as they properly point out (let us ignore probability weighting). Then they describe loss aversion as utility steeper for losses. Then they say that loss aversion is the desire to avoid a sure loss. They probably think that loss aversion enhances risk seeking in a choice between a sure loss $-\beta$ and a risky prospect $\alpha_p(-\gamma)$, which is incorrect because loss aversion here enhances risk aversion, i.e., preference for the sure loss (Wakker 2011 Exercise 9.3.8). Then they seem to think that the risk seeking enhanced by loss aversion (which can only affect mixed prospects) explains the Asian disease. Thus, they conclude their reasoning: "In other words, the idely accepted prospect theory explains uncertainty-seeking ehavior as the result of loss aversion." %}

{% **real incentives/hypothetical choice**: subjects had to rate how likely it was that they would choose risk gambles (??), both hypothetically and real. %}
Levin, Irwin P., Daniel P. Chapman, & Richard D. Johnson (1988) "Confidence in Judgments Based on Incomplete Information: An Investigation Using Hypothetical and Real Gambles," *Journal of Behavioral Decision Making* 1, 29–41.

{% Children and some adults could do risky choices (which each really paid, in some prizes) between sure prize or fifty-fifty gambles to get two prizes. Same for

losses. Each choice was really paid (so, repeated payments).

risk seeking for symmetric fifty-fifty gambles: they find more risk seeking than risk aversion for gains, and even more risk seeking for losses. (Also for 0.2 probability gambles.) %}

Levin, Irwin P. & Stephanie S. Hart (2003) "Risk Preferences in Young Children: Early Evidence of Individual Differences in Reaction to Potential Gains and Losses," *Journal of Behavioral Decision Making* 16, 397–413.

{% This paper reviews (and interprets) studies of framing and loss aversion, as alternative to the review by Kuhberg (1998) that they cite much. This paper received many citations. For me nonpychologist it was hard to relate to it. I am interested in two different aspects of loss aversion (of, say, size 2), which may explain loss aversion:

(1) At a loss that in physical units is as big as a corresponding gain, the suffering when experiencing the loss is twice as big as the happiness when experiencing the gain.

(2) For a loss that in suffering is as big as the joy is of a corresponding gain, it still weights twice as much in decisions because the agent pays more attention to losses.

Under (1) loss aversion is part of utility, under (2) it is not. In (2) one can distinguish between this happening deliberately, with the agent thinking that it is rational to pay more attention to losses than to gains, and this happening psychologically, not as a deliberate act but automatically perceptionally and probably not rationally.

It was not easy for me nonpsychologist to understand whether the distinctions the authors make relate to the above distinction or not.

The authors distinguish three frame types of loss aversion, being risky framing, attribute framing, and goal framing.

The second, attribute, is when people are asked for straight introspective evaluations without these being related to decisions. "How much do you like beef 75% lean" versus "How much do you beef 25% fat?" and subjects indicate their likings on a scale. Subjects like more the 75% lean formulation, which is not surprising as the authors point out somewhere (p. 159). For one thing, it has the same ambiguity-problem as the well-known Asian disease problem (75% nonfat does not mean the other 25% has to be fat). (Now in 2024 I find this term Asian disease politically incorrect.) The authors feel it necessary, p. 159 4th para, to make explicit that the above judgment does not involve risk.

The third, goal framing, is, if I understand right, decision problems where one option is doing nothing. Breast self-examination is done more with negative info (not doing has decreased chance of finding tumor) than with positive (doing so has increased chance of finding tumor), p. 168 2nd para.

For the first, risky framing, the authors do point out at some stage that loss aversion can and has been used also for decisions if tradeoffs do not concern getting some more with 60% probability versus some less with 40% probability but also getting some more on one attribute at the cost of getting some less on another. They do point out this is like goal framing (p. 180 top). The useful summary p. 181 2nd para also suggests so. But then why risky framing is considered a different category escapes me.

Then 2nd framing of evaluation without relation to decision interests me economist less anyhow.

The paper often writes in a boasting manner, praising itself (p. 177 bottom, p. 179 penultimate para “unique,” p. 181 penultimate para; p. 182 last para “The discovery of the distinguishing features ..”)

P. 150 $\ell\ell$. 3-8 is funny for economists. When the authors want to show how diverse the areas are where loss aversion has appeared, they mention 7 subdisciplines of psychology and then one other discipline: business. Later for decisions also medical (and clinical!) decisions are mentioned, and bargaining, and some more, but, sorry for economics, it did not make it to the list. %}

{% **real incentives/hypothetical choice**: actual payment was done at the end after dividing by 1,000

decreasing ARA/increasing RRA: accept decreasing absolute risk aversion (DARA) but find no increasing RRA (IRRA), says it's decreasing or at best constant.

SPT instead of OPT: no explicit formulas are given of theories, but most clear from p. 763 2nd para.

Sixty-two subjects had to play 10 rounds of investing, experimental amounts in order of $30,000, actual payment was done at the end after dividing by 1,000. If their game-asset became negative during the game, they had to stop and pay (ruin). That setup made the subjects conservative, indeed none ended in ruin. The latter may explain the DRRA found: Those with little money become very risk averse so as to avoid ruin, those with much money were lucky and, thus, are encouraged to risk more. This holds the more so as only the game-rewards, not the actual richness of the subjects, played a role.

Results on absolute risk aversion and RRA were derived from intermediate choices (time series) and, thus, assume the isolation effect. However, the isolation effect is not easy to defend here because the subjects clearly are aware of the dynamic repeated setup, the more so as they get a sum total in the end. %}

{% %}
Lewbel, Arthur & William Perraudin (1995) "A Theorem of Portfolio Separation with General Preferences," *Journal of Economic Theory* 65, 624–626.

{% The author, with an economic background although the style suggests more of psychology and sociology, wrote this before receiving Ph.D, and developed own ideas on ordinal revolution and history. Although I disagree with several (such as difference between ordinalism and behaviorism), the paper gave me many new insights and I enjoyed it.

Argues that ordinalism does not work because, first, it does not get good data (I agree) and, second, it ignores sociological (institutional) effects (not my focus of research).

P. 1294 §B: I don't think there was an attack by psychologists on marginal utility. The attack was initiated by the other side.

conservation of influence: pp. 1298-1304 is nice on the role of introspection ("verstehen") and teleology in economics, and ordinalism as an attempt to get rid of that and turn economics into a mechanic science, with nice citations of Weber. P. 1299 footnote 7 defines teleology discussed jointly with psychological hedonism, which is close to utilitarianism.

Pp. 1301-1302 has nice text by Veblen on teleological nature of utility rendering it unscientific.

P. 1304: Behaviorism was movement away from teleology, to turn sychology into a mechanical science like physics. (Also p. 1308 for ordinalism in economics.)

P. 1305: psychological hedonism took utility as primitive, and it was not observable.

She lets force (and energy similar, but mostly force) from physics (not a primitive concept but only derived from movements of bodies) have a role similar to utility.

P. 1309, as so many, misunderstands Pareto (1901). Pareto writes: "Let others concern themselves with the *nature*, with the *essence* of value. I am interested only in seeing whether I can discover which regularities are presented by prices (1901, p. 204)." So, Pareto does not say there is anyhing wrong in inspecting value and essence, only that he now does not do so. However, Lewin will take him to say the former (which he did not say).

P. 1310 announces difference between ordinalism and behaviorism but only discusses revealed preference of Samuelson which is a nice contribution but in which I see no difference.

P. 1312: “Cardinal utility was more than a particular theoretical concept; it symbolized verstehen.”

P. 1313: according to Knight, we cannot dispense with motives as we can dismiss with force in physics because there is more error in measuring.

P. 1315 and elsewhere (p.; 1317): “It was simply not empirically possible to base preference theory on behavior alone.”

P. 1315 refers to several economic studies in the 1930s trying to measure utility empirically, such as Thurstone (1931). %}

{% **natural sources of ambiguity;**
Contributions: (1) First comprehensive measurement of ambiguity attitude,

including insensitivity, in the developing world (p. 242 3rd para); (2) Introduces an important new source of ambiguity: linguistic ambiguity; (3) Studies wealth effects on ambiguity with big income difference (factor 10) but more similarities and fewer differences between the subjects otherwise than in other studies, made possible because of a typical local difference between mountain- and city inhabitants (pp. 241-242 & p. 258 bottom); (4) contributes to literature showing importance of a(mbiguity-generated) insensitivity, capturing more variance than ambiguity aversion.

Within the rural group the poor are more ambiguity averse and a-insensitive (p. 251 2nd para). Within the urban group, the rich are more insensitive, maybe because they are so rich that they can be lazy. For the poor group, higher irrationality (my interpretation) of the poor group can add to poverty trap. (p. 241 4/5). Between group, rural are more ambiguity averse and a-insensitive (p. 242 3rd para).

P. 242: "a-insensitivity captures to what extent people understand the ambiguous decision situation from a cognitive perspective." P. 258 middle reiterates it.

P. 242 last para: "the clear classification of a-insensitivity as irrational … it is easier for people to learn about their cognitive mistakes than the emotional ones."

P. 243 middle: "But this symmetry [as in Ellsberg urn] does not hold in general for natural ambiguity sources." P. 249 last line reports asymmetry found in data.

P. 243: Subjects (high school age 17) were given phrases in foreign languages of which three possible meanings were given (one correct), and sudents had to gamble money depending on the correct meaning. Every sentence was taken as a different source of uncertainty (p. 243).

P. 244: difference between subjective (= a-neutral) probability and matching probability can be taken as an ambiguity premium.

P. 246: RIS was used where each subject played one randomly chosen choice for real.

P. 248/249: correlation between multiple switching and score on Fredricks' cognitive reflection.

P. 249, on subjective probabilities in source method:

"capture subjects' subjective beliefs (although distorted by their ambiguity attitudes)"

P. 256: rich urbans were **ambiguity seeking**.

P. 257: discusses policy implications of insensitivity, not in the cliché way as in most papers, but nicely. %}

{% **ordering of subsets**: This paper examines choices between subsets of a finite set X whose elements are called alternatives. It considers a model where, for a subset A c X, first a subset A' c A is chosen, the subset that receives attention. Because of inattention, the omitted alternatives were not considered. Next, A' is evaluated by the sum of the utilities of its elements. Utilities are nonnegative. If there is no inattention, then the model concerns an additive-measure representation of subsets, whose characterization has long been known, following from the theorem of the alternative for instance. For a set A, the set A' can be found by A' ~ A. Here idempotence is assumed. That is, for A' then all elements receive attention. So, inattention does not pile up. Then after that, it becomes as standard with no attention. %}

{% %}

Li, Hao & Wing Suen (2004) "Delegating Decisions to Experts," *Journal of Political Economy* 112, 311–355.

{% **dynamic consistence**: This paper considers decision under uncertainty as with Savage (1954), although the outcome set is a convex subset of a vector space so that the Ansombe-Aumann structure is available. The paper assumes constant-act independence, building on the linearity of the Anscombe-Aumann structure.

The paper assumes static a priori preferences together with preferences conditioned on events E, for all E. The first part specifies a recursive model, the separability condition that is equivalent to it, and consequentialism & dynamic consistency, again, equivalent. Thus, it deviates from SEU only by violating reduction/event collapsing, i.e., the uncertainty analog of reduction of compound lotteries (p. 1079).

The second part of the paper considers certainty equivalent substitutions and ambiguity attitudes. It only considers aversion to ambiguity, and that ambiguities conditional on different events can be used to hedge against each other. One could also imagine that ambiguity conditional on one event reinforces the effects of ambiguity conditional on another event, but this is assumed not to happen. Then, replacing a conditional act by a "neutral" certainty equivalent (nicely called ironing out) can only be bad because it, first, can only reduce the hedging effects and, hence, increase ambiguity perception and, by ambiguity aversion, decrease preference. This condition is called event complementarity. The condition can be reinterpreted as aversion to receiving partial info (**information aversion**). Partial info can only reduce ambiguity hedging. The conditions are shown to hold under some ambiguity models.

The aversion to certainty equivalent substitution is similar to that in cautious utility by Cerreia-Vioglio, Dillenberger, & Ortoleva (2015). Both conditions go purely for pessimism and aversion. The author refers to this related condition on p. 1072 citing Dillenberg (2010) who introduced it.

Kops & Pasichnichenko (2023) presented an empirical test of this model. %}

{% Players play a coordination game. For instance, they rank three metals, copper (E_1), gold (E_2), iron (E_3) in places 1-3. A player is matched with a random opponent. If they ranked the same metal first, they receive £20, and otherwise nothing.

Next they must assess percentages of subjects with E_i for all i, and then E_{ij} (= $E_i \cup E_j$) ($i \neq j$), that is probabilities, through probability equivalents, i.e., matching probabilities are measured (using BDM (Becker-DeGroot-Marschak)). The singleton matching probabilities add to more than 1 (would be 1 under Bayesianism; **ambiguity seeking for unlikely**), the composite to less than 2 (would be 2 under Bayesianism). This agrees with the common fourfold pattern of ambiguity attitude, although the overweighting of singletons is greater than usual. They do and find the same for seven other triples, flowers, etc. They also measure other things, such as certainty equivalents, but do not use those in the analysis. %}

{% The paper has three topics:

(1) Choice of reference points. The paper provides a clean design to identify choices of reference points, both exogenous (by changing the fixed option in the choice list) and endogenous, confirmed in the results.

(2) Role of reference points in choice lists.

(3) Time preference. This paper properly measures discounting and utility. It allows for two nonzero outcomes, which is needed to identify discounting and utility. The novelty is, again, that this paper is the first to properly reckon with reference dependence.

More impatience if present-oriented fixed option than if future-oriented. %}

{% First consider the standard Savage model, with acts mapping states to outcomes. Imagine the agent chose an act f. She next is not informed about the true state of nature s, but only about the outcome f(s) received. So, then she only knows that $f^{-1}(f(s))$ happened, and she can update subjective probabilities accordingly. (In the version of this paper of Nov. 11 2019, the latter assumption is made implicitly.) This paper considers, one step more complex here, the Anscombe-Aumann (AA) framework where an act maps every state to a probability distribution over outcomes. (I maintain this term here instead of the term prize commonly used in the AA framework, or the term consequence used by Savage.) Given an act, every outcome induces a likelihood function on the state space. Thus, if a subject is informed only about the outcome received, she can update using that likelihood function.

This paper considers a model where preferences are represented by the sum of subjective expected utility and a rather general function of the value of info provided by the likelihood function. So, the info has additional value, possibly for future unmodeled decisions or something intrinsic (although I find that word close to being a dirty word in decision theory). Information aversion (seeking) is defined in a way making it equivalent to concavity (convexity) of the info-value function. Information seeking holds if and only if there is a hidden act representation (like a future unmodeled decision).

In the axiomatization, there is a special role for sets of acts that provide the same info about states. Preferences within them are governed by standard expected utility. %}

Liang, Yucheng (2019) "Information-Dependent Expected Utility," working paper.

{% **updating under ambiguity**; The paper considers unknown probability where the true probability either is high, p_h, or low, p_l. Subjects receive info and the paper considers updating. Special here is that there may be uncertainty about the correctness of the info received. It finds that people exhibit both pessimism and insensitivity, the latter by underreacting. The underreaction is more pronounced for good news than for bad news. The attitudes towards uncertainty itself and towards belief updating are uncorrelated. The paper considers the various proposals for updating in the literature. Pessimism and insensitivity are stronger for genuine ambiguity than for compound uncertainty. Full Bayesian updating with pessimism and insensitivity best explains the data. %}

{% Measure risk aversion, simply via # times of preference for smaller variance, whilst it is specified what fixed outcome a nonanonymous opponent gets. The latter was an opponent before in a Bertrand game (where both choose price and the lowest price gets the whole market, so very competitive). When the opponent's outcome is above the lottery outcomes, there is (just) more risk aversion than when not. If the opponent's outcome serves as a reference point, this finding goes against the less risk aversion for losses that prospect theory posits. I am interested in speculations on the emotions that the prior Bertrand game may have generated to explain this.

losses give more/less noise: P. 51 speculates that, because utility is steeper for losses, there will be fewer errors for losses. Although early studies suggested more errors for losses, several studies by Eldad Yechiam, e.g. Yechiam, Retzer, Telpaz, & Hochman (2015) confirmed fewer errors, showing that with losses involved subjects pay more attention.

§2.2 cites the circle test for measuring other-regarding attitude. You choose a point on a circle with center (0,0) and radius 1, say. Then the first coordinate is your payment, and the second is your opponent's. At your maximally selfish point, (1,0), the exchange rate is ∞. The direction of your point shows your degfree of selfishness. Pretty! %}

{% The paper cites several surveys on discount measurements, including meta-analyses, of Amlung et al. (2019), Frederick et al. (2002), Percoco & Nijkamp (2009), Cohen et al. (2020), and Matousek, Havranek, & Irsova (2022). This paper kind of updates but its focus is different, as its title says: on measuring methods. A valuable feature is that it connects economic literature with the vast health literature, and also with the psychological literature.

P.151, Table 2, nicely gives (almost) all discount functions used in the literature. I think the current (in 2024) literature overemphasizes decreasing impatience, and there should be more attention for increasing impatience. Unfortunately, this paper pays no attention to the latter. %}

Lipman, Stefan A. & Arthur E. Attema (2024) "A Systematic Review of Unique Methods for Measuring Discount Rates," *Journal of Risk and Uncertainty* 69, 145–189.
https://doi.org/10.1007/s11166-024-09439-1

{% Nudge originated as a subtle way of improving decisions by reckoning with descriptive insights while avoiding (strong) paternalism. (Nowadays, 2020, the term has inflated and is often used more broadly.) In many situations, this is not possible and we must be paternalistic. E.g., if forbidding by law that adolescents use heroine. Thus, Bleichrodt, Pinto, & Wakker (2001) proposed to use prospect theory (PT) to improve utility measurement. More precisely, they took expected utility (EU) is normative theory and PT as descriptive theory. PT's deviations from EU then are taken as irrational biases, to be corrected. Thus, recommended decisions can deviate from expressed subjects'/patients' preferences. This sounds paternalistic, but if one does not do this one can almost never improve others' decisions. (Raiffa 1961: "we don't have to teach what comes naturally"). It is called the corrective approach. This paper follows that approach and discusses many applications and practical implications.

This paper does not consider much the measurement of utility of life duration/discounting. It focuses on the measurement of quality of life of health states, also called utility of health states or, sometimes, weight of health states. Box 1 on p. 817 explains the TTO and SG measurements of quality of life. In general, whenever a bias has a particular effect, then the corrective procedure for it, serving to neutralize, will impose the opposite effect. And, in general, given the scaling U(death) = 0, U(perfect health) = 1, the more concave utility is, i.e., the more risk averse we make it, the higher utility values for intermediate health states. Thus, loss aversion and the, mostly pessimistic, probability weighting increase risk aversion. The corrective approach then increases risk seeking and decreases quality of life estimations. Same things when correcting for loss aversion in TTO. A bit of a different story regarding normative/descriptive is correcting TTO for concave utility of life duration but, anyway, it leads to increases in quality of life estimates. Because most of these corrections lead to more convex utility, they lead to higher evaluations of getting back perfect health (the "perfect heath gap").

This paper uses the term loss aversion differently than I and Bleichrodt, Pinto, & Wakker (2001) do. I use it only for framing effects that, by definition, are irrational. Rational part are put into utility, more precisely, “basic utility.” This is by definition, and terminological. This paper does not do so and also uses the term loss aversion for components that may be rational.

P. 818 top: criticism of parametric fitting.

P. 819 end of 1st column: compression is not an explanation, but a restatement of the perfect health gap.

P. 819 top of 2nd column: compression need not explain consistency because the different measurements can get compressed at different levels.

P. 820 2nd para: never in my life, so, never in Diecidue & Wakker (2001), did I call a deviation from EU such as probability weighting rational. %}

{% **updating under ambiguity with sampling**; P. 278 shows that the Samuelson colleague example does not violate EU if not the single rejection is imposed in all situations.

All choices hypothetical …

Do choice under risk and ambiguity (Ellsberg urn and market choice with 40-80% success chance indicated). Do single choice and repeated (twice). In repeated choice less ambiguity aversion. This is the simple finding of this paper. A plausible and even normative explanation, not mentioned by the authors, is that for repeated ambiguous choice one can learn about (unknown) probabilities in later choices from the first choice. In the Ellsberg experiment subjects were told that on each choice the computer anew determined the composition of the unknown urn, but we can then still learn about the computer from repeated

choice.

The authors put up loss aversion as explanation. I do understand that for repeated choice sometimes the probability of a loss is smaller than for single choice, but not why that reduces ambiguity aversion. %}

Liu, Hsin-Hsien & Andrew M. Colman (2009) "Ambiguity Aversion in the Long Run: Repeated Decisions under Risk and Uncertainty," *Journal of Economic Psychology* 30, 263–516.

{% Whereas for moderate-outcome events with nonlow frequencies probabilities are known, for rare events of extreme magnitudes (p. 132 1/3) they are not (**(very) small probabilities**). Hence, adding additional ambiguity aversion and ambiguity-premium (the paper calls it uncertainty premium) can help explain asset prices. So it does. Especially for options out of the money, which are very sensitive to rare events (unlike equity for instance, see p. 146), this works well. The effect is independent of risk aversion (they assume EU for given probabilities and, hence, risk aversion = concave utility). For instance, Eq. 27 (p. 143) displayes the additional component in the equity premium. They explain that recursive utility cannot do it because it should be only for rare events and recursive utility does it for all events. For example, p. 135: "In particular, the rare-event premium component, which is linked directly to rare-event uncertainty in our setting, cannot be generated by the recursive utility." Reiterated on p. 139

P. 135 footnote 8: "We show that recursive utility cannot resolve the smile puzzle. … In effect, it does not have the additional coefficient to control the market price of rare events separately from the market price of diffuse shocks."

ambiguity seeking for unlikely: The paper does not show that, but it does show that ambiguity attitude is different for events of different likelihoods. It also supports **event/outcome driven ambiguity model: event driven**.)

P. 137 footnote 11: impossible events get weight 0. (As in neo-additive models.)

Helps explain equity premium puzzle and volatility smile (or smirk, which is a skewed version; see p. 150).

P. 152: Points out that their model can only work because they add a new dimension: "since we add a new dimension to the problem: rare events and uncertainty aversion only toward rare events." This is nice support for likelihood insensitivity, and

against universal ambiguity aversion.

P. 155: "these restrictions do become important as we apply the model to a range of securities with varying sensitivity to rare events." %}

{% This paper examines transformations T transforming probability distributions into other probability distributions. Shape transformation results from what economists would call utility transformation of outcomes. Probability transformation results from transforming the distribution function, which is what

economists call rank-dependent probability weighting. Such T transformations provide a nice unified framework to capture many things under one umbrella.

Theorem 1 shows that, under some regularity assumptions, a transformation is commutative with a shape transformation if and only if it is rank-dependent probability weighting transformation. That is, whether you first transform outcomes into their utilities, and then transform the distribution, or you first transform the distribution and then transform the outcomes into their utilities, does not matter. While a mathematical result, it nicely supports the natural nature of rank dependence, where transforming the outcomes and transforming the probabilities are sort of orthogonal operations. Further properties, such as convexity, are studied. %}

{% **ambiguity seeking for unlikely**: pp. 81-82: -"To sum up, we propose that time has a differential influence on high probability and low-probability prospects. Specifically, for high probabilities, time will reduce ambiguity aversion by increasing the reliance of cognitive processing. For low probabilities, the influence of time is trivial because of the predominance of cognitive processing for small probabilities." They use experimenter-specified probability intervals to generate probabilities (through urns with upper and lower bounds on compositions specified), taking, as usual, arithmetic midpoint as ambiguity neutrality.

Study 1: choices were hypothetical, with introspective strengths of preferences.

Study 2: Matching probabilities were determined. The authors use the term ambiguity-probability trade-off task. The authors use biseparable utility, calling it α-maxmin, and use α as index of ambiguity aversion. Here RIS was used where 1 subject played for real, with one future payment possibly one year later.

Study 3 is most interesting. A control group is like study 2 (although hypothetical). But one other group before answering the immediate questions is primed cognitively by being asked five calculation questions, and another group before answering the future-decision questions is primed affectively by first answering five affect-questions ("if …, what do you feel?"). The cognitively primed indeed become more ambiguity neutral (rational!?) and the affectively primed opposite. %}

{% Elaborates on all standard sufficiency implications concerning risk aversion and the like for RDU. %}

Loehman, Edna (1994) "Rank Dependent Expected Utility: Stochastic Dominance, Risk Preference, and Certainty Equivalence," *Journal of Mathematical Psychology* 38, 159–197.

{% An individual nonparametric estimation of RDU, PT, and other things is presented, based on pairwise choices between gambles, for N = 21 subjects. No real incentives were used. The way of getting nonparametric fittings resembles the method of Gonzalez & Wu (1999). That is, outcomes 300, 200, 150, 100, 50, 0, −50, −100, −200 are considered and the utilities of these outcomes are treated as parameters to be estimated. Similarly, probabilities .10, .25, .50, .75, .90 are taken and their weighting function values (possibly different for gains than losses) are treated as parameters to be estimated. P. 293 brings up the interpretation as parametric fitting of piecewise linear functions. Note that the Gonzalez & Wu paper had been around long before publication, with Gonzalez presenting it in a Mathematical Psychology conference of '92.

The numerical algorithm, explained on p. 293, is iterative, again similar to Gonzalez & Wu (1999). First w(.5) = .5 is taken and then from a number of .5 prob gamble prefs ("Set I") utility is estimated. Next these utilities are taken as given and from other gamble-prefs ("set II") the weights of the probabilities considered are estimated. The resulting weight of probability .5, which is usually different from .5, is used to re-estimate the utilities based on set-I-prefs. These are used to recalculate the weighting function, until the process converges. At each step, the solution closest to linear is chosen.

The gambles have either one nonzero outcome or one positive and one negative outcome. Here:

PT: original (1979) prospect theory, which is in fact PT with reflection in the domain considered. **SPT instead of OPT**: happens in Eq. 1

EURDP: what I call RDU.

SDM: on this domain it is in fact PT, generalizing OPT by allowing for different weighting of gains and losses. (It is taken from Currim & Sarin 1989.) It performs poorly.

The most pronounced effect in the data is, remarkably, never noted or discussed in the paper! It is loss aversion. That is, the slope of utility is big just below zero and then strongly drops when passing through zero. This effect can be seen in Tables 4 and 5 in the slope-of-utility tables, given for eight "smooth" subjects chosen out of a total of N = 21.

concave utility for gains, convex utility for losses: The paper finds concave utility for losses, in deviation from the commonly found convex utility. This finding may be explained because losses are framed as insurance questions which is known to enhance risk aversion (see keyword **insurance frame increases risk aversion**). The paper finds concave utility for small gains which may result from loss aversion. The paper finds convex utility for large gains (100-300 I guess) which is harder to explain. (Maybe a numerical effect of overmodeling loss aversion, so coming up with overly small slopes just after zero?)

inverse S: P. 289 says that insurance was accepted mostly for small-prob-high-losses. P. 295 finds inverse S for RDU which is the special case of PT where weighting for gains is dual to weighting for losses (loss aversion is captured in curvature of utility). P. 296 bottom mentions the results for PT (called SDM) briefly with no clear pattern.

P. 299, in the Conclusion, writes that there is clearly predictive power between RDU and OPT, but does not say how. The only thing I find is on p. 293 where, of 25 subjects, RDU fits two subjects more than OPT.

P. 299 last line: "Thus, the assumption that subjective probabilities sum to one has a strong effect on subjective probability estimates." %}

Loehman, Edna (1998) "Testing Risk Aversion and Nonexpected Utility Theories," *Journal of Economic Behavior and Organization* 33, 285–302. https://doi.org/10.1016/S0167-2681(97)00097-8

{% **real incentives/hypothetical choice**: §5 argues that real monetary incentives are not very important, because ten incentives other than monetary are more important (status, being best, other emotions).

Paper discussed behavioral economics versus experimental economics. The author sometimes gets carried away with his enthusiasm for behavioral economics and against experimental economics. Such as footnote 2 (p.F31): "Because context cannot be eliminated, experiments should never be used for the purpose of measuring individual propensities. … Some EE's [experimental economists] seem to believe they know the answer: whatever context gives results that are closest to the standard economic model." Or the final sentence of the paper: "Given that BEs [behavioral economists] have proposed some of the most novel and provocative hypotheses about individual behaviour, BE may well be the single best application of EE [experimental economics] methods."

§6 (p.F32) brings up a very strange exaggerated accusation of experimental economics: "a common failure by EE's [experimental economists] to assign subjects randomly to different treatments."

I agree with the criticism in §1 that experimental economists have not been well aware of issues of internal-external validity for a long time, and the present popularity of field studies is an unbalanced counterswing to catch up with what other social sciences have routinely known for longer times. %}

Loewenstein, George F., Daniel Read, & Roy F. Baumeister (2003, eds.) "*Time and Decision: Economic and Psychological Perspectives on Intertemporal Choice.*" Russell Sage Foundation, New York.

{% **time preference**. **dominance violation by pref. for increasing income**: Assume that two wage profiles give the same sum of money over time but the first, at each timepoint, gives a higher total up to that timepoint than the second (e.g., first decreases, second increases). Then in fact by no more than monotonicity (if money is the only relevant attribute), one should prefer the first profile. Discounting only adds to that. However, the majority of subjects prefers the second profile.

They explained the issue to the subjects, also mentioning psychological arguments for why one might still want to prefer the second profile. A little more than half of the subjects adhered to a preference over profile 1. This suggests that it is not irrationality, but people deliberately have their utility depend on other things than absolute level of money.

intertemporal separability criticized: sequence effects

P. 71: "An important question concerns whether violations of present value maximization (and therefore dominance) should be treated as errors in decision making or as rational manifestations of a preference function that includes arguments other than absolute levels of consumption. This question is analogous4 to the debate over the status of Savage's independence axiom."

P. 82: "Whether the observed preference for increasing payments is treated as rational or as a mistake depends on whether we are willing to accept a more complex utility function than has generally been assumed." %}

Loewenstein, George F. & Nachum Sicherman (1991) "Do Workers Prefer Increasing Wage Profiles?," *Journal of Labor Economics* 9, 67–84.

{% **time preference;** cite data of very high discount rates, exceeding 25%.

P. 184 seems to write:

> In this study, and some others described here, the questions asked were hypothetical. Of course, all things being equal it would be better to study actual choices. However, there are serious trade-offs between hypothetical and real money methods. Using hypothetical questions one can ask subjects to consider options that incorporate large amounts of money, both gains and losses, and delays of a year or more. In studies using real choices, the experimenter must reduce the size of the stakes and the length of the delay, and it is difficult to investigate actual losses. Also, in a hypothetical question, one can ask the subject to assume that there is no risk associated with future payments, while in experiments using real stakes, subjects must assess the experimenter's credibility. %}

{% This paper expresses many subjective opinions about paternalism, and I agree with all of them. §2 describes the history of the ordinal revolution, and the new developments of economics opening up more to nonrevealed preference inputs as propagated by Kahneman and others, which fully agrees with the history described in §§2-3 of Abdellaoui, Barrios, & Wakker (2007).

paternalism/Humean-view-of-preference

conservation of influence: p. 1796: "The strong preference people show for the default option suggests that more than rational self interest is at work."

P. 1797 "the main problem with experienced utility is its failure to incorporate non-hedonic aspects of experience, such as meaning and capabilities (even if such capabilities are not used) that are important to people but have little impact on their subjective happiness."

P. 1797: "Given the limitations of measures of welfare based either on decision utility or on experience utility, is there any hope for coming up with a normatively compelling welfare criterion? In Section 6, we argue that no simple criterion based on either concept can surmount these problems. Instead, evaluations of welfare will inevitably have to be informed by a combination of both approaches, patched together in a fashion that will depend on the specific context."

P. 1804, §5.7: "In this section we have argued that a major—indeed perhaps fatal—problem with experience utility is its failure to incorporate dimensions of experience other than simple happiness that people justifiably care about. To some extent, we may be able to overcome these flaws by expanding and improving the measures we include as part of experience utility. It is theoretically possible to capture people's experience of meaning and purpose in their lives, independent from their moment to moment affect. But we expect that this will not address all the problems we have raised with experience utility. Instead, we believe that there are circumstances that matter to people independent of their influence on moment to moment experience. Despite other patent flaws, decision utility has the advantage of capturing these values in a way that experience utility does not—e.g., if an individual cares about meaning, he or she can incorporate that concern into their choices."

P. 1805, §6.1.2 is on debiasing, citing studies by Ubel et al. trying to debias the overweighting of small probabilities.

Several sentences show the enthusiastic style of Loewenstein. P. 1798 ℓ. 4-5: "an issue of growing importance in an age of increasing income inequality."

P. 1804 ℓ. –9: "Such a policy ignores the problems raised by the phenomenon of hedonic adaptation,": hedonic adaptation is not the problem, but one of many symptoms of the problem, being that people have no anchor for the scales offered to them so that interpersonal comparisons (and even between- over time, as with adaptation) are problematic, as often in between-subject studies.

P. 1805 4th para, suggests that, in order to investigate if a decision of nonsafe sex was wise, the ultimate criterion should come from investigating neural processes in the brains of the people involved. "If we could investigate the brain waves of each partner." %}

{% **standard-sequence invariance**: P and Q are jazz records. (A,P) designates receiving $A and P. An additive model is assumed. It is pointed out that (A,P) ~ (B,Q) and (A',P) ~ (B',Q) imply that the utility difference between A and B is the same as between A' and B'. It is studied with five subjects and four such indifferences. %}

Loewenton, Edward & R. Duncan Luce (1966) “Measuring Equal Increments of Utility for Money without Measuring Utility Itself,” *Psychonomic Science* 6, 75–76.

{% **foundations of statistics**; criticizes hypotheses testing on six points: (1) The usual “point” H_0 is impossible beforehand; you don’t want to know it is untrue, you want to know by how much it is untrue; sufficiently large samples always become significant (I think that has been called “statistically significant but not psychologically/economically/medically meaningful”). (2) Often H_0 is rejected but it is not clear what the alternative is (“A depends on B” can be just anything). (3) With H_1 vague, also power is vague. Power is especially important if H_0 is not rejected. (4) Artificial dichotomy reject/not-reject: Jf one study accepts H_0 and the other not that does not mean a contradiction! (5) One routinely assumes linear relations (regression) or normal distributions. A nice example can be found in Fig.1 about high-learned people who forget as low-learned but with a delay of two days, but this relationship is not detected by common methods. (6) The Bayesian point that p-value does not consider the relevant conditioning.

Then four remedies are given: (1) Plots are clearer than tables. (2) Confidence intervals help to describe power (can be depicted in plots around the estimations). (3), about normalization in meta-analyses, I will not discuss here. (4) “Contrasts” (I think, specify alternative hypotheses and see how well they fit data)

Conclusion: "Hypothesis testing provides appearance of objectivity ... only illusion of insight.," suggesting different preferable frequentist methods (confidence intervals, plots, etc.). Gives many references to discussions of hypothesis testing. %}

{% **error theory for risky choice**; **Best core theory depends on error theory**: seems to be. %}

Loomes, Graham (2005) "Modelling the Stochastic Component of Behaviour in Experiments: Some Issues for the Interpretation of Data," *Experimental Economics* 8, 301–323.

{% The author considers the probability triangle, with probability distributions over three fixed outcomes $x_3 \succ x_2 \succ x_1$. Then prospects can be characterized as $S = (p_1, p_2, p_3)$ and $R = (q_1, q_2, q_3)$. Nontrivial choices will have $p_1 < q_1$ & $p_3 < q_3$ (then R is more risky than S). Under EU, S is preferred iff $(q_1-p_1)/(q_3-p_3) \geq (U(x_3)-U(x_2))/(U(x_2)-U(x_1))$. The author proposes a generalization $\varphi(P) \geq \xi(X)$ where P is a measure depending only on the probabilities and X one depending only on the outcomes. This model is called PRAM (perceived relative argument model), with P the perceived relative argument due to probabilities and X the one due to outcomes. It entails a kind of separability between probabilities and outcomes.

The most salient aspect is that the model violates transitivity, somewhat like regret theory but now with a similar thing in the probability dimension. The author considers special cases of the functions, pointing out that they can accommodate known paradoxes and preference cycles, with some forms in Eqs. 11-13 adding only one or two parameters to EU. (P. 910: the version with one parameter is violated by common consequence.)

Some limitations: I cannot imagine how this model could in any tractable way be extended beyond the probability triangle. Further, intransitive models are hard to extend beyond binary choices. It would be interesting to pin down more precisely what the implications of the model are; it has some separability of outcomes and probabilities, with may be the possibility to build in rank dependence.

A detail: P. 903 Eq. 2 on RDU is not correct because q_1 and p_1 should be handled as worst ranks, with $1-w(1-p_1)$ rather than $w(p_1)$ the weight of p_1 for instance. This affects the following analysis in details but not in substantive manners.

P. 906 footnote 8 erroneously thinks that in modern 1992 PT (called CPT by the author) there would be no more certainty effect.

P. 913: “CPT (taken to be the flagship of non-EU models)” (**Prospect theory/Rank-Dependent Utility most popular for risk**)

The experimental evidence in §5 does not test the basic model, but only qualitative add-on predictions (such as testing risk aversion when supposedly testing EU). The RIS is used to incentivize. %}

Loomes, Graham (2010) “Modeling Choice and Valuation in Decision Experiments,” *Psychological Review* 117, 902–924.
https://doi.org/10.1037/a0019807

{% **utility elicitation**; relates PE (if I remember well, they call it SG) to TTO; p. 305 top of 2nd column explicitly leaves it open if patient utilities or community utilities are to be used, in agreement with what I think, and deviating from the unfortunate viewpoints of Gold et al. (1996).

intertemporal separability criticized: p. 303 (quality of life depends on past and future health)

risk seeking for small-probability gains: p. 305, bottom of 2nd column, points out that even people who are generally risk averse can be risk seeking for treatments with low-probability-high-effects, such as for heart and liver transplants, and coronary and neonatal intensive care units.

P. 306 middle of 2nd column: “Given that decisions have to be made, and cannot be postponed until researchers have perfected the decision tools, the use of QALYs at their present stage of development may be defended as being no worse than any alternative measures.” Then warns that we should not be too quick.

P. 307 first column suggests that nonEU theories be used in utility measurement. %}

Loomes, Graham & Linda McKenzie (1989) “The Use of QALYs in Health Care Decision Making,” *Social Science and Medicine* 28, 299–308.

{% N = 234 volunteers all individually interviewed at their homes! Are asked some simple statistical questions (prob of picking diamond card for instance), some public-risk questions (new monarch next year), and some private risks (you lose wallet in next X days). First asking statistical questions lowers other probability estimates, and “insensitivity to temporal scope” (burglary in your house next X years too independent of X), mostly for personal risks, then for public risks, then for statistical). Findings and tests are thin given the experimental investment. %}

Loomes, Graham & Judith Mehta (2007) "The Sensitivity of Subjective Probability to Time and Elicitation Method," *Journal of Risk and Uncertainty* 34, 201–216.

{% **error theory for risky choice**: Test EU and prospect theory/RDU, with error-theories added. Their footnote 11 points out that they do not consider losses, so that RDU is the same as PT.

Watch out: they do old-fashioned bottom-up RDU integration, with w around 0 relevant to worst outcomes and w around 1 relevant to best outcomes.

P. 104, next-to-last para: "expected utility theory and with its most prominent rival, rank-dependent theory." P. 115, beginning of §6: "In part, we made this choice in recognition of the prominence of RD [rank-dependent utility] in the literature: it is probably the most widely-used non-EU theory. But we were also influenced by the properties of the data." (**Prospect theory/Rank-Dependent Utility most popular for risk**)

P. 119, next-to-last para: "these results establish that RD [RDU] model has significantly greater explanatory power than the EU model."

They find (p. 123) that deviations from EU decrease as subjects get more experienced (more repeated choices). Conclusion will claim convergence to EU

inverse S & **risk seeking for small-probability gains**: They find and model overweighting of the best outcome (called "bottom-edge effect") and, remarkably, not of the worst (see their p. 115 last para, and p. 116 between Eq. 11b and 12a); (**EU+a*sup+b*inf**). It implied that the Prelec one-parameter family performed worse than the simple overweighting of best outcome.

equate risk aversion with concave utility under nonEU: unfortunately, in their writing they often equate utility with risk attitude, which is not correct for rank-dependent utility.

Endnote 12 points out that non-cumulative weighting theories (they say it for Viscusi's prospective reference theory) cannot treat overweighting of good outcomes differently than of bad outcomes.

They also test which probabilistic choice model works best.

parametric fitting depends on families chosen: seem to point that out. %}

Loomes, Graham, Peter G. Moffat, & Robert Sugden (2002) "A Microeconometric Test of Alternative Stochastic Theories of Risky Choice," *Journal of Risk and Uncertainty* 24, 103–130.

{% They propose a model of consumer preference with loss aversion, explaining the discrepancy between WTP and WTA. They assume that consumers are uncertain about what their true preferences are (reminding me of Kreps' 92 work on it). For instance, an owner of a mug, when exchanging it for a chocolate, may just be uncertain whether the exchange is a gain or loss. Then the usual loss aversion can come into play, with status quo bias and so on. P. 121 end of §1 describes it clearly. They do the Sugden extension of allowing the reference point to be random (what I like to call random reference theory).

For multiattribute outcomes such as commodity bundles, it is well known that one can do loss aversion in two ways. One is attribute-wise, having within each attribute a reference level, and maybe gains in some attribute levels and losses in others, such as in Tverky & Kahneman (1991, QJE). The other is global, taking one indifference class of multiattribute outcomes as reference level, and all preferred outcomes as gains, and the dispeferred ones as losses. In the latter case, being a gain or a loss is a holistic property. The latter was the approach of, for instance, Wakker & Tversky (1993, JRU) in which outcomes can even be from connected topological spaces, which includes commodity bundles as special case and works globally. The authors call the former, attribute-wise, approach dimension-based, and the holistic approach they call taste uncertainty approach. The attribute-wise approach has only been considered in the literature in combination with additive separability across attributes, and the authors go at great length to emphasize the empirical failures of it.

They also compare extensively with Köszegi-Rabin (2006), where reference point is endogenous and not exogenous as in this paper. There also is a μ function in K-R applying only to m differences (m something like basic utility) so that absolute m levels then do not affect degree of loss aversion. In this paper, the degree of loss aversion can depend entirely on the wealth level and the authors emphasize this much.

P. 118 end of 2nd para is interesting: one can measure the degree of loss aversion by finding sequences of exchanges, all much disliked, that end where they started, and finding a net compensation required to implement the cycle.

I liked §4, which discusses how experience can reduce uncertainty and, hence, loss aversion, and discrepancy between WTP and WTA. But p. 131 is strange in claiming that attribute-wise models of loss aversion cannot accommodate reduction of loss aversion by learning. What they mean to say is that these models do not consider learning explicitly in their model. Of course everone using them will say that, if learning is incorporated, then it will reduce loss aversion. %}

Loomes, Graham, Shepley Orr, & Robert Sugden (2009) "Taste Uncertainty and Status Quo Effects in Consumer Choice," *Journal of Risk and Uncertainty* 39, 113–135.

{% **PT falsified**: Measure certainty equivalents of prospects, allowing for choice errors. Find violations of PT, and suggest that a similarity theory may fit better. The authors are negative on PT (which they call CPT): "If CPT is to justify its current status as the front runner among alternatives to EUT, it should be able to organise the data from our CREPROBS treatment; but it cannot do so," (p. 209). The main purpose of the paper is to argue for the use of error theories. %}

Loomes, Graham & Ganna Pogrebna (2014) "Testing for Independence while Allowing for Probabilistic Choice," *Journal of Risk and Uncertainty* 49, 189–211.

{% Abstract opens with the cliché word policy, as does the 2nd column on the opening page 166. The paper tests preference reversals reckoning with probabilistic choice, and still finding preference reversals, consistently with other papers. %}

Loomes, Graham & Ganna Pogrebna (2017) "Do Preference Reversals Disappear When We Allow for Probabilistic Choice?," *Management Science* 63, 166–184. https://doi.org/10.1287/mnsc.2015.2333

{% Subjects chose x to optimize (p+ε:x, p–ε:T–x, 1–2p:K) with the other parameters fixed, ε > 0. K = T/2 (so that certainty results with x = T/2) or K = 0 was chosen. Under EU's second-order risk aversion, x > T/2, under 1st order risk aversion x =

T/2 can occur. The authors indeed found x = T/2 for several subjects. Unfortunately, no statistical analysis is given, so it is not clear if the data can result from merely noise.

Because the common outcome K was displayed as such, subjects may have ignored it. %}

Loomes, Graham & Uzi Segal (1994) "Observing Different Orders of Risk Aversion," *Journal of Risk and Uncertainty* 9, 239–256.

{% Typical of their early experimental papers. They find more preference cycles in direction predicted by regret theory than the other way around. They argue that preference reversals may reflect genuine intransitivities, as predicted by regret theory. Later papers by (some of) these authors will argue that event-splitting effects rather than intransitivities may explain the early findings of regret theory.

The authors used a version of RIS where, prior to the experiment, subjects received an envelope containing the no. of the choice implemented for real at the end, which, as the authors argue, reduces the risk of hedging. The same procedure was used by Epstein & Halevy (2018), and it is similar to the Prince method of Johnson et al. (2021 JRU). However, it crucially differs and loses several pros of Prince, as explained in my annotations at Johnson et al. (2021 JRU). %}

{% **risky utility u = strength of preference v (or other riskless cardinal utility, often called value)**: P. 807: assume experienced utility, called "choiceless." Say it is Bernoullian

§V argues that regret is not irrational.

P. 818: Probabilistic reduction is called the "equivalence axiom." It is what Wakker (2010, Assumption 2.1.2) called the decision under risk assumption.

utility = representational, p. 817: "While we do not share the methodological position that the only satisfactory theories are those formulated entirely in terms of empirical propositions, …"

Some drawbacks of regret theory:

(1) The psychological regret that explains much of common ratio, is fundamentally different than what regret theory does. It is that if an outcome 0 has certainty of foregoing sure $1M (M: Million), then regret is strong, but if it is

only a probability of foregoing $1M then regret almost entirely disappears. It is a nonlinearity in probability, a sort of certainty effect. It then is important that the regret of getting the smallest outcome 0 instead of the second-smallest $1M is big. The regret theory explanation goes in the other direction: The regrets of getting the smallest outcome 0 instead of the 2^{nd}-smallest outcome 1M, and of getting the 2^{nd} smallest outcome 1M instead of the largest outcome, should be relatively small, and the regret of getting the smallest instead of the highest outcome should be disproportionally large. So, the regret of getting 0 instead of 1M should not be big, but small. This is unrelated to what happens in reality. By implying the sure-thing principle regret theory is not well suited for explaining Allais.

(2) Regret is clearly a second-order effect relative to utility difference. Probability weighting, for instance, is an independent component that may explain even more than utility, but regret is second-order and only adds nuances. %}

{% There is a clear definition of SP/A theory, clearer than Lopes' papers, in Ch. 26 of Shefrin, Hersh M. (2008) "*A Behavioral Approach to Asset Pricing Theory;* 2nd *edn.*"

In SP/A theory, a prospect (lottery over money) depends on

(1): SP. This is a rank-dependent utility, with linear utility, and a weighting function that is a convex combination of a power function p^r and a dual power function $1 - (1{-}p)^{r'}$, where the first captures pessimism and the second optimism. For the claims about mixed weighting functions in Eqs. 9 and 10 (p. 290), it is important to know that the parameters q_r and q_p are supposed to be positive (I assume), so that the w-weighted curve is convex and the (1−w) weighted curve is concave, and the convex mix gives an **inverse S**-shape.

(2) A: an aspiration level, i.e., an outcome, is chosen, and A is the probability of (weakly!?) exceeding it.

A weak point is that how these two are combined is not specified. Lola must have thought: "Attack is the best way to defend." So, she emphasizes this as a strong point. P. 291 end of penultimate para writes that, if these two components prefer a different prospect (so, if the case is not totally trivial), then SP/A predicts “conflict.” This gives a revealed-preference oriented economist little hope of being informed about what choice then results. The text then writes that such conflict cannot result from “single-criterion” models such as CPT (p.s.: CPT and all economic models can consider multi-criteria optimization in utility), which further reduces my hope of being informed about the resulting choice in any not-completely-trivial situation. P. 300 2nd para will mention an aggregation of the two components but it is not clear how, apparently through a numerical Table 5.

The first para on p. 292 confuses monotonicity with absolute risk aversion, and erroneously claims that CPT would have constant absolute risk aversion.

Although in several places the paper writes that it, unlike prospect theory, has no reference point but *instead* an aspiration level, SP/A theory turns out to have a reference point still because it does distinguish between gains and losses, where every parameter in the model (including probability weighting, contrary to what Shefrin, 2008, p. 429 last sentence, claims) can depend on the sign (pp. 290-291 & 299). In particular, the aspiration level can be different for gains than for losses (then how about mixed prospects?), and will later (p. 300 top) be taken to be 0 for losses and, ad hoc, 1 for gains.

P. 302, Eq. 16 suddenly does aggregate SP and A into a decision formula, although it is a probabilistic choice model, with no deterministic model specified. For me, the formula comes out of the blue, seeming to assign the same weight to SP as to A. (I’d expect SP to have more weight.) Does this satisfy stochastic dominance? Some form of transitivity?

P. 310 penultimate para has a nice text on risk aversion being conflated with utility.

Shefrin (2008 p. 431 bottom) writes that the weighting function in prospect theory captures perception, but in SP/A it captures emotions.

In Table 5 it is amazing that the very crude A-criterion alone (just the probability of exceeding aspiration, which is nothing but probabilities related to 0) explains data so well. Then SP/A will do better than PT! Makes me wonder about the stimuli.

PT falsified: not strongly. Mostly, Lopes’ SP/A theory fits data better than her implementation of PT (which is questionable given that she, erroneously, thinks that PT satisfies constant absolute risk aversion).

1. **convex utility for** loss**es**: for losses subjects are risk-neutral more than risk-seeking

2. Subjects seem to prefer (0.5: 50, 0.5: 150) to 100 for sure. Seems to agree with Lopes SP/A theory, while violating PT. (Is like {**risk seeking for symmetric fifty-fifty gambles}**, but not symmetric about 0.)

risk averse for gains, risk seeking for losses: seem to be risk neutral for losses; multioutcome lotteries.

loss aversion without mixed prospects: they claim to estimate loss aversion λ, but they do not consider mixed prospects and, therefore, it is impossible to estimate λ.

linear utility for small stakes: p. 290 footnote 1 %}

{% This paper, in a prominent journal, with quite some citations, and coverage in the popular press, is very very weak. It illustrates how the academic system can malfunction. It is interesting because of its extremity and I, hence, provide details.

Wisdom of the crowd: Imagine asking many individuals to estimate something, say the weight of a particular cow (Dalton 1907). Let w denote the true weight, x_i the estimate of individual i, and x the average (arithmetic or geometric) or median estimate, depending on context; I will write average in what follows. The individual estimates can be far off ($|x_i - w|$'s large), but sometimes not systematically so, and then $|x - w|$ can be small meaning that x is a good estimate of w. The latter can be surprisingly good, of course depending much on the stimuli considered. If surprisingly good, people use the term wisdom of the crowd, or wisdom of crowds.

This paper studies the wisdom of the crowd. Individuals estimate, being rewarded for small distance from truth, and it is inspected whether group average is close to truth, where the latter is (to be) taken as wisdom of group-as-a-whole. In a first round, subjects just submit their estimates. Then in later rounds they receive feedback about the estimate of one or a few or all others, and then can change their estimate. Unsurprisingly, and shown by many studies, the estimations usually converge, giving same group-average but smaller within-group group variance. (Some paradoxical opposite findings, usually for emotionally loaden topics such as the desirability of capital punishment with no clear true answer and with richer information-sharing, are known as confirmatory bias.) This convergence is also the empirical finding of this paper. What the paper adds is many provocative, but all erroneous, interpretations.

Although many statistic books warn against interpreting a null found, the authors do interpret their null of group average x not being affected by their ways of information sharing. And although I would interpret their ways of info sharing then as irrelevant to the goodness of group prediction, x not being affected, the authors interpret their null as “undermining” for wisdom of the crowd. They seem to have in mind that wisdom of the crowd is driven by group diversity and that hence every decrease in group diversity is bad, forgetting that the real criterion is how close x is to w and that group diversity is only an instrument to make x get close to w. If not the average w were the criterion, but something like the union of the info of the members of the group, then it could be different and diversity could be desirable. This point may underly many interpretations of the authors although it should not do so in the situation specified by the authors themselves (where only $|x-w|$ matters).

With some effort, I could think of a situation in which group diversity does impove the group average: If we vary the group diversity *under the condition* of keeping the average individual distance, so, the average of $|x_i-w|$, fixed. So, not the distance of the average, but the average of the distance, is kept fixed. This condition is very rarely satisfied, and absolutely not in the experiments of this paper. My best guess for this paper is that the authors (+ referees + editor + many citing it affirmatively) are continuously confused on this point: whereas in reality the distance of average remains constant, they think that the average of distance remains constant.

The convergence of individuals can be interpreted as improvements of the individual wisdoms, implying that the crowd has less wisdmom to add to the individuals and, hence, the wisdom-of-the-crowd effect became less? This interpretation is highly irrelevant because only $|x-w|$ really matters.

Another problem of the authors' accepted null just discussed is that it is not really an accepted null. As the authors call it somewhere (last footnote on p. 9022), it is "partially supported by the significance tests," and they sometimes find that x actually has come closer to w, so, has really been improved. The end of the footnote reassures us that we need not worry here: "as this effect may be different for different sets of questions." The latter holds not only for this claimed accepted null but for everything else in this paper too. Although p. 9022 (colum 1 ℓ. −7) properly indicates that the above effect is just a statistical effect, the authors still use the misplaced term "social influence effect" for it (p. 9022 1st column last para).

The authors signal a second supposed problem, using what they call a "new indicator" on p. 9021. The perfect wisdom of the crowd according to this indicator occurs if the true value is a median (so, it is between the two middle scores if even group). The indicator considers how many group members should change their opinion to achieve this perfectness. This indicator is served by increasing variance given constant average x (which surely is not always a good thing I would say). Here is an algorithm of achieving universal maximal wisdom for all questions ever to be faced by mankind, simply by maximizing variance: You form a two-person group with one other person (so, even number). Take a big number M, exceeding any other number you will ever meet in your life. Your guess (of whatever; you don't care what) is M, and your partner's guess is −M. Every answer to every question ever faced is between your two (middle) scores and, hence, you two have achieved universal maximal wisdom. Of course, this is nonsensical, showing that the criterion proposed by the authors is not sensible.

And then the authors signal a third supposed problem. If the individuals in the crowd converge, with diversity decreasing, then their confidence in their judgments will increase. If their average x is close to the true value w, then this increase is good. If, however, x is far off, then it is bad. The authors only consider the latter case in their discussion.

The writing is annoying. I think that it is obvious that info sharing usually improves group estimates. The authors claim on p. 9021, ℓ. 2, that it "can undermine" wisdom of the crowds, and this claim can be. But p. 9021 2nd column ℓ. −5 claims that the wisdom of the crowd "is undermined" which at best is misleading, can only be defended if they claim to only refer to their own experiments. P. 9021 2nd column end of 1st para crosses the line by writing "The reason to use two different kinds of social influence was to demonstrate the robustness of our effects with regard to the specific kind of social influence." This erroneouly suggests universality of their finding.

It seems that their statistics is problematic. Figure 2 on p. 9023, seems not to give what the text claims, with full info in fact going the other way. Close inspection of, for instance, degrees of freedom in their estimates, seems to show errors there.

Farrell (2011) properly criticizes the main mistakes in this paper. %}

{% %}

Luce, R. Duncan (1997) “Associative Joint Receipts,” *Mathematical Social Sciences* 34, 51–74.

{% **coalescing**;

SPT instead of OPT: P. 101 incorrectly writes that Fennema & Wakker (1997) had proposed Luce’s Eq. (11) for gains and losses separately. This is not true. Fennema & Wakker explicitly state on p. 54, two lines above their Eq. (1): “We only give the PT value for prospects … with both positive outcomes (gains) and negative outcomes (losses).”

P. 103 gives concise description of configural weight theory.

In later writings Luce pointed out, based on cummunication with Marley, that the derivation of RDU in this paper is not correct. Status-quo event commutativity is too weak because it only gives a decomposition into utility and decision weight for the best outcome, not for the worst. %}

Luce, R. Duncan (1998) “Coalescing, Event Commutativity, and Theories of Utility,” *Journal of Risk and Uncertainty* 16, 87–114.

{% **criticisms of Savage’s basic framework** §1.1.6.1.

Note: Luce uses term accounting indifferences and not term accounting equations.

P. 7 explains why Luce’s gambles are not formally acts à la Savage.

Pp. 22-23, §1.3: This section illustrates something that I regret. The author explains that he wants to get cardinality (my term) for consequences. For this purpose he introduces joint receipts (his 4th approach). The first approach he suggests is to assume multiattributes on the consequences and then use joint analysis techniques. What he does not realize is that one can consider different events or disjoint probabilities in lotteries to be attributes, and then use the conjoint techniques there. (I do that, using conjoint analysis techniques treating events as attributes, in many papers, using for instance a tradeoff technique.) Similarly, for intertemporal choice one can treat the different timepoints as different attributes. But he lists such use of timepoints as a third, different, approach. He clearly does not realize here that uncertainty and intertemporal can be treated as special cases of conjoint analysis, as done for instance in Ch. 6 of Krantz et al. (1971). This explains his unfortunate move of using joint receipts.

Luce cites Keeney & Raiffa (1976) for deriving cardinality (my term) from multi-attributes. But Keeney & Raiffa use the probabilities of lotteries, and the EU assumed there, to get cardinality, which is more in the spirit of using events/disjoint probabilities as attributes.

Pp. 22-23: "People are surprisingly flexible about doing unusual things for an experimenter even though they have had no experience in life with such judgments."

Paternalism: p. 25, on conditions that are normative but not descriptive: "It is equally important to know about these, for it is here where prescriptive training can come into play."

P. 26, **total utility theory**: "The approach to utility measurement we are taking is thus a very classical one—purely behavioral. Within the psychological, but not the economic, community, such behavioral approaches are decidedly out of fashion, and have been ever since the so-called "cognitive revolution"."

linear utility for small stakes: p. 86 argues for this claim.

P. 55, opening sentence of §2.4.2 is nice: "Although this line of rational argument seems fairly compelling in the abstract, it loses its force in some concrete situations." Wu, Zhang, & Gonzalez (2004 p. 401) have a similar sentence.

biseparable utility: Ch. 3 gives biseparable utility; i.e., RDU representations for binary acts. Unfortunately, there are difficult technical assumptions such as gains partition in Def. 3.6.1, p. 113. Event commutativity is a kind of weakened version of bisymmetry (or autodistributivity), restricted to two outcomes x,y. Luce's repeated-events setup would have been the perfect context for full-force multi-symmetry such as used by Nakamura (1990, JET) and others!

binary prospects identify U and W

concave utility for gains, convex utility for losses: p. 83, end of §3.3.1: "Taken together, these studies provide sufficiently many examples of all four patterns that any overall generalization about the convexity or concavity of utility functions seems unwarranted. The most one can say is that concavity for gains and convexity for losses appears to be the most likely of the four patterns."

inverse S: p. 100, §3.4.2.5: "Conclusion: from all of the data in this section, I think one must conclude that the inverse S-shaped pattern for weights describes a majority of people. I remain perplexed about why so much of the earlier data failed to detect this."

In all the discussion of data here, Luce considers only the case of known probabilities, and not unknown probabilities.

P. 262: "In addition, of the several proposed weighting functions, the Prelec one is by far the most satisfactory." %}

Luce, R. Duncan (2000) "*Utility of Gains and Losses: Measurement-Theoretical and Experimental Approaches*." Lawrence Erlbaum Publishers, London.

{% **dynamic consistency: favors abandoning RCLA. E**qs 3 & 4 show that power probability weighting holds iff the simplest RCLA ((x,p),q) ~ (x,pq)). Luce also gives N-reduction invariance as a simpler condition to axiomatize Prelec's compound invariance family.

Big caveat in this all is that Luce assumes backward induction, as in all his works: In the compound gamble ((x,p),q), (x,p) can be replaced by its unconditional certainty equivalent. Under nonexpected utility this condition is not a simple monotonicity condition but it is a highly questionable separability condition (**restrictiveness of monotonicity/weak separability**). Because of this extra assumption, he can simplify Prelec's axiom otherwise. %}

{% P. 5 seems to write: "Indeed, one hopes that the unrealistic assumptions and the resulting theory will lead to experiments designed in part to improve the descriptive character of the theory."

P. 27/28 do EU-axiomatization by substitution axiom. (**substitution-derivation of EU**)

P. 28 has discussion of mountain climber whose utility of outcomes essentially depends on the probabilities ("gestalt" of prospect as they nicely write), something Deneffe and I once discussed. (**utility depends on probability**)

Fallacy 2: an agent might care about variance of utility.

P. 32, Fallacy 3: people who equate risky utility with cardinal utility (without further ado)

P. 280-282 points out that regret leads to intransitivities, citing Chernoff's observation entailing a violation of independence of irrelevant alternatives.

revealed preference; p. 288, §13.3, Example:

> A gentleman wandering in a strange city at dinner time chances upon a modest restaurant which he enters uncertainly. The waiter informs him that there is no menu, but that he may have either broiled salmon at $2.50 or steak at $4.00 this evening. In a first-rate restaurant his choice would have been steak, but considering his unknown surroundings and the different prices he elects the salmon. Soon after the waiter returns from the kitchen, apologizes profusely, blaming the uncommunicative chef for omitting to tell him that fried snails and frog's legs are also on the bill of fare at $4.50 each. It so happens that our hero detests them both and would always select salmon in preference to either yet his response is "Splendid, I'll change my order to steak." ... He, like most of us, has concluded from previous experience that only "good" restaurants are likely to serve snails and frog's legs, and, so, the risk of a bad steak is reduced in his eyes.

§13.4: on decision making under complete ignorance.

§13.5: pp. 304-305 present the maxmin EU model and the α-maxmin model, referring to Hurwicz (1951, Econometrica) for it. %}

Luce, R. Duncan & Howard Raiffa (1957) "*Games and Decisions.*" Wiley, New York.

{% P. 380 top writes, nicely, about recent developments in psychology that do not use techniques of measurement theory:

"A general comment: we are very aware that the measurement approach we take here is not currently fashionable, having been "replaced" by various process models. Unlike the measurement models for which the behavioral assumptions are directly testable, the process models are composed of unobservable, hypothetical mechanisms. We feel that the added flexibility of process models comes at the (usually unacknowledged) very high cost of unobservable mechanisms which, to this day, has not really been resolved by such imaging techniques as fMRI. And we feel that the very successful approach of four centuries of classical physics has not been given anything like a comparable effort in psychology. The first author has devoted the last 12 years of his career attempting to apply our knowledge of measurement to developing both psychophysical and utility measurement models, and collaborating with the second author and others he has focused on experimental studies suggested by these models."

Section 2 first points out that preference conditions such as double cancellation, in the presence of separability/monotonicity, are somewhat redundant relative to their indifference versions such as the Thomsen condition. Then it argues that the Thomsen condition is not statistically symmetric in a way that I did not really try to understand. I guess that the hexagon condition and the Reidemeister condition are symmetric. The hexagon condition is, in the presence of separability (= independence = monotonicity) and the other conditions, where unrestricted solvability can readily be weakened to restricted solvability, necessary and sufficient for additive representation. All alternative conditions discussed here are (necessary) and stronger than hexagon and, hence, trivially are also necessary and sufficient.

P. 380 discusses a nice alternative reinforcement of the hexagon condition, being the less known commutativity axiom defined by Falmagne (1976) and discussed by Gigerenzer & Strube (1983). I formulate it directly in terms of indifferences:

If

(a,r) ~ (m,s) & (m,p) ~ (c,q)

(a,p) ~ (n,q)

then (n,r) ~ (c,s) .

In words, both the upper two and the lower two indifferences show that the distance from a to c is matched by that from p to q plus that from r to s.

The hexagon condition is the special case where we impose the implication only if s = p and m = n. This observation provides a proof alternative to that in the Appendix of this paper, using the well-known result that the hexagon condition characterizes additive representation in the presence of the other conditions (Karni & Safra 1998). %}

Luce, R. Duncan & Ragnar Steingrimsson (2011) "Theory and Tests of the Conjoint Commutativity Axiom for Additive Conjoint Measurement," *Journal of Mathematical Psychology* 55, 379–385.

{% **error theory for risky choice**: Chs. 19.5-19.8, pp. 331-402, are on probabilistic choice theories. §19.5.3 is on random utility, and Ch. 19.7 on probabilistic choice for decision under uncertainty. P. 334 footnote 6 provides the counterargument against Fechnerian (strong) utility model of p(x,y) and p(y,z) being close to 0.5, but y dominating z by very small differences but clearly, so that p(y,z) = 1. They cite Leonard J. Savage (personal communication) for it. Definition 22 (p. 340) defines weak stochastic transitivity.

inverse S: §4.3 reviews the literature up to that point on probability transformation, finding inverse S as the prevailing pattern. %}

Luce, R. Duncan & Patrick Suppes (1965) "Preference, Utility, and Subjective Probability." *In* R. Duncan Luce, Robert R. Bush, & Eugene Galanter (eds.) *Handbook of Mathematical Psychology*, Vol. III, 249–410, Wiley, New York.

{% Derives additively decomposable representation for two components, by means of weak ordering, unrestricted solvability, the Archimedean axiom, and a cancellation axiom that is the Thomsen condition with preference instead of equivalence. Introductory text is nice. It first demonstrates the conjoint measurement technique in physical examples when a direct concatenation operation is also available. Next it extends that to cases (prevailing in social sciences) where no concatenation operation is available but still the conjoint measurement techniques can be adopted.

P. 5 gives a useful sentence for people who inefficiently apply "ordinal" conjoint measurement techniques in situations where cardinal information is easily available: "That we can devise alternative ways to measure familiar physical quantities is philosophically interesting, but is of little practical significance to physics as long as conventional measurement based on concatenation is possible. In the behavioral and biological

sciences, however, these new methods may be of considerable importance. Many of the quantities that one would like to measure, and that many scientists have felt it should be possible to measure, do not come within the scope of the classical axiomatization because no one has been able to devise a natural concatenation operation."

(P. 12/13: They don't give correct description of Debreu (1960) by writing joint independence condition but not the hexagon condition. P. 14 shows that Pfanzagl's bisymmetry implies the preference-version of Thomsen condition.

§9, p. 14, presents standard sequences. %}

{% **risky utility u = strength of preference v (or other riskless cardinal utility, often called value; time preference: comparing risky and intertemporal utility)**: The authors study choices with time and risk. Reckoning with parsimony (avoiding overfitting) they find that assuming one common utility function is best. With my interest in one common cardinal utility for all decision contexts, I like this much.

Unfortunately, the authors consider only risky prospects with one nonzero outcome, and this implies that a joint power of probability weighting and utility is indeterminate in the multiplicate prospect theory (w(p)U(x)) assumed. Similarly, the authors consider only intertemporal prospects with one nonzero outcome, and this implies that a joint power of the discount function and utility is indeterminate in the multiplicative discounted utility (D(t)U(x)) assumed. Because they consider power (CRRA) utility, this means that the utility functions are unidentifiable and any conclusion about equal or different utility cannot be drawn. %}

{% Find extremity orientedness in DFE. (**DFE-DFD gap but no reversal**) The authors say that this gives more risk seeking for gains and more risk aversion for losses, and is opposite to prospect theory. However, a crucial point here is whether the extreme outcomes have low or high probability because, if low, then the finding agrees with prospect theory. I did not see this point discussed, although I may not have searched long enough. The authors do discuss 50-50 probabilities, e.g. p. 153 penultimate para, but I did not see this solve my problem. %}

Ludvig, Elliot A., Christopher R. Madan, & Marcia L. Spetch (2014) "Extreme Outcomes Sway Risky Decisions from Experience," *Journal of Behavioral Decision Making* 27, 146–156.

{% Study DFD-DFE gap for events with probability ½. Find usual reflection with risk aversion for gains and risk seeking for losses for DFD, but find the entire opposite for DFE. The authors suggest that their finding for DFE may be due to utility being convex for gains and concave for losses, but it may equally well be the w(½) > ½ for DFE and, in fact, the latter explanation is more plausible because the uncertainty about outcomes is different under DFE than under DFD and not the outcomes themselves. My biggest problem is that it is not at all clear what the subjects are maximizing in this experiment. My main problem is not that the choices are hypothetical per se, but that even when allowing for that it still is not clear what the (hypothetical) motivation should be. They do repeated choices, receiving points after each choice, but it is unclear what these points serve for. In the first experiment, during the experiment, some high total scores up to then were displayed and subjects were encouraged to try to beat these scores. Whatever findings this paper has, can be driven by whatever motivation came from such encouragements, and thus does not speak to general risk attitudes. %}

{% **biseparable utility violated**;

This paper was previously entitled: "Ambiguity Aversion, Malevolent Nature, and the Variational Representation of Preferences." It generalizes the existing axioms of maxmin EU in a natural manner, coming with an easy-to-write new model unifying many existing things, so, the paper is important and pretty.

They consider the following generalization of maxmin EU, with S a Savagean state space and infimum INF below over all probability measures over S

$$\mathrm{INF}\ [\int_S \big(U(f(s)\big)dP(S) + c(P)]$$

with c a convex function of probability measures. The maxmin EU, with set D of probability measures, results by letting c be 0 on D and infinite outside of D. In general, the bigger c(P), the less likely it is that P will deliver the inf and be relevant. Hence, P's judged implausible by the agent have higher c values. One way to go is to take some "most plausible" probability measure Q as starting point, and then to use the above model where c is a distance measure of P from Q. One such distance measure could be the relative entropy or that multiplied by some positive factor, and this is what Hansen & Sargent did in macro-economics. Thus, the authors have obtained a joint generalization of maxmin EU and Hansen & Sargent. Another distance measure could be a generalized Gini index and then, if I understood right, the mean-variance model comes out, that is, the mean-variance model only where it is interesting; i.e., where it is monotonic. (Because of their monotonicity imposed on c their functional simply truncates mean-variance where it starts violating monotonicity).

The interpretation that P is less plausible the larger c (c is better taken relative to a utility level of P), suggests a belief interpretation.

The authors use the Anscombe-Aumann framework which, in my interpretation and also put central by them, means just linear utility. They use the axioms of Gilboa & Schmeidler (1989) with certainty independence weakened. They do not take, for all prospects f,g and constants (certain acts) c, c´

$$\alpha f + (1-\alpha)c \succcurlyeq \alpha g + (1-\alpha)c \text{ n } \Rightarrow \beta f + (1-\beta)c' \succcurlyeq \beta g + (1-\beta)c'$$

(which is one way to state certainty independence) but they take this axiom only for $\beta = \alpha$. It amounts to considering translation invariance $\big($adding the constant $\alpha(c-c')$ to everything$\big)$ but not scale invariance.

Relative to maxmin EU they seem to add only one "parameter" being c. But c is a formidable parameter. First we go from S to the set of all probability measures on S which is of higher cardinality, and then c maps this set to the reals, being again a higher level of cardinality. So, c is not just one parameter/dimension added like U, but it is an infinity more. (Basu & Echenique

2020 give a formal way to assess such cardinality.) Thus, that they can accommodate so many existing models may be no surprise, and measurability/testability and prediction is the problem. Maxmin EU is already of an untractably high dimensionality because of the set of priors to be chosen, and this model goes way beyond it. It may however be a convenient starting point for specifying special cases, showing unity.

Axiom A8 (weak monotone continuity) ensures that only countably additive probability measures are involved. %}

{% Dynamic version of their variational model. %}

Maccheroni, Fabio, Massimo Marinacci, & Aldo Rustichini (2006) "Dynamic Variational Preference," *Journal of Economic Theory* 128, 4–44.

{% Use a variation of mean-variance analysis that avoids violation of monotonicity. For mean-variance, such a violation of monotonicity can result if an outcome is increased that is much higher than the expectation, so much that its increase worsens the variance more than that it improves the expectation. The basic idea of this paper is to simply truncate at the level of outcomes where the worsening of the variance becomes worse than the improvement of the expectation (and, I guess, condition on the non-truncated event). This is a special case of their variational preference model. They use their model to get a variation of CAPM. I do not understand their claim that they avoid arbitrage. They base this claim on not violating monotonicity, but arbitrage involves more, being linear combinations of prospects.

Even if they fix the monotonicity violation of mean-variance, I find it crude to simply ignore the best outcomes. %}

Maccheroni, Fabio, Massimo Marinacci, Aldo Rustichini, & Marco Taboga (2009) "Portfolio Selection with Monotone Mean-Variance Preferences," *Mathematical Finance* 19, 487–521.

{% The authors bring useful generalizations of Yaari (1969) type preference conditions, extending them from Yaari's expected utility to biseparable utility. The authors use the term solvable somewhat differently than done in mathematical psychology (Krantz et al. 1971). They give several useful technical results. Proposition 3 shows that, once we have a nondegenerate biseparable representation and the topology on the outcome set X is connected, then continuity on X and existence of certainty equivalents is enough to give full continuity. It is based on Lemma 8: Jf X is connected and has a real-valued representation, then continuity of preference is equivalent to existence of a continuous representation.

The central preference condition is as follows. There are two preference relations $\succcurlyeq_1$ and $\succcurlyeq_2$ for decision under uncertainty, both bisepartable, with the same outcome set X but possibly different events.

$x_{A_2}y \succ_2 z \Rightarrow x_{A_1}y \succ_1 z$

Again, A_2 and A_1 may be different. By Lemma 5, which I think is the main result, this implies $\rho_1(A_1) \geq \rho_2(A_2)$, where ρ is the authors' notation of the weighting function. This is relatively easy to prove under differentiability, but is more difficult in general. The proof is by contradiction. First step is to show that the negation to be proved contradictory implies that u_2 is more concave than u_1. This brings in enough differentiability.

Theorem 6 shows that two decision makers are equally willing to bet (on two different events) iff they have the same utility (up to unit and level of course) and the same ρ values of the two events. This greatly improves a related result by Ghirardato & Marinacci (2002), as explained in the bottom of p. 694. It is well consistent with common uniqueness results for biseparable representations. %}

{% **dynamic consistency: favors abandoning RCLA when time is physical**

Mark cites Markowitz (1959), Mossin (1969), and Spence & Zeckhauser (1972) on induced preferences in temporal choices. The basic example is as follows:

I have to choose, to take a train or bus tomorrow. I am indifferent. However, (0.5: train, 0.5: bus) I prefer strictly less. Do I violate betweenness, expected utility, and am I non-Bayesian? No. The explanation: one thing (I had not yet told), the lottery will only be resolved tomorrow. Now, if surely train, I now have to order a train ticket, a day ahead. Bus, similarly. However, with the lottery I don't know what to order. What is going on is that the option "train" in the lottery is different than if certain. It is endowed with less info. It is "train without knowing so a day ahead."

Such situations arise if besides the decision considered, choosing from a set X, and receiving it real time elapses, and we have to make another decision, choosing from a set A, in the meantime. Then every $x \in X$ is combined with the $a \in A$ that maximizes U(x,a). Then preferences are quasiconvex in probability. (**quasi-concave so deliberate randomization**: well, Mark uses the term quasiconvex; these terms are nonuniversal).

The paper writes on the maths of using Mark's 1982 model in such situations. %}

{% **dynamic consistency**: **favors abandoning forgone-event independence, so, favors resolute choice**; this is the spirit of this paper.

@@@@@BEGINNING OF ABBREVIATED READING@@@@@@@

Reading the most essential subparts, on nonEU with dynamic-choice arguments, goes as follows:

Pp. 622-1636, i.e., up to and including §3.2, present elementarities of decision under risk, in a very didactical manner. Very good for novices, but can be skipped by experts. Experts only note that RCLA is assumed throughout. One then reads §3.3 and §4, skipping the right half of p. 1637 and the rest of §3.3 ("Classical Argument … the information!"), the last four lines of §4.1 in the left column of p. 1642 and the rest of §4.1 ("Consequentialism in … two prospects"), and the right part of p. 1644 and the rest of §4 ("Analogy with … nonsensical behavior."). Instead of the rest of the paper, one can read the following summary, where I explain Machina's preferred solution, what he thinks is rational, in words. I do it for Figure 7 (p. 1637), the right figure there. From the prior perspective, the agent prefers going up. If she were at the decision node and the past had not existed, she would have preferred going down there, going for certainty. However, in the tree as is, the posterior agent at the decision node, will go up as the prior agent wanted. But this is not against the preference of the posterior agent. The posterior agent really herself prefers going up there: Beause of the risk borne in the past. Because at some past time there was a 0.89 probability of going down to 0, even if it is now known that it did not happen. So, risks borne in the past continue to be relevant, also if now counterfactual. This approach is sometimes called resolute choice. It is neither naïve nor sophisticated (in the usual interpretation). It is a bit like precommitment also if there is no precommitment device. The parental example should justify this approach. Mother can tell Bernjamin that there is no unfairness because in the past there has been a chance that Benjamin would win, even if now we know that that just did not happen.

@@@@@@@END OF ABBREVIATED READING@@@@@@@@@

dynamic choice

Dutch book; **dynamic consistency**;

(**consequentialism/pragmatism**). in mom-example argument that incorporating all relevant aspects in consequences is intractable. This argument is discussed extensively and in detail in §6.6. P. 1662 writes, for instance, that EU and its separability may be rational if we can observe consequences in sufficient detail:

"For my part, I will grant that sepa rability may well be rational provided the descriptions of the consequences are sufficiently deep to incorporate any relevant emotional states, such as disappointment (e.g., at having won $0 when you might have won $5 million), regret (at hav ing forgone a sure chance of $1 million and then landing a 1 percent chance of $0), jealousy (over your favorite movie star), feelings of un fairness (that Benjamin won the treat in an unfair flip), and so on."

Mark cites related views by Samuelson.

The paper clarifies many issues in this domain and introduces the current terminology for dynamic decisions in decision under risk, although it did not define it explicitly and the readers have to infer it from the context. In other fields in economics, the term dynamic consistency is often used in a weaker sense, and in philosophy the term consequentialism is used in vaguer/broaer ways. What Mark calls dynamic consistency is what in intertemporal choice, after Halevy (2015), is called time consistency.

P. 1624 middle of right column writes that expeted utility automatically has consequentialism satisfied. Strictly speaking, EU is a static theory, and it is open what dynamic principles it satisfies. But it is very natural to implement it dynamically while satisfying the natural conditions, so much that this is often considered part of EU theory,

On p. 1624, 2nd column, ℓ. 13, Mark discusses the, sometimes hidden, assumption of consequentialism (= what I like to call forgone-branch independence). This assumption is discussed on p. 173, as part of the "first objection" in §4 of Wakker (1988) "Nonexpected Utility as Aversion of Information," *JBDM* 1 (e.g. through the requirement that information should be free of charge).

Points 2 & 3 on pp. 1662-1663: That EU can be satisfied if consequences are described in any detail, but that economists cannot have such descriptions and, also, that EU then becomes irrefutable. P. 1663: "The above compromise tries simultaneously to acknowledge (a) the normative appeal of separability at some deep enough level of consequence description, (b) normative reasons why preferences might be nonseparable at the level of description typically used by economists"

P. 1663: last sentence argues for nonEU normative: "Along with the critique of Section 4 and the dynamic model of Section 5, it is offered as a contribution to what I have termed the "normative goal" in the campaign for the general acceptance and use of non-expected utility models."

Some criticisms:

- Pp. 1623-624: his argument against intransitivity: If it existed, we should constantly see people get money pumpted. Since we don't see that, there are no intransitivities in economics. My objection: such money pumping can only happen in free markets where intransitivities are known to others. (There is also Sugden's counter that agents seeing the money pump coming will stay out.)

- His discussion of replacement vs. mixture separability does not make clear that replacement separability is a bit weaker, readily implied by mixture separability, but that the other implication needs continuity for its proof (see Fishburn & Wakker 1995).

- The discussion of incoherent probabilities on pp. 1635-1636 suggests that he does not know the Dutch book/nonarbitrage argument.

I once asked Mark about when the risk is not randomness in nature, but epistemic. Say, the risk concerns something about the 101-200th digit of the number pi. Then, if the uncertainty gets resolved, one knows that in a way the risk from the past never existed. Does Mark then still advocate his approach? Mark did not answer in the sense that he said he had to think about it. %}

{% Assumes preference functional V over acts under uncertainty in Savage-model. State space is interval such as s = temperature of Bejing, etc. Assumes that V is differentiable w.r.t. small variations in state. This implies that acts depending only on kth digit of s become like objective probability distributions as k increases. So, we can infer the risk preference functional therefrom. It has often been said, and I agree, that risk (known probabilities) is not different from uncertainty (unknown probabilities), but instead is a limiting case. This paper substantiates this claim, and even proves it in a formal mathematical manner. Those who say that objective probabilities do not exist and should not be used, and that only a subjective Savage state space should be considered, get objective probabilities delivered in their backyard by this paper.

The two-stage Anscombe-Aumann framework with mixing before states is more general than this model as commonly used today, with mixing after the states (the former can allow for correlations, latter can concern only marginals). As a model, Mark's model comes out equivalent to mixing before, but further preference restrictions follow that in fact make it equivalent to mixing after (p. 16).

As regards dynamic decision principles, the paper seems to assume the RCLA + **dynamic consistency** of Machina (1989) (§2.2 & p. 15) as if generally accepted. The model of the paper comes out equivalent, not by assumption but by implication (p. 16).

P. 23 middle para epresses source dependence. P. 24 uses the term "source of uncertainty."

P. 32 points out that monotonicity in Grant (1995) can be generated from set-inclusion. %}

Machina, Mark J. (2004) “Almost-Objective Uncertainty,” *Economic Theory* 24, 1–54.

{% The result of over ten years of work, presented already in Cachan 1992 under the title “Robustifying the Classical Model of Risk Preferences and Beliefs” %}

Machina, Mark J. (2005) “Expected Utility/Subjective Probability’ Analysis without the Sure-Thing Principle or Probabilistic Sophistication,” *Economic Theory* 26, 1–62.

{% The paper provides two examples of plausible preferences that violate RDU (CEU (Choquet expected utility) as Machina call it) for uncertainty. Baillon, L’Haridon, & Placido (2009) later showed that the examples also violate most other nonEU models for uncertainty popular today in the Anscombe-Aumann framework; without that framework, Machina’s counterexamples only concern RDU. In particular, the examples violate the comonotonic sure-thing principle and even tail independence. I find the second example, the reflection example (pp. 389-390), impressive, nay, brilliant. But other than that I prefer different interpretations and explanations than the author gives for almost everything. The basic problem is that I think that the cognitive component of ambiguity is decisive in Mark’s examples, as explained well by Baillon, L’Haridon, & Placido (2009), and confirmed empirically by L’Haridon & Placido (2010). But Mark, having worked almost exclusively on risk, is not open to the cognitive side and goes for motivational diminishing marginal effects-type arguments.

The reflection example (with my interpretations): An urn contains 100 balls. 50 balls marked 1 or 2 in unknown proportion, and 50 marked 3 or 4 in unknown proportion. One ball is drawn randomly. E_j: the number drawn is j. Consider (with $1000 as unit) preferences between f_5 and f_6, and then between f_7 and f_8:

		#50	#50
f_5	=	(E_1:4, E_2:8,	E_3:4, E_4:0),
f_6	=	(E_1:4, E_2:4,	E_3:8, E_4:0),
f_7	=	(E_1:0, E_2:8,	E_3:4, E_4:4),
f_8	=	(E_1:0, E_2:4,	E_3:8, E_4:4),

Ambiguity averse people will have $f_6 > f_5$ because f_6 has one outcome, 4, resulting with known probability ½, whereas f_5 has all outcomes ambiguous. For

exactly the same reason, ambiguity averse people will have $f_7 > f_8$. These claims were later confirmed empirically by L'Haridon & Placido (2010).

Btw., because of informational symmetry, f_7 is like f_6 and f_8 is like f_5, so that the second preference follows from the first from informational symmetry.

RDU however predicts indifference between the four acts because RDU considers likelihoods of what are known as goodnews events ("decumulative events;" "ranks"). For all four acts, the goodnews event of receiving 8 contains one E_j, the goodnews event of receiving 4 or 8 contains three E_js, and the goodnews event of receiving 0, 4, or 8 contains all four E_js. Beause of informational symmetry, each goodnews event has the same weight under each act, implying immediately that the four acts are indifferent by RDU, simply having identical Choquet integals. (Btw: Machina uses a different reasoning, being that the comonotonic sure-thing principle, and even tail independence, require that a strict preference between f_5 and f_6 be the same as between f_7 and f_8, rather than between f_8 and f_7 as informational symmetry has it. Because informational symmetry is unquestionable, RDU hence cannot have strict preferences and must have indifferences.)

(Another btw.:

Sarin & Wakker 1992 axiomatized RDU using an axiom that acts are equivalent whenever all goodnews events have the same likelihood, in an axiom called cumulative dominance.)

I like Machina's reflection example much because it addresses a fundamental issue of RDU, being that RDU focuses on likelihoods of goodnews events, but Machina's example shows that subjects are also partially driven by likelihoods of separate-outcome events, as considered in old pre-rank-dependent nonadditive probability models such as separable prospect theory. (**PT falsified**)

I regret that Machina does not refer to the role of separate-outcome events and the unambiguity of one outcome in his reasoning against indifference. He instead uses a complex riding-on reasoning (f_5 has two small ambiguities and f_6 one big; if one had something like aversion to mean-preserving spreads one would prefer f_5). As Baillon, l'Haridon, & Placido rightfully point out, ambiguity is more cognitive than motivational, is more subject to diminishing sensitivity, and it is more categorical ambiguous versus unambiguous than more versus less. Hence, Machina's reasoning that the two ambiguities of f_5 will count more negatively than the one ambiguity of f_6 can only be understood by specialists, and then after some effort. It will not enter the mind of any natural subject. Mark thus does not choose side for one strict preference or the other even though it is clear enough I think, and he further refers to an unclear tradeoff between objective and subjective uncertainty.

Machina's 50-51 example, while equally valid as the reflection example, is less clear. Now unambiguity must be traded against an objective-likelihood argument in a first choice problem (between f_1 and f_2) and also in a second choice problem (between f_3 and f_4). In the second choice problem the ambiguity degree of all goodnews events is the same as in the first and it can be proved under RDU that the preference in the second choice problem should be the same as in the first. In the second choice problem the ambiguity degree of all separate-outcome events is not the same as in the first, and therefore choices can be different. Because of the tradeoff with objective probability this example is less clear, and will work less well empirically than the reflection example. Machina's explanation on pp. 388-389 again (as in the reflection example) does not raise the argument of a separate-outcome event, unfortunately. Instead, it raises an unclear correlation argument. One problem is that correlation is not defined as he discusses it. You need numbers to correlate, so, how should this be with events? Indicator functions will not help. He could formalize the first point in terms of stochastic-like or sigma-algebra-like independence. (Btw., p. 388 last line "corrected" should be "correlated" and this is a typo.) Mark proceeds with claiming that in the second choice problem some correlations are lower, and this is not clear either.

Mark also overstates implications. P. 389 4th para suggests that models like RDU, which maintain comonotonic separability, kep the Ellsberg problem. He tries to suggest there that his example is as strong and fundamental as Ellsberg's. This is not so; it is different, and less strong, albeit surely interesting.

P. 390 writes: "If there is a general lesson to be learned from Ellsberg's examples and the examples here, it is that the phenomenon of ambiguity aversion is intrinsically one of nonseparable preferences across mutually exclusive events, and that models that exhibit full—or even partial—event-separability cannot capture all aspects of this phenomenon.."

This text suggests that all models of nonEU for ambiguity should consider interactions and violations of separabililty of events. I in fact agree with this general point but I disagree that Machina's examples, which are only two examples, (nor the Ellsberg examples which Machina puts on the same footing there), could prove this in general, as Machina is suggesting. Even worse, Machina claims that *every* partial form of event-separability will fail. This claim is completely unfounded. Machina has done no more than show a problem for comonotonic separability (sure-thing principle) and even for tail-separability (independence). Theories that completely give up any event-separability may be very general and, thus, intractable. For the same reason, the general Machina (1982) nonexpected utility, while useful to bring some theoretical points, is too general for most purposes.

Something else I found amazing is that on several occasions (p. 390 2nd para "the issue is not how individuals *ought* to choose …" and the closing sentence on p. 391) Machina treats ambiguity purely descriptively, and nothing normatively. I as Bayesian like to have ambiguity only descriptively, but still would not explicitly exclude any normatively-based discussion of it. %}

Machina, Mark J. (2009) "Risk, Ambiguity, and the Rank-Dependence Axioms," *American Economic Review* 99, 385–392. https://doi.org/10.1257/aer.99.1.385

Machina, Mark J. (2010), lecture

{% Considers the Ellsberg 3-color paradox. The two commonly assumed strict preferences violate the sure-thing principle, as is well known. This paper shows, nicely, that one of the two strict preferences implies the other by the sure-thing principle (+ some natural symmetry assumptions), so that one strict preference already gives a violation of the sure-thing principle. Moreover, in the derivation of the one strict preference from the other one only needs the restriction of the sure-thing principle to events with known probabilities, where the sure-thing principle is less controversial. (Jaffray always pleaded for the latter condition.) Thus, one of the two strict preferences, together with the symmetry conditions, already implies a violation of the sure-thing principle.

As for source method: Another thing I like is that the paper shows that the Ellsberg 3-color urn is best taken as a mix of two sources of uncertainty (what Mark calls pure objectivity and pure subjectivity). This point had been alluded to before by Ergin & Gul (2009) and Abdellaoui et al. (2011 American Economic Review p. 718), but Machina makes it more clear than anyone else did. Unfortunately, he does not explicitly connect to the idea of sources.

There are interpretations in the paper that I find unfortunate. The sure-thing principle for events with known probabilities is best taken as a special case of the general sure-thing principle, and not as a different condition. This paper tries to suggest that the conditions for purely objective and "purely subjective" (a term of this paper that I do not find very useful) are two different animals. What could prove the paper's claim better than the (erroneous) claim that, whereas the general sure-thing principle is violated by the two strict preferences of Ellsberg, the sure-thing principle for known probabilities would even imply those preferences, rather than be violated by them? So, the paper makes this, incorrect, claim (end of abstract: "the standard Ellsberg-type preference reversal is actually implied by the Independence Axiom over its purely objective uncertainty;" there are similar claims on p. 433 1st para & end of p. 435).). This is not so. Only that condition TOGETHER WITH one of the two strict preferences (and some natural symmetry conditions) does so.

Claims of compatibility with the sure-thing principle over *purely* subjective uncertainty (p. 433 top) are also misleading, because it is only compatible in the sense of not directly violating a very particular version of the condition restricted to very particular events chosen by Mark.

The demonstration that one strict preference in the 3-color Ellsberg paradox, together with the usual informational symmetries, and the sure-thing principle for events with known probabilities implies the other strict preference, is as follows. Assume 1 R(ed) ball and 2 B(lack) and Y(ellow) balls in unknown proportion, the usual informational symmetries, the sure-thing principle, and $100_R0 \succ 100_B0$. Number the three balls, with ball R no. 1. Denote by BY (ball 2 is B and ball 3 is Y), YB, BB, and YY the four possible compositions of the urn, where the one R ball is suppressed. Now, subtly, as in Table 4 (p. 432), interpret 100_B0 as (1/3:0, 1/3:($100_{\{BB,BY\}}0$, 1/3:$100_{\{BB,YB\}}0$), where the first probability 1/3 describes what happens under ball 1 (a payment contingent on the composition of the urn, yielding 100 if BB or BY and 0 otherwise), the second what happens under ball 2, and the third what happens under ball 3. Interpret 100_R0 as (1/3:100, 1/3:0, 1/3:0). So, we rewrite the assumed preference (reordering outcomes for the unambiguous prospect) as

(**1/3: 0**, 1/3:0, 1/3:100) ≻ (**1/3: 0**, 1/3:($100_{\{BB,BY\}}0$, 1/3:$100_{\{BB,YB\}}0$).

By the s.th.pr. we get, replacing the bold common outcome,

(**1/3: 100**, 1/3:0, 1/3:100) ≻ (**1/3: 100**, 1/3:($100_{\{BB,BY\}}0$, 1/3:$100_{\{BB,YB\}}0$), rewritten as

(1/3:0, 1/3:100, 1/3:100) ≻ (1/3:100, 1/3:($100_{\{BB,BY\}}0$, 1/3:$100_{\{BB,YB\}}0$). The latter says: $100_{\{B,Y\}}0 \succ 100_{\{B,R\}}0$. This is the second strict preference that is traditionally taken as second assumption. QED %}

Machina, Mark J. (2011) "Event-Separability in the Ellsberg Urn," *Economic Theory* 48, 425–436.

{% This paper presents some examples on choice under ambiguity that trigger new thoughts and insights. It discusses implications for some theories. I have different opinions about interpretations of RDU (I prefer this term to CEU (Choquet expected utility)) and about Anscombe-Aumann (AA), and also about the Allais paradox, explained below.

The paper is entirely focused on the Anscombe-Aumann framework, as if the only way to go as soon as a model has both risk and ambiguity, which is the common thinking in the field today (2015), but that I disagree with. A first stage has ambiguous (horse) events, a second stage has risk (roulette) events, and backward induction is used where first the second-stage lotteries are replaced by their certainty equivalents according to EU, then processed according to an ambiguity theory handling the uncertainty about the horses. Not only the EU assumption is empirically questionable here, but also the backward induction assumption is. It entails conditioning on each individual ambiguous event, that is, treating each such event as separable. While still questionable, it is relatively least questionable if the resolution of risk comes in a stage after the resolution of ambiguity, so, if it is two-stage as usually assumed in Anscombe-Aumann and as also assumed above. A typical case is where the second-stage risk is conditional on the first-stage resolution; i.e., the roulette lottery l_i will only be carried out if horse h_i wins the race. This is the case of pp. 3821-3822 where first the composition of the Ellsberg urn (the horse) is determined and the corresponding objective risk (roulette lottery) is only carried out if the corresponding composition of the urn obtains. However, this paper assumes all resolutions of uncertainty simultaneously (p. 3818 footnote 11), making it yet more questionable. For instance, Eq. 6 on p. 3819 is without further ado or justification taking the order of integration as in AA, taking each event E_i as separable. 2021: I think that Machina was well aware of all this but was very political and did it so as to fit with the fashion in the field, which I regret.

Several authors argued that the two-stage setup of Anscombe-Aumann with the risky events second and then backward induction is unfortunate. Conditioning and separability are, under the assumption of EU for risk, more plausible for roulette events and, hence, it would work better to put the horse race first. Wakker (2011 Theory and Decision, p. 19 top and p.19 penultimate para) cites Jaffray (personal communication) for this viewpoint. Further arguments are in Wakker (2010 §10.7), Baillon, Chen, & Halevy (2015), and Bommier (2017).

For the above reason, footnote 11 on p. 3818, claiming simultaneous resolution of all uncertainties in this paper, is misleading. It makes the backward induction assumed throughout the paper less convincing. As I wrote above, pp. 3821-3822, describing Ellsberg's urn as two-stage, is for instance very very hard to reconcile with the simultaneity claim of footnote 11.

P. 3815: The slightly bent coin example is a small variation of Machina's (2009) reflection example. The risk in the 2009 example need not be perfect risk, but can be a little ambiguity, close to risk, maintaining the paradox. This is what the bent coin example illustrates. These two examples are genuine counterexamples to RDU. RDU assumes that people go entirely by cumulative events, but in reality people are still guided a bit also by single-outcome events, and these examples beautifully show it.

P. 3815 thermometer example uses the basic idea of Machina (2004 ET). If the DM is subject to the Allais paradox for risk, then in a continuum state space with enough differentiability it will show up. For instance, if we measure temperature, we can gamble on the 5^{th} & 6^{th} digits and these are by all means subject to objective probabilities (my country-man the philosophical mathematician L.E.J. Brouwer would say that it is undetermined), and can be used to bring up the

Allais paradox with risk. This point can be understood without reading the mathematical proofs that Machina provides for completeness.

P. 3815, the third example on ambiguity at high versus low outcomes, considers Ellsberg's 3-color paradox, with outcomes 100, c, and 0, where c is the CE (certainty equivalent) of $100_{0.5}0$, assuming EU for risk. In urn 1 we have the highest outcome 100 at the unambiguous color red, and the other outcomes at the other colors (0 for black and c for white). In urn 2 we have the lowest outcome 0 at the unambiguous color red, and the other outcomes at the other colors (c for black and 100 for white). In the former case, ambiguity is at the lower outcomes, and in the latter it is at the higher outcomes. DMs may well strictly prefer one urn to the other and not be indifferent. If we, however, use an Anscombe-Aumann framework conditioning on the true composition of the urn, then, as shown in the table on p. 3831, conditional on each composition of the urn, the two urns assign the same EU to each composition. Hence, all Anscombe-Aumann based models require indifference. The example, if not giving indifference, falsifies the Anscombe-Aumann approach.

DETOUR [Wakker (2010 Figure 10.7.1] I hope that the readers can now bear a self-reference. Wakker (2010 Figure 10.7.1) illustrates the same kind of failure of Anscombe-Aumann but I think more clearly. It assumes two horses s_1 and s_2. In the first choice situation in the left figure the choice is between (s_1: $100_{0.5}0$, s_2: $100_{0.5}0$) and (s_1: c, s_2: $100_{0.5}0$). It assumes c such that we have indifference, and assumes $c = 40$, but I will maintain Machina's notation c here. Under Anscombe-Aumann, c must then be the CE of $100_{0.5}0$. The second choice situation in the right figure has a choice between (s_1: $100_{0.5}0$, s_2: c) and (s_1: c, s_2: c). So, the common outcome under s_2, $100_{0.5}0$, has been replaced by another, under Anscombe-Aumann equivalent, common outcome c. It is plausible that ambiguity aversion gives a strict preference for the sure c in the second situation, but Anscombe-Aumann requires indifference. This example considers two choices as does Machina's (c is derived from an indifference there too), but has simpler stimuli and the violation of indifference is more plausible, with a clear direction predicted. Note that under Anscombe-Aumann all four prospects considered in my example assign the same EU to s_1 and s_2, and should all four be indifferent. A difference with Machina's example is that my example does not appeal to whether ambiguity aversion is increasing or decreasing in outcomes, but to ambiguity aversion per se.

[END OF DETOUR]

P. 3815: "objective uncertainty … specification of subjective uncertainty as a *distinct* concept" [italics added]

P. 3818: If we face the simultaneous uncertainty of an ambiguous horse race and a risky lottery, then in general under nonEU correlations between conditional lotteries may be relevant. If lottery 1 gives a high outcome conditional on s_1, then does lottery 2 give a high outcome under s_2? Outside the separability of EU this can be relevant. However, by the very notation on p. 3818, by describing only the roulette lotteries conditional on the horses (explicitly called conditional on p. 3820 ℓ. 3), Machina already excludes such info, and is already focusing on the Anscombe-Aumann framework with the questionable conditioning-on/separability-of horses. This affects all models considered, in Eqs. 1-6. Whereas smooth preferences, variational preferences, and multiple priors, have only been considered in the Anscombe-Aumann framework, RDU has well been considered outside of it (Gilboa 1987; Wakker 2010), and I regret that Machina implicitly assumes that it satisfies Anscombe-Aumann. Footnote 34 on p. 3832 states the point, and p. 3835 lines −4/−2 also:

"and hence cannot be strictly ranked by models which evaluate the objective uncertainty in mixed prospects solely through these statewise values."

P. 3821 ℓ. −3 is misleading in calling the Anscombe-Aumann framework the "appropriate state space" although a linguistic escape route for the author can be that some lines before he has conditioned on the Anscombe-Aumann framework.

P. 3829 ℓ. −3 and elsewhere: I would not take the example as single-source. The 7th decimal generates a different subalgebra than the 1st digit and East-West, and these different subalgebras are better taken as different sources. The whole source method assumes one grand state space, with sources different subalgebras (or more general systems than algebras because intersection-closedness is not a natural requirement here).

Conclusions of the paper such as RDU being violated by examples are often misleading because it is not RDU but it is RDU-joint-with-Anscombe-Aumann. A linguistic escape route for the author can be that on p. 3819 he *defines* RDU as incorporating Anscombe-Aumann, so, whatever he says about RDU is to be taken that way.

In the *ambiguity at low versus high outcomes problem, RDU (without Anscombe-Aumann) can very easily accommodate strict preferences*. I write v for weighting function rather than the usual W to avoid confusion with W for white. For empirical plausibility we would need nonEU for risk, but let me stay with the paper and Anscombe-Aumann and have EU for risk. Then we let the decision weight of event R always be 1/3, so $v(R \cup E) - v(E) = 1/3$ for each disjoint event E. We set $v(R \cup W) = 0.6 < 2/3$ inducing pessimism for the low-ranked events in Urn 1, and $v(W) = 0.4 > 1/3$ generating optimism for the high-ranked events in Urn 2. A strict preference for urn 2 results. If we want to use a more detailed state space specifying the compositions of the urns, then we take the weighting function v such that the union of all events giving W has v-value 0.4, the union of all events giving $R \cup W$ has v--value 0.6, and so on. The latter weighting function does NOT have the horse events (composition of urn) separable and, hence, does not fit in the Anscombe-Aumann framework, but this is desirable to avoid the unwarranted separabilities.

P. 3835 end of 1st para, misleadingly, writes: "But for that same reason so would each of the four major models, which suggests that correcting for attitudes toward objective risk, none can depart from SEU in the direction of a Friedman-Savage (1948)-type aversion to ambiguity in low-likelihood disasters coupled with a preference for ambiguity in low-likelihood high-stakes gains." Not only can RDU without Anscombe-Aumann do this easily, but more than that, what the author describes is the major empirical finding (likelihood insensitivity generated by ambiguity; **ambiguity seeking for unlikely**). Footnote 42 there nicely points out that the smooth model cannot accommodate the ambiguity seeking for unlikely combined with ambiguity aversion for likely.

criticism of monotonicity in Anscombe-Aumann (1963) for ambiguity: p. 3835 3rd bulleted point: One has to read this point three times before one sees that the diplomat/politician Machina in fact says that the Anscombe-Aumann framework itself is violated here. The Anscombe-Aumann framework is described using the complex words "by models which evaluate the objective uncertainty in mixed prospects solely through these statewise values."

Another disagreement: I think that the Allais paradox, for which common

consequence is most important, reveals the certainty effect and violation of the sure-thing principle, and shows violation of expected utility as much for risk as for uncertainty. It shows the violation in an absolute sense, and the Ellsberg paradox shows it in a relative sense. I thus deviate from people who say “Allais is for risk and Ellsberg is for uncertainty.” This paper is entirely in the latter spirit. See, for instance, §III on p. 3822. %}

{% **natural sources of ambiguity**
Throughout, measure everything by asking for minimal selling prices and taking those as certainty equivalents. This can be expected to have generated a general overestimation of the certainty equivalents and, thus, to a general underestimation of risk aversion, which is indeed found.

EXPERIMENT 1 (N = 25): Do usual Ellsberg urn. In addition, fictitious elections where highly reputable opinion polls agency says the probability of some party winning is from [0.4,0.6], [0.3,0.7], [0.2,0.8], [0.1,0.9], or [0.0, 1.0], respectively. So, it is always for probability 05 plus ambiguity. They find risk neutrality and ambiguity aversion. The latter increases as the ambiguity (the interval around 0.5) gets larger.

ambiguity seeking for unlikely: they report this on p. 222.

EXPERIMENT 2 (N = 34): They used the **random incentive system** with random prize system (Becker DeGroot Marschak; BDM). Now it referred to some real elections in Italy and the UK, taking place some days after the election (**natural sources of ambiguity**). First minimal selling task for known probabilities 0.1, 0.2, …, 0.9, where they find risk neutrality. Then subjects had to give minimal selling prices for a number of disjoint events related to the elections. The authors assumed linear utility, and thus derived decision weights. The decision weights turn out to add to considerably more than 1 in total. Together with the risk neutrality found for given probability, it suggests massive **ambiguity seeking** (comparing with risk neutrality for given probabilities makes it interpersonal comparison, which as such is not affected by the underestimations of risk aversion generated by asking for minimal selling prices). Strange and interesting.

correlation risk & ambiguity attitude: although they have the data, they do not report this. %}

{% The author assumes prospect theory (new '92 version). He lets π-expectation denote the PT value if utility were linear and there were no loss aversion; i.e., of decision weights were probabilities. In terms of these, gives results on risk aversion. In particular he shows that if utility functions for gains and for losses are both power functions, with powers between 0 and 1 and loss-power closer to 1 (closer to linear), then weak risk aversion in sense of π-expectation must be

violated. Note that the preference conditions use probability weighting as input, and are directly observable to the extent that probability weighting is. This paper further demonstrates that power-utility is questionable near 0. In 2022 I added here that this is related to Wakker (2008, Health Economics). %}

{% Considers decision under risk. Start from a risk averse expected utility (EU) model, say with logarithmic utility (this is what the author does, writing it a bit differently). This model will not be used subjectively, but objectively, as an

objective risk measure serving as objective input for determining subjective preferences. Under this model, for any lottery we can calculate: (1) expected value (EV); (2) certainty equivalent (CE) (3) risk premium (RP), being EV – CE. The RP is an index of risk aversion. Under this EU model, one evaluates every lottery by its CE, i.e.:

(1) EV – RP

The novelty of the paper is to instead use an evaluation

(2) EV - rRP

for some $0 \leq r < 1$. Thus, one can choose all kinds of reduced risk aversion. For instance, one can let the starting EU model be the most risk averse model that is conceivable. Then all intermediate levels of risk aversion can be obtained by choosing z.

The model can be rewritten as

(4) (1-r)EV + rCE.

So, it is not a convex combination of functionals, but of their CEs. %}

{% **loss aversion: erroneously thinking it is reflection**: In several places, for instance in the title, the authors suggest that they investigate loss aversion. In reality they only investigate reflection, i.e., risk aversion for gains versus risk seeking for losses. Although they are in the context of prospect theory, they unfortunately equate risk aversion with concave utility and risk seeking with convex utility (**equate risk aversion with concave utility under nonEU**). This is only correct if we assume no probability weighting (an assumption common in finance) and nonmixed prospects. The latter the authors seem to assume

throughout although it is not clear (see below).

The authors consider WTP-WTA for gain or loss lotteries, which they designate as gain- or loss domain. My concern here is that if one pays for a gain prospect in WTP, then because of the payment one may still lose. Hence one in reality then deals with mixed prospects, and not with gain prospects as the authors assume. The authors, however, throughout assume to be either in a gain-domain where there are only gains, or in a loss domain where there are only losses. Then loss aversion never plays a role. All their speculations, indeed, only concern reflection and not loss aversion, although they suggest otherwise.

P. 104 bottom affirmatevely cites a strange claim from another paper that subjects with an unbounded utility function for gains and a bounded utility function for losses are risk seeking, with some other similar claims. Probably this claim was only made for a particular utility family used, probably CARA (linear-exponential) and then in EU I guess.

The first two experiments do WTP-WTA with 2nd price sealed bid auction, and the third does money allocation. The authors investigate patterns of risk attitude such as the fourfold pattern, but find all kinds of patterns (**reflection at individual level for risk**). Because of my confusion about whether the authors deal with mixed prospects or not, I do not know how to interpret their results. %}

{% Argues for non-revealed-preference inputs, such as neuroeconomic measurements of utility.

Cardinality and ordinality are meta-properties in the sense that they relate to properties of, say, utility functions. Consider the property of being vNM utility in the sense that probability-weighted average represents choices over prospects (EU). For each preference relation, the set of vNM functions consists of one such function together with all of its strictly increasing affine transforms. The general concept of vNM utility can be called cardinal. Each single vNM utility u can also be called cardinal. One can look at the set of all strictly increasing affine transforms of u; i.e., the set of all possible u's to represent the given preference through probability-weighted average. Work by Luce & Narens on n-point uniqueness and m-point homogeneity, and other works by Eichhorn if I remember right and in Foundations of Measurement Vol. II if I remember right, give reasons why ordinal and cardinal scales naturally arise, as do nominal scales, ratio scales, absolute scales, and possibly metric scales (preserving orderings of differences that need not be cardinal if the range is coarser than a continuum) and why other kinds of scales are not natural to arise. One thing is that sets of admissible transformations have nice group structures.

This paper looks only at the latter thing, taking sets of functions. It designates such sets with the broad term psychology. It considers, for instance, the set of all concave functions, or the set of all continuous functions, without yet relating it to defining properties. A nice illustration is from work on stochastic dominance and

incomplete preferences: Jf we only know that utility is concave, we can already conclude that a prospect is more preferred than a mean-preserving spread.

The paper organizes concepts such as one "psychology" being weaker than another if being a superset; etc. Then the set of all concave utility functions is intermediate between an ordinal and cardinal class.

A nice example of a singleton psychology is in health, where cardinal utility is further pinned down by setting U = 0 at death and U = 1 for perfect health, so that utility is uniquely determined and so that all utility results from all different studies can immediately be compared.

The paper points out that properties such as continuity of utility can now be given a background justification, being of a continuous psychology (p. 1131). %}

Mandler, Michael (2007) "Strategies as States," *Journal of Economic Theory* 135, 105–130.

{% On **revealed preference** with choice functions and incompleteness.

Considers sequential trades but one-shot consumption at the end of all trades. We can thus observe several preferences. Distinguishing incompleteness and indifference is not possible in one-shot decisions, but it is in sequential decisions. Real indifference is preference substitutability. Incompleteness must be involved if a sequence of nonpreferences, if taken as indifference, would lead to the choice of a dominated option. %}

Mandler, Michael (2009) "Indifference and Incompleteness Distinguished by Rational Trade," *Games and Economic Behavior* 67, 300–314.

{% **one-dimensional utility**: A preference relation can be rewritten as a lexicographic combination of binary criteria. The length can be taken as an index of complexity, i.e., of the number of free parameters, important in parsimony-fit discussions. However, the results of this paper concern one-dimensional utility and cardinalities, whence they are not directly useful for empirical purposes.

I sometimes disagree with interpretations. Thus, §4, p. 565, claims that psychologists object to utility theory because they doubt the concept of indifference, but I think that there do not exist such general conceptions. And pp. 567-568, §5, write that the most important result in utility theory is the equivalence, for weak orders, of a countable order-dense subset and the existence of quantitative utility, but I think that this result is not particularly useful. %}

Mandler, Michael (2021) "The Lexicographic Method in Preference Theory," *Economic Theory* 71, 553–577.

{% Imagine maximization of a preference relation with 2^n indifference classes. We can do this maximization by asking n yes-or-no questions, each time dropping the alternatives with the "no" answer: First question separates upper and lower half, 2nd separates upper half of upper half and upper half of lower half from lower half of upper half and lower half of lower half, and so on. So, this is an efficient procedure-like way to maximize utility. Nice! %}

Mandler, Michael, Paola Manzini, & Marco Mariotti (2011) "A Million Answers to Twenty Questions: Choosing by Checklist," *Journal of Economic Theory* 147, 71–92.

{% N = 74. Hypothetical (footnote 11, p. 447: Because BDM (Becker-DeGroot-Marschak) needs (according to the authors) EU. Btw, although EU, implemented the natural way in dynamic choice, is sufficient for BDM, it is not necessary! A common confusion.

PT falsified: when they tried to refine EU by CEU (Choquet expected utility), they actually got worse results. So, CEU picks up more noise than essential things (overfitting). To elicit CEU, they first assume EU for given probabilities so as to get utility and then elicit capacities from that. Or they equate the capacity of an event with the probability of a matched known-probability event, which also requires EU for risk. Martin Weber (personal communication) conjectured that the poor performance of CEU may be due to subjects first getting many known-probability questions preceding the ambiguity questions which may have distorted their ambiguity perception.

ambiguity seeking for losses: They find ambiguity aversion for gains but, on average, ambiguity neutrality for losses. P. 448 2nd para: significant difference between gains and losses. Capacities for losses are significantly different than for gains.

reflection at individual level for ambiguity: although they have the data, within-subject, they do not report it.

P. 442 $\ell\ell$. 4-5: they apparently assume EU for risk. %}

Mangelsdorff, Lukas & Martin Weber (1994) "Testing Choquet Expected Utility," *Journal of Economic Behavior and Organization* 25, 437–457.

{% They give subjects hypothetical info, such as imagining $1500 damage to their car and what would they do, and then after do simple cognitive task. Poor people do worse on the cognitive task than rich people. In a control treatment poor behave as well as rich, so, it is the info that does it. In a 2nd treatment, they ask farmers in India to do the cognitive task shortly before their harvest (then pressure and uncertainty) and after. Again, before the farmers do worse than after. The authors interpret their findings as meaning that financial uncertainty makes poor cognitively worse and, hence, makes them take worse decisions (poverty trap). Problem is that there are too many confounds. It may just be that the hypothetical info in the first treatment just at that moment annoys poor people more than rich and nothing more than that causes the difference. The authors try to control for some things such as physical measurements of stress (**decision under stress**), but there remain too many emotions uncontrolled to come to their interpretations. Psychologists, when studying such vaguely defined concepts, will use 15 rather than 2 experiments, each individually questionable but together making the story plausible. There are many studies into priming effects, where small ad hoc details rather than something as far reaching as cognitive ability impacts choices.

When the authors write, top middle column first page: "This suggests a causal, not merely correlational, relationship between poverty and mental function. We tested this using two" they are overly optimistic about the possible correlations found and even more about that being causal. %}

{% Gives many arguments for why inconsistency of preference may be rational. That it may be rational to maintain ambiguity about "true" preferences. There are many nice sentences, although I disliked the bombastic writing in his 1996 paper.

On advantage of representative agent for decision models:

P. 588: "So long as we use individual choice models to predict the behavior of relatively large numbers of individuals or organizations, some potential problems are avoided by the familiar advantages of aggregation."

This paper uses term ambiguity in sense of uncertainty/variability of

consumer's preference relation. Pp. 591-592 discuss aspiration levels and step-function-tastes.

P. 593: posterior rationality: Intentions discovered as interpretation of action afterwards; evaluation after the fact.

The central focus of the paper is **paternalism/Humean-view-of-preference**: p. 594: Simon showed that actual human choice behavior is more intelligent than it appeared, and that conforming it more to normative theory may be bad. The paper lists many arguments in favor of not-well-specified preferences. I interpret the author's arguments in favor of ambiguity as criticisms of completeness more than of other consistency conditions. Such as p. 597: to avoid being manipulated by others in game situations (≈**suspicion under ambiguity**). And pp. 598-599 that list five reasons. And P. 603, which can be taken to argue that for th rule for organisations that for criteria to judge people, such as employees or students, an advantage of being vague is that people, not knowing the criteria well, will just do best-quality work because that is their best proxy of the criterion. If a criterion is very clear, people will work for the criterion, not for intrinsic goodness: "And precision in objectives does not allow creative interpretation of what the goal might mean (March, 1978). Thus, the introduction of precision into the evaluation of performance involves a tradeoff between the gains in outcome attributable to closer articulation between action and performance on an index of performance and the losses in outcomes attributable to misrepresentation of goals, reduced motivation to development of goals, and concentration of effort on irrelevant ways of beating the index." (**completeness criticisms**)

P. 597: "We do not believe that what we do must necessarily result from a desire to achieve preferred outcomes."

P. 597 properly criticizes Stigler & Becker (1977):

"to trivialize the issue into a 'definitional problem.' By suitably manipulating the concept of tastes, one can save classical theories of choice as 'explanations' of behavior in a formal sense, but probably only at the cost of stretching a good idea into a doubtful ideology (Stigler & Becker, 1977)."

The text then immediately continues with a nice statement of the point that a normative theory can be useful only if it sometimes !deviates! from actual behavior, the point also stated nicely by Raiffa (1961):

"More importantly from the present point of view, such a redefinition pays the cost of destroying the practical relevance of normative prescriptions for choice. For prescriptions are useful only if we see a difference between observed procedures and desirable procedures."

P. 602, on inconsistency: "the other problems probably require a deeper understanding of contradiction as it appears in philosophy and literature" %}

{% Assumes α-maxmin ($\alpha \times \min + (1-\alpha) \times \max$) for $\alpha \neq 1/2$. An event is defined to be unambiguous if the binary acts w.r.t. the event can be represented by SEU (i.e., all probability measures in the set of priors assign same probability to the event). Note that this definition is not in terms of prefs. Pref. defs can be given by using existing axiomatizations of SEU. Pfanzagl (1959) already axiomatized it. This definition is typical for people interested only in ambiguity aversion/seeking, and ignores insensitivity. (**Ambiguity = amb.av = source.pref, ignoring insensitivity**)

The paper shows under regularity assumptions that, if α-maxmin holds, probabilistic sophistication holds, and there exists one unambiguous event in the above sense, then SEU must hold throughout. It is like a continuous strictly increasing function w from [0,1] to [0,1] with w(0) = 0 and w(1) = 1, if it is convex and if there is a p with w(p) + w(1−p) = 1 (implying that not both w(p) and w(1−p) can be below the diagonal), then w must be linear.

Without the assumption of an unambiguous event the implication need not hold. Any RDU with convex probabibility weighting is maxmin EU (α = 1), not SEU, and there exists no nontrivial unambiguous event (there is such an example at the end of §3). Although this model is maxmin EU in a formal sense, it is not "in spirit." My interpretation is not so much that we may study ambiguity attitudes in the maxmin EU model while assuming SEU as ambiguity-neutrality benchmark, so, not so much that we may assume probabilistic risk attitude away without loss of generality (see p. 756 3rd para). Instead, my interpretation is that multiple priors (in the classical sense with EU for each probability measure) may only be appropriate if we have extraneous prior reasons to believe that probabilistic risk attitude plays no role; i.e., that people do EU for given probabilities. So, it is not a consequence but a prior requirement. %}

This paper can take the space to didactically and well explain the author's general views on ambiguity comprehensively. It well presents mainstream thinking today, even though my views are quite different. The paper has many valuable historical references.

The author throughout assumes that there is a true objective (physical) but unknown probability model. P. 1024 end of 3rd para states this, not as a general fact, but as an assumption and focus of the paper. The author uses here, as in other papers, the broad term probability model for probability measure, and the broad term model (uncertainty) for (uncertainty only about) that true probability measure. The author mostly assumes a two-stage setup, where in the lowest, first, stage uncertainty is objective, captured by the objective probability measure. P. 1024 bottom states this, not as a general fact, but as an assumption and focus of the paper, where the set of possible probability measures is taken as a datum. The author uses the term generative (or data generating) mechanism (p. 1024 3rd para) and calls this uncertainty physical. (So, they cannot be purely and only subjective as in Savage, 1954, as I understood them to possibly be in the smooth model.) However, the end of p. 1024 end of 4th para confuses me because it writes that this uncertainty is epistemic, apparently because the agent knows/has info about this uncertainty (reiterated on p. 1040). But if I understand this right then every physical object can be called epistemic.

As often done today, a two-stage model is introduced by first specifying a set of possible 1st stage probabilized uncertainties on Savage (outcome-relevant) states, and only then imposing second-order uncertainty over them, thus appealing to the popular concept of sets of priors. The set of possible priors is then the support of the second-order uncertainty (expressed through a probability measure μ). P. 1024 last line (also p. 1037 2nd para) takes the set of possible probabilities as datum, so, exogenous. I assume that μ is not datum, but subjective.

The author refers here, as in other places (p. 2037 footnote 32), to statistics. Classical statistics has a same informational structure, with probabilities over observations objective, but a second stage (what the true hypothesis/statistical parameter) with the uncertainty unprobabilized. But this is the only analogy there is. There is a big difference with statistics. It is that in statistics the second-stage events are outcome-relevant and the first-stage is only instrumental, whereas in the authors' model it is the other way around. Next I give a more detailed explanation of this difference:

[DIFFERENCE STATISTICS AND AUTHOR'S MODEL; BEGINNING] In the author's model, the 1st stage generative mechanism with objective probabilities ("physical") is about (Savage) states and they are outcome relevant. The 2nd stage epistemic ("model") uncertainty is only instrumental, to give info about the 1st stage uncertainty. Once you know which Savage state is true, you know which outcome you get and you don't care anymore about the 2nd stage epistemic uncertainty. In statistics these things are the other way around. The 1st stage generative mechanism with objective probabilities ("physical") is about observations of statistics and they are NOT outcome relevant. They are only instrumental to give info about the epistemic 2nd stage uncertainty. The 2nd stage epistemic ("model") uncertainty is about the statistical hypotheses (using the author's term; or statistical parameters in estimations) and these are outcome relevant. Once you know which hypothesis is true, you know which outcome you get and you don't care anymore about the 1st stage objective uncertainty.

[DIFFERENCE STATISTICS AND AUTHOR'S MODEL; END]

P. 1025: "The often-made modeling assumption that a true generative mechanism exists is unverifiable in general and so of a metaphysical nature" P. 1045 bottom repeates this. This interpretation gets closer to the smooth model as I understand it. If no explicit physical mechanism (such as unknown composition of an urn) can be specified that underlies the physical probabilities, then I think that this physical interpretation is not very useful and I would just leave it at subjective (so, epistemic).

P. 1025: In the sentence "In any event, the assumption underlies a fruitful causal approach that facilitates the integration of empirical and theoretical methods—required for a genuine scientific understanding." The intimidating "required" can only refer to the latter integration and not to the former modeling assumption.

P. 1025: "We assume that the DMs' ex-ante information also enables them to address model uncertainty through a subjective prior probability over models" restricts the author's approach to cases where RCLA is abandoned. Although later he will consider alternatives such as alpha maxmin in which no such 2nd order distribution is assumed, as then explained.

P. 1025: "The second layer is ignored by classical statistics." is negative about approaches that do not assume a 2^{nd} order probability distribution.

P. 1026: 'The two layers of analysis motivated by such a distinction naturally lead to two-stage decision criteria: actions are first evaluated with respect to each possible probability model, and then such evaluations are combined by means of the prior distribution." This is in fact assuming backward induction, giving up RCLA, which in nonEU is controversial. Machina (1989) argued against it for decision under risk.

P. 1027 discusses physical probability as propensity, citing Popper. I find Ramsey (1931) the best text on this point.

criticisms of Savage's basic framework: well, a discussion. P. 1029, §2.2, presents the Wald decision framework, with act set A, state space S, and a consequence function ρ mapping each (a,s) to a consequence c from a consequence space C.

P. 1035: The term consequentialism used here is not to be confused with the dynamic decision principle of Machina (1989). P. 1036 then presents Savage's framework as a special case, suggesting and citing Marschak & Radner's (1972) arguing that Wald's framework is more natural. The author supports this view by writing that the Savage construction can give artificial objects. I see things differently. First, all other approaches can equally well give artificial objects. Further, I feel that of acts, states, and consequences, acts are most basic (first thing is that a decision is faced), and states and consequences are next equally (non)basic. But this gives me no preference between the two frameworks. What is best in applications depends on which acts, states, and consequences come naturally, and which additional artificial constructions are then useful. There is no general rule what would always be best. I guess that Savage's framework is most natural in most situations. And that it is the one used in more than 95% of the papers in our field, to the extent that many researchers only know it and even are not aware of alternatives sometimes being preferable.

P. 1038 health insurance example, and other examples similarly: If four experts each give one guess of the physical probability measure, then the set of priors is taken as the set of those four. But I think that in such situations many other probabilities are possible too, and it is not the case that one of the four estimates of the experts must be THE exact true physical probability measure.

Experts are not generative mechanisms. The author writes in the overview that model misspecification will be ignored, and thus can justify treating expert opinions this way. Probably model misspecification would magnify issues without making them fundamentally different. In personal communication the author told me that this, just taking the probabilities expressed as set of priors, is a pragmatic way of modeling such situations and the set of priors should not be taken too literally as the set containing the true but unknown probability.

P. 1039 footnote 37 cites the evidentialist view of probability, with several references. I know this under the name logical view of probability, with Carnap the main advocate. Carnap is not cited here, but in footnote 14 (p. 1027), and I am not sure if for the author evidentialist and logical view are the same, as they are for me.

P. 1042: crisp acts are not affected by ambiguity.

P. 1045 reiterates that the generative mechanism, taken as physical, may be unobservable and then the second-order probability measure μ can only be observed from hypothetical betting behavior.

Section 4 is useful in describing the smooth model including the assumptions underlying it.

Footnote 52, p. 1050, cites works related to the smooth model. I would also cite Kahneman & Tversky (1975, p. 30 ff.), who had the smooth model for ambiguity for two outcomes, Dobbs (1991) who had a different but similar model, and recursive EU by Neilson (cited in Footnote 56), and Kreps & Porteus (1978) who used the same functional form.

P. 1051 in §4.1 is especially useful in discussing portability. In the smooth model, φ, the utility transformer in the second stage, is assumed to depend only on the subject and to be invariant across different decision situations. So, it is assumed that once φ has been elicited using, say, Ellsberg urns, then it applies to all situations of uncertainty. This is a strong assumption, giving the richness of uncertain events, but it is then very good in being tractable.

SEU = risk: It is discussed on p. 1051 bottom ff. P. 1061 will cite someone arguing that it is not intuitive to treat objective and subjective (in the sense of comprising ambiguity) probabilities the same way.

P. 1052 ff. discusses source dependence, but takes source differently than I do.

P. 1052 2nd para 2nd sentence: "We distinguished two sources of uncertainty, physical and epistemic." So, this is how the author takes it: one source is the epistemic 2nd stage uncertainty, the attitude to which is captured by the utility-transformer φ. The other source(s) are the generative mechanisms the attitude to which is captured by the risk-attitude function u. So, it is categorical and dichotomous, with only two (kinds of) sources, epistemic or physical, and there are two kinds of attitudes, φ and u respectively. The only thing that can bring changes, and a gradual path from one kind of uncertainty to the other, is the 2nd order distribution μ. My work on the source idea is different. There can be many kinds of sources of uncertainty, inducing many kinds of attitudes with higher and lower degrees of pessimism (and insensitivity). In this respect my use of sources is more general and accordingly less tractable.

P. 1052 2nd para 2nd sentence: The sentence cited above restricts applicability of the smooth model. It must then be possible to interpret the first-order (subjective?) probability distributions on the Savage state space as physical. This is conceivable for the Ellsberg urn, but not for virtually all natural uncertainties. P. 1024 end of 3rd para has stated that this paper assumes that a "true probability" on S exists (but is unknown) but, again, this is restrictive.

P. 1052 penultimate para also writes: "different confidence in such [probability] judgements (whatever feature of a source causes it) translate as different degrees of aversion to uncertainty across sources, and so in different von Neumann-Morgenstern utility functions." I think that here he is confused. The vNM utility function u reflects only taste and φ is taken to reflect the ambiguity attitude of the agent which in the author's interpretation is separate from the state of info, so, the confidence in probability judgments. This was discussed by Hill (2019 pp. 247-249).

P. 1052 footnote 54: Smith (1969) did not have the idea of source. He did discuss the competence effect, one of the several factors that impact ambiguity attitude, several of which were studied by Yates and co-authors in several papers. But mentioning a factor that impacts ambiguity attitude is too far a cry from the source idea, being way more general. Tversky has the priority of the source concept, in Heath & Tversky (1991), mentioning it briefly in Tversky & Kahneman (1992), where I usually take Tversky & Fox (1995) as the main reference for introducing it in a mature form.

P. 1053 2nd para refers to the "negative attitude" of the DM towards ambiguity, focusing on ambiguity aversion.

P. 1055, §4.2, middle, discusses CARA and CRRA φ. In the former case, it can be argued that ambiguity attitude is constant and in this way independent of outcomes. But it is constant only in an absolute sense then. In the second case, it is constant and independent of outcomes only in relative sense. Footnote 60 there discusses constant absolute ambiguity aversion w.r.t. utility units, by Grant & Polak (2013) and others.

§4.1, p. 1057 ff. discusses the Ellsberg two-urn paradox, assuming all priors.

P. 1072 ff., §4.6, discusses the maxmin EU model of Gilboa & Schmeidler (1989). P. 1063 points out that here the set of priors can be taken subjectively, to induce ambiguity aversion. P. 1063 middle points out that priors are only in or out, and the 2nd stage μ plays no role. P. 1082 2nd para ff. repeats the point.

P. 1066 gives examples and calculations, interpreting some quantities as ambiguity premiums.

The analysis of ambiguity attitudes on p. 1070 focuses on ambiguity aversion. (**Ambiguity = amb.av = source.pref, ignoring insensitivity**?) %}

{% **Z&Z**; Re-analyze hypothetical choices in the famous RAND data using prospect theory. Find support for loss aversion and risk seeking for losses (**risk averse for gains, risk seeking for losses**). Unfortunately, there are so many unclear points in their modeling of prospect theory that the results are not clear to me. They do not consider probability weighting (which in itself can be an OK working hypothesis for pragmatic reasons, made by many) but do consider the certainty effect. The latter is, however, typically modeled through probability weighting. Apparently they have some utility-of-gambling model in mind such as for instance Diecidue, Schmidt, & Wakker (2004), but this is not clear. They do what they call seggregation, where they do not integrate the riskless and risky payments but evaluate them separately and additively, as a kind of additive version of Luce's joint receipt. Kahneman & Tversky (1979) considered something in this spirit but, for a positive prospect that yields \$x >0 as minimal outcome and with probability p y > x, took as evaluation, where I write U for utility = value function, U(x) + w(p)(U(y) − U(x)) which is just the regular rank-dependent evaluation and y is the INTEGRATED payment to be added to the reference point r so that final wealth is r+y. These authors further seggregate payments added to the reference point as a kind of mental accounting, which is a fundamental deviation from PT.

Pp. 422-423 has nice distinction between initial wealth and reference point.

utility concave near ruin: p. 423 takes utility for losses first convex but for large losses concave.

P. 425: their parameter estimates find CONSTANT utility on [−200,0] which is as much against loss aversion as one can think of and is clearly absurd.

They do not consider loss aversion.

P. 423 footnote 7 points out that they tested their model not only with status quo as reference point but also with complete insurance, but this fitted the data worse. %}

{% Stigler Footnote 250 refers to p. 94 of 8th edn. for example of carpet to cover floor where last yard has more utility than yards before. To preserve diminishing marginal utility, Marshall says that whole carpet should be taken as one object.

marginal utility is diminishing: pp. 398-400: Risk aversion is ascribed to diminishing marginal utility; Footnote IX in Mathematical Appendix proves that risk aversion iff u concave, well he derived it only for two-outcome gambles. Marshall seems to have been the first to demonstrate this point. Bernoulli 1738 §13 also suggests it and §14 first sentence claims it in general, but does not really prove it.

Citation: "The argument that fair gambling is an economic blunder is generally based on Bernoulli's or some other definite hypothesis. But it requires no further assumption than that, firstly the pleasure of gambling may be neglected; and, secondly, φ´´ is negative for all values of x, where φ(x) is the pleasure derived from wealth equal to x" (Then Marshall gives a proof,

only for two-outcome gamble. He continues: "It is true that this loss of probable happiness need not be greater than the pleasure derived from the excitement of gambling, and we are thrown back upon the induction that pleasures of gambling are in Bentham's phrase "impure;" since experience shows that they are likely to engender a restless, feverish character, unsuited for steady work as well as for the higher and more solid pleasures of life." (Marshall, 1920: 843).

linear utility for small stakes: This is crucial for Marshall to obtain cardinal utility. Seems to be in Book III.

{% In a lab experiment, a simple lottery decides if subjects gain a prize. But they only get it, and are informed about it, in half an hour. At the beginning of that half hour, they can choose signals about the chance of winning the prize. Here the info is clearly almost entirely noninstrumental, only they have half an hour more or less to think about it, which doesn't count for anything. So, preference for info must be entirely intrinsic. It does mean that we are studying here something of very very small value.

A field experiment in a way is opposite. Subjects can get informed about the potential of getting Alzheimern or about their IQ, and can choose between dfferent signals (hypothetical I assume). Here the info is very instrumental and things will depend much on the particular value of the particular info, rather than on a general intrinsic attitude towards info.

value of information: The lab and field experiments show that people have a preference for positively skewed information structures and against negatively skewed information structures. The authors analyze it theoretically using Machina's (1982) local utility, giving equivalence results in terms of concavity/convexity of 2nd derivatives, and relate their findings to related findings on violations of RCLA. An easier theoretical explanation comes from source theory with insensitivity. Insensitivity in fact means oversensitivity to info coming (close to) certainty, which more easily explains the preference for positively skewed information structures and against negatively skewed information structures. %}

{% This paper is on rational inattention. Agents can receive info, maybe even perfect, but info is costly, so costly that they may prefer not to get all kinds of info. It can be taken as a special case of models where cost of information is incorporated. Marschak worked on that long ago.

The agents can, in a first stage, choose between several information structures. Each gives a signal with some probability. The signals are used to condition on, so as to improve subjective probabilities over outcome relevant events. Outcomes are monetary and utility is linear. There are costs of information structures. The agent maximizes expected value. This leads to a two-stage optimization problem. The agent may have to forego good and even perfect info if it is too expensive. This is called rational inattention. Beccause, after choice of an info structure, there is randomness of the signal that will result, there is randomness in the act that the agent will choose. The authors assume an entropy-based cost function. That leads to a Luce probabilistic choice model.

P. 273 Eq. 1: I did not understand that the choice probability depends only on the real payoff v_i of action i,f and not on the other payoffs possible. This real payoff requires knowledge of the true state of nature - to be determined a priori before the choice of act, in the probability of that choice of act?? α_i is derscribed as a weight attached to action i based on prior information and information-processing strategy, but then it is added to outcome v_i so that it has a monetary unit?? They depend on the cost of info parameter λ, a dependency not expressed on notation. It seems that priors of agents can also change.

P. 278 displays an entropy formula. I understand well what entropy is, but the interpretation written by the authors below I do not understand. It is claimed to measure “the average unlikeliness of events.” They see how it varies if M, the nr. of elements in the partition of events considered, increases, and then so does the entropy. But this holds for EVERY increasing function instead of $-\log(P_i)$ in the entropy formula, and is just a trivial fact. The essence is that, for fixed M, entropy increases with uniformity, due mainly to convexity of $-\log(P_i)$.

I regret that this paper and its outlet has the proofs of theorems online. In cases where I as a mathematician can play the role of specialist who checks proofs, something I often did, I will not do it for online proofs. Those texts have too little quality guarantee and maybe even too little stability guarantee. I rather treat such cases as unreliable, unverifiable, and better to be ignored and not used. For a good view on this point, see Spiegler (2023). %}

{% **foundations of statistics**

Nice discussion of the main issues in statistics, but purely from the frequentist classical perspective, often taking it as self-evident that this is the thing to do.

The authors take as self-evident that tests by default are two-sided.

A central topic in this paper is whether or not one should take thresholds with binary decisions. Several authors argued against it ("no threshold view"), arguing for instance that one should just give p-values without discussing a threshold such as 0.05. However, I have no difficulty with thresholds. Often one had to take a decision of choosing between two things and then a threshold is to be specified.

P. 5 discusses that in classical tests one does not consider the probability of the observation, but of that observation or any other observation that would give even stronger evidence against H_0. They write: "The error probability is accorded to the test procedure, not to the observed data."

P. 6, §2.2: Neyman saw statistical testing more as deciding than as inference.

They often write circularly, just describing meaning of p-value and then saying that this is what is needed. For example, p. 7: "Data x provide evidence for a claim H to the extent that H has passed a severe test with x." Here they out of the blue declare p-value to be the exactly right criterion. P. 8 5th para cites Fisher making a similar claim.

P. 220 bottom: It is tantalizing that the majorit of papers and textbooks give incorrect definitions of confidence intervals. Glad to see that this paper does it right: "a confidence interval (CI) at level 1– c consists of parameter values that are not statistically significantly different from the data at significance level c."

Pp. 11-12: that the probabilistic assumptions underlying a statistical test can be taken flexibly and need not hold exactly.

Pp. 13-14, §4.1, cites people favoring the likelihood principle. They write: "A central problem is that any hypothesis that perfectly fits the data is maximally likely." My reply: then arguments against the hypothesis should come from elsewhere than the data.

P. 15 §4.2: "However, some critics charge that unless the p-value is mistakenly interpreted as a posterior probability, it is of questionable relevance to inference. That assumes a philosophy of inference at odds with statistical significance testing."

P 18: "any measure for showing apparent structures in data is susceptible to the generation of spurious results via data dredging, and would be susceptible to the same perverse incentive."

Pp. 19-20, § 3.1.1, is interesting on a case in the US supreme court.

P. 19: "It is important to recognize that the problem of selective reporting and data dredging can occur when using Bayes factors, likelihood ratios, and other alternative methods."

Pp. 20-21, §5.1.2, is on the stopping rule paradox

Pp. 220-221, §5.3.2, is on the Bayesian approach. P. 220 writes a characteristic sentence: "Computing a PPV [Bayesian posterior predictive value] is apt in given contexts of predicting the prevalence of properties, e.g., the presence of disease in high throughput screening, but it does not provide an assessment of plausibility or well-testedness of a particular hypothesis." p-values say more about whether the experiment/experimenter are good than whether the statistical hypothesis holds true. However, the primary purpose of research is not to push the career of a researcher or to please his ego, but to provide useful info to mankind. Hence p-values are not the relevant quantities.

P. 221 1st para writes a sentence I do not understand: "Moreover, from the fact that

H comes from a pool where k% are true, we do not get the probability that this particular H is true. Such an assignment is fallacious, for the same reason a confidence level is not the probability a particular interval is true." I think we do get the prob, which is k/100.

P. 26 1st para is circular: "But, as we have already noted, any account that obeys the LP [likelhood principle] violates error statistics principles. Hearing them laud the LP, the practitioner is rightly worried that their recommendations will not control error probabilities." It is circular because error probabilities are simply defined as p-values.

P. 27 middle: "For example, thoughtful tests turn on specifying ahead of time outcomes that will not be allowed to count in favor of a claim." Yes, for p-values the test has to be specified beforehand, but for Bayes factors not.

P. 29, closing sentence: "This is another reason that calls to abandon statistical significance are damaging scientific practice." %}

{% **dynamic consistency** %}
McClennen, Edward F. (1983) "Sure-Thing Doubts." *In* Bernt P. Stigum & Fred Wendstøp (eds.) *Foundations of Utility and Risk Theory with Applications*, 117–136, Reidel, Dordrecht.

{% **dynamic consistency**; discusses resolute choice. P. 100/101 describes **sophisticated choice**. This paper is, to the best of my knowledge, the first to introduce resolute choice. He says that, if prior agent did planning, then posterior agent prefers following that because of the very fact of prior planning. P. 103: "For such agents, the ex post situation is different from what it would have been if there had been no ex ante resolve."

Proposes that because of that the prior agent can get it his way in the dynamic Allais paradox, that Ulysses can sail past the Syrens without extraneous things such as being tied up by his men.

Final paragraph suggests that not only prefs but also consequences themselves, can have been changed as a result of the very fact of prior planning; i.e., that prior planning can be an attribute of a consequence.

Also discusses prisoner's dilemma but I will not discuss that here. %}
McClennen, Edward F. (1985) "Prisoner's Dilemma and Resolute Choice." *In* Richmond Campbell & Lanning Sowden (eds.) *Paradoxes of Rationality and Cooperation*, 94–104, University of British Columbia Press, Vancouver.

{% **dynamic consistency**: f**avors abandoning forgone-event independence, so, favors resolute choice**, mostly in context of prisoners dilemma where it is part of the defended cooperative solution. It is argued that by cooperating the opponent is also made to cooperate so that it is really for higher monetary benefits that one is resolute and cooperative. The term context-sensitive preferences (e.g. §6) and the text show that McClennen thinks, à la Machina, that preferences at some moment depend on counterfactual forgone events. Argues on p. 110/11 that resoluteness can do the same, endogenously, as precommitment, but cheaper. §11 discusses forgone-branch independence (often called consequentialism) and deliberately wants to deviate from it. %}

McClennen, Edward F. (1988) “Constrained Maximization and Resolute Choice,” *Social Philosophy and Policy* 5, 95–118.

{% **dynamic consistency** %}

McClennen, Edward F. (1988) “Dynamic Choice and Rationality.” *In* Bertrand R. Munier (ed.) “*Risk, Decision and Rationality,*” 517–536, Reidel, Dordrecht.

{% **dynamic consistency**: f**avors abandoning forgone-event independence, so, favors resolute choice**

Describe a.o. history of ?independence? in Chs 3 and ??, Par.3.5 and Chrs. 7,8 tell about role of forgone-branch independence with descriptions of contributions by Ramsey and others (Chernoff?)

de novo tree (cut off prehistory);

normal form tree (prior choice, choose from strategies)

Separability of McClennen = consequentialism of Machina = what I like to call forgone-branch independence

dynamic consistency + consequentialism of McClennen =

dynamic consistency of Machina

Myopic: SEP + CON of McClennen, not dynamic consistency

Sophisticated (Strotz schijnt ’t): SEP + DC of McClennen, not CON

Resolute: DC + CON of McClennen, not SEP

Cubitt (1996) mentions “NEC” (normal-extensive coincidence), suggesting it is vague because normal and extensive have not been defined, but suggesting it comprises RCLA + Machina-DC (minus Cubitt-DC?) %}
